CLXXXV.—*Hydroxynaphthoic Acids. Part II.*

By CARLTON BUTLER and FRANK ALBERT ROYLE.

INFORMATION concerning the monohydroxy- β -naphthoic acids is even scantier than that available in the case of the derivatives of α -naphthoic acid described in the preceding paper.

Two β -hydroxy- β -naphthoic acids have been described, namely, 3-hydroxy- β -naphthoic acid, m. p. 216° (Schmitt and Burkard, *Ber.*, 1887, 20, 2699; Möhlau and Kriebel, *Ber.*, 1895, 28, 3089), and 7-hydroxy- β -naphthoic acid, m. p. 262° (Friedländer, Heilpern, and Spielfogel, *Mitt. tech. Gewerbe Muscums Wein*, 1898, 8 [11 and 12], 316; see also *J. Soc. Chem. Ind.*, 1898, 17, 836).

Of the α -hydroxy- β -naphthoic acids, the only one known is 1-hydroxy- β -naphthoic acid, m. p. 186–187° (Schmitt and Burkard, *loc. cit.*).

Battershall (*Z. Chem.*, 1872, [ii], 7, 673; *Annalen*, 1873, 168, 144), from the sulphonation product of β -naphthoic acid (*iso*-naphthoic acid), was able to prepare an α -hydroxy- β -naphthoic acid (α -hydroxyisonaphthoic acid) melting at 210–211°. Stumpf (*Annalen*, 1877, 188, 1) prepared the same acid by the same process, and also detected the presence of another sulphonic acid in the sulphonation product, but was not able to obtain the corresponding hydroxy-acid owing to lack of material. The constitutions of these acids were never fully established.

The four unknown isomeric acids of this series are therefore the 4-, 5-, 6-, and 8-hydroxy- β -naphthoic acids, respectively, with the possibility that one of these may be identical with Battershall and Stumpf's α -hydroxyisonaphthoic acid.

Using methods similar to those which have been so successful in the preparation of various hydroxy- α -naphthoic acids (Part I, this vol., p. 1641), the authors have prepared 5-, 6-, and 8-hydroxy- β -naphthoic acids from β -naphthylamine-5-, -6-, and -8-sulphonic acids. 4-Hydroxy- β -naphthoic acid has been prepared from β -naphthylamine-4-sulphonic acid by the method employed by Friedländer, Heilpern, and Spielfogel (*loc. cit.*) for the preparation of 7-hydroxy- β -naphthoic acid.

Prepared by these methods, the acids obtained had the following constants:

Acid.	Acid.	Melting point of		Anilide.	Battershall and Stumpf's acid.
		Acetyl deriv.	Ethyl ester.		
4-Hydroxy- β -naphthoic acid	182–183°	167–168°	—	—	—
5. " "	211–212	214–215	150–151°	163–164°	210–211°
6. " "	240–241	221–223	111–112	197–198	—
8. " "	228–229	176–177	135–137	239–240	—

VOL. CXXIII.

The present authors have established the identity of Battershall and Stumpf's α -hydroxyisônaphthoic acid and 5-hydroxy- β -naphthoic acid by the preparation of the acid from the sulphonation product of β -naphthoic acid.

Stumpf (*loc. cit.*) succeeded in isolating only one pure compound from the sulphonation product of β -naphthoic acid. He detected a small quantity of another sulphonic acid, which was not, as he had first suspected, a derivative of α -naphthoic acid that might have been present as an impurity in the β -naphthoic acid used.

The authors have been able to show, not only that 8-hydroxy- β -naphthoic acid can be produced from Stumpf's unidentified sulphonic acid, but also that the sulphonation product of β -naphthoic acid contains yet a third acid, from which 7-hydroxy- β -naphthoic acid has been prepared. When β -naphthoic acid is heated with 98 per cent. sulphuric acid at 100°, 5-sulpho- β -naphthoic acid is the main product, only small amounts of the 7- and 8-sulphonic acids being formed; at 160°, 7-sulpho- β -naphthoic acid is almost the sole product.

For purposes of comparison, the authors have prepared 7-hydroxy- β -naphthoic acid from β -naphthylamine-7-sulphonic acid, and have shown that the melting point of this acid given by Friedländer, Heilpern, and Spielfogel (*loc. cit.*) is too low.

EXPERIMENTAL.

Materials.— β -Naphthylamine-5- and -8-sulphonic acids. Pure, steam-distilled β -naphthylamine, sulphonated by Green and Vakil's method (T., 1918, 113, 55), gave a product consisting of 41 per cent. of β -naphthylamine-8-sulphonic acid and 58 per cent. of the 2:5-isomeride, the remaining 1 per cent. being a mixture of the 2:6- and 2:7-acids. The separation of these acids was effected by the Dahl process (Eng. Pat. 7712 of 1884). The purity of the 2:5- and 2:8-acids was proved by means of Green and Vakil's qualitative tests (*loc. cit.*).

β -Naphthylamine-6-sulphonic Acid.—This was a commercial product obtained by the action of ammonia on β -naphthol-6-sulphonic acid.

α -Naphthylamine-3-sulphonic acid was prepared in the manner described in Part I (*loc. cit.*).

Diazotisation of β -Naphthylamine-5 and -8-sulphonic Acids.—A solution containing 245 grams of the sodium salt and 70 grams of sodium nitrite in 2100 c.c. of water was added to a well-cooled mixture of 900 c.c. of concentrated hydrochloric acid and 2000 c.c. of water, the temperature being kept below 15° during the reaction. Addition of a little alcohol and ether facilitated filtration of the viscous, yellow paste that was produced owing to separation of the diazo-compound.

Diazotisation of β -Naphthylamine-6-sulphonic Acid.—A mixture of the freshly precipitated, finely divided acid (from 200 grams of the sodium salt) and concentrated hydrochloric acid (650 c.c.) was diazotised at 0° by the addition of sodium nitrite (60 grams in 500 c.c. of water). The diazonium chloride was much more soluble in water than those of the 2:5- and 2:8-naphthylaminesulphonic acids, and therefore the whole of the liquor was used for the preparation of the cyano-derivative.

Diazotisation of β -Naphthylamine-7-sulphonic Acid.—This process was identical with the preceding. The diazonium chloride was filtered off and used in a damp state for the preparation of the cyano-derivative.

2-Cyanonaphthalene-5-, -6-, -7-, and -8-sulphonic Acids.—The method adopted was similar to that described for the preparation of the corresponding α -derivatives (Part I, *loc. cit.*). The sodium and potassium salts of the β -cyano-sulphonic acids are much less soluble in water than those of the α -derivatives and therefore are more easily isolated.

Potassium 2-cyanonaphthalene-5-sulphonate* crystallises from water in long, colourless, extremely friable rods of square cross-section (Found: K = 11.0; H_2O = 20.9. $C_{11}H_6O_3NSK \cdot 4H_2O$ requires K = 11.4; H_2O = 21.0 per cent.). The sodium salt crystallises from water in long, thick prisms tapering to a point at each end. They are transparent immediately after filtration but become opaque after standing in the air for a few hours and break up across the length of the crystal into small, diamond-shaped plates. The sodium salt is more soluble in water than the potassium salt (Found: Na = 7.1; H_2O = 21.8. $C_{11}H_6O_3NSNa \cdot 4H_2O$ requires Na = 7.0; H_2O = 22.0 per cent.).

Potassium 2-cyanonaphthalene-6-sulphonate is fairly readily soluble in water and crystallises in tufts of fine needles: these are to some extent similar to the preceding potassium salt, but are usually more slender in growth (Found: K = 13.3; H_2O = 6.1. $C_{11}H_6O_3NSK \cdot H_2O$ requires K = 13.5; H_2O = 6.2 per cent.).

The sodium salt is slightly less soluble than the potassium salt in water and crystallises from this solvent in glistening plates (Found: Na = 7.5; H_2O = 17.4. $C_{11}H_6O_3NSNa \cdot 3H_2O$ requires Na = 7.4; H_2O = 17.5 per cent.).

Potassium 2-cyanonaphthalene-8-sulphonate is readily soluble in both hot and cold water. It crystallises from concentrated aqueous solutions in tufts of fine needles (Found: K = 11.7; H_2O = 16.4. $C_{11}H_6O_3NSK \cdot 3H_2O$ requires K = 12.0; H_2O = 16.6 per cent.).

* This potassium salt has previously been prepared by the same method as Weisgerber and Krüger (*Ber.*, 1919, 52, 354). The figures given by them for the analysis are, Found: K = 7.19. $C_{11}H_6O_3NSK$ requires 6.25 per cent. $C_{11}H_6O_3NSK$ appears to us to require K = 14.39 per cent.

5-, 6-, 7-, and 8-Sulpho- β -naphthoic Acids.—The nitrile was boiled with aqueous sodium or potassium hydroxide for a few hours and the solution was faintly acidified with hydrochloric acid and evaporated on the water-bath until the sodium or potassium salt crystallised in needles.

The acid potassium salt of 5-sulpho- β -naphthoic acid crystallises from water in long, colourless needles (Found: K = 12.6; H₂O = 5.8. C₁₁H₇O₅SK, H₂O requires K = 12.7; H₂O = 5.8 per cent.).

The acid sodium salt is more soluble than the potassium salt and crystallises in wart-like clusters of needles (Found: Na = 8.1; H₂O = 5.9. C₁₁H₇O₅SNa, H₂O requires Na = 7.9; H₂O = 6.2 per cent.).

The acid potassium salt of 6-sulpho- β -naphthoic acid separates from water in very small, glistening needles (Found: K = 11.8; H₂O = 11.1. C₁₁H₇O₅SK, 2H₂O requires K = 12.0; H₂O = 11.0 per cent.).

The acid potassium salt of 7-sulpho- β -naphthoic acid crystallises in clusters of long needles (Found: K = 12.5; H₂O = 6.0. C₁₁H₇O₅SK, H₂O requires K = 12.7; H₂O = 5.8 per cent.).

The acid potassium salt of 8-sulpho- β -naphthoic acid crystallises without water of crystallisation in groups of needles (Found: K = 13.4. C₁₁H₇O₅SK requires K = 13.4 per cent.).

Fusion of 5-, 6-, 7-, and 8-Sulpho- β -naphthoic Acids with Potassium Hydroxide.—These fusions were conducted in exactly the same manner as those described in Part I (*loc. cit.*). The yields of hydroxynaphthoic acids were about 90 per cent. of the theoretical and no traces of naphthols were detected. Snow-white products and quantitative yields were obtained by carrying out these fusions with 25 per cent. potassium hydroxide solution in an autoclave at 260°—the pressure at this temperature was about 30 atmospheres.

4-Amino- β -naphthonitrile, NH₂C₁₀H₆CN.—On distilling a mixture of sodium α -naphthylamine-3-sulphonate (prepared from α -naphthylamine-3:8-disulphonic acid by the method given in Part II with twice its weight of finely powdered potassium ferrocyanide, an appreciable quantity of ammonia was evolved and a yellow oil produced. This solidified to a light yellow solid which, after reprecipitation from dilute hydrochloric acid solution with alkali crystallised from dilute alcohol in clusters of colourless, silky needle melting at 123–124° (Found: N = 17.0. C₁₁H₈N₂ requires N = 16.7 per cent.).

4-Amino- β -naphthoic Acid.—The nitrile was hydrolysed by boiling with six times its weight of 70 per cent. sulphuric acid for several hours, and from the solution, made alkaline with aqueous ammonia, acetic acid precipitated 4-amino- β -naphthoic acid, which crystallised from dilute alcohol in masses of slender needles melting at

204—206° (Found: N = 7.6. $C_{11}H_9O_4N$ requires N = 7.5 per cent.).

4-Hydroxy- β -naphthoic Acid.—4-Amino- β -naphthoic acid was diazotised in dilute sulphuric acid at 0°, and the solution poured into 60 per cent. sulphuric acid at 90° and gradually heated to 100°. The deposit of hydroxynaphthoic acid was collected, washed with water, and dissolved in aqueous sodium bicarbonate. The solution was treated with a little animal charcoal and acidified with hydrochloric acid, and the precipitated acid was recrystallised from dilute alcohol.

General Properties of 4-, 5-, 6-, 7-, and 8-Hydroxy- β -naphthoic Acids.

These acids are very similar in regard to their general properties; they are all readily soluble in alcohol, ether, acetic acid, or acetone; almost insoluble in chloroform, benzene, or cold water, but are moderately soluble in hot water. They are most conveniently recrystallised, large quantities from aqueous alcohol, small quantities from water.

The *acetyl* derivatives, prepared by means of acetic anhydride, are soluble in alcohol, acetic acid, ether or boiling water, slightly soluble in benzene, and moderately soluble in hot toluene. Suitable solvents for recrystallisation are water, dilute acetic acid, and dilute alcohol.

The *ethyl* esters are obtained by passing dry hydrogen chloride into an ethyl-alcoholic solution of the acid, keeping the solution over-night, and then pouring it into water. The esters thereby precipitated may be recrystallised from dilute alcohol. They are soluble in alcohol, ether, acetic acid, or acetone.

The *anilides* also are similar in their general properties and are prepared by Schoepff's method (see Part I). They are soluble in acetone, alcohol, or acetic acid, but scarcely soluble in the other usual organic solvents. From dilute alcohol or dilute acetic acid they crystallise in fine needles. Except in the case of 7-hydroxy- β -naphthanilide, where the coloration is reddish-gold, ferric chloride produces a greenish-yellow colour, but only that of the 8-hydroxy-derivative is really pronounced.

4-Hydroxy- β -naphthoic acid, m. p. 182—183°, crystallises from water in clusters of small needles. Aqueous-alcoholic solutions, when treated with ferric chloride, give a golden turbidity (Found: C = 70.2; H = 4.4. $C_{11}H_8O_3$ requires C = 70.2; H = 4.2 per cent.). The *acetyl* derivative, m. p. 167—168°, crystallises in needles from dilute alcohol or dilute acetic acid (Found: C = 67.7; H = 4.5. $C_{12}H_{10}O_4$ requires C = 67.8; H = 4.3 per cent.).

5-Hydroxy- β -naphthoic acid, m. p. 210—211°, crystallises from water or dilute alcohol in colourless needles. An aqueous-alcoholic solution, treated with ferric chloride, deposits a dirty red precipitate

which turns violet and finally black (Found: C = 70.2; H = 4.5. $C_{11}H_8O_3$ requires C = 70.2; H = 4.2 per cent.). The *acetyl* derivative, m. p. 214–215°, crystallises in needles from dilute alcohol (Found: C = 67.8; H = 4.5. $C_{13}H_{10}O_4$ requires C = 67.8; H = 4.3 per cent.). The *ethyl* ester, m. p. 150–151°, crystallises from dilute alcohol or dilute acetic acid in slender needles. The aqueous-alcoholic solution gives a yellow coloration with ferric chloride (Found: C = 72.2; H = 5.5. $C_{13}H_{12}O_3$ requires C = 72.2; H = 5.5 per cent.). The *anilide*, m. p. 163–164°, crystallises from dilute acetic acid in bulky clusters of glistening needles (Found: N = 5.2. $C_{17}H_{13}O_2N$ requires N = 5.3 per cent.).

6-Hydroxy- β -naphthoic acid, m. p. 240–241°, crystallises from hot water in opaque needles. Ferric chloride produces an orange coloration but no precipitate. An aqueous solution of the sodium salt in presence of ammonium or potassium hydroxide or sodium carbonate develops a purple fluorescence (Found: C = 70.1; H = 4.3. $C_{11}H_8O_3$ requires C = 70.2; H = 4.2 per cent.). The *acetyl* derivative, m. p. 221–223°, crystallises from water in tufts of silky needles (Found: C = 67.8; H = 4.4. $C_{13}H_{10}O_4$ requires C = 67.8; H = 4.3 per cent.). The *ethyl* ester, m. p. 111–112°, crystallises from dilute alcohol in needles or from dilute acetic acid in clusters of needles. Ferric chloride produces a yellow coloration in aqueous-alcoholic solution (Found: C = 72.4; H = 5.5. $C_{13}H_{12}O_3$ requires C = 72.2; H = 5.5 per cent.). The *anilide*, m. p. 197–198°, crystallises in clusters of feather-like needles from dilute acetic acid (Found: N = 5.5. $C_{17}H_{13}O_2N$ requires N = 5.3 per cent.).

7-Hydroxy- β -naphthoic acid, m. p. 269–270°, crystallises from dilute alcohol in clusters of glistening needles. The ferric chloride coloration is orange, but no precipitate is formed (Found: C = 70.3; H = 4.2. $C_{11}H_8O_3$ requires C = 70.2; H = 4.2 per cent.). The *acetyl* derivative, m. p. 209–210°, crystallises in needles from dilute alcohol (Found: C = 67.9; H = 4.5. $C_{13}H_{10}O_4$ requires C = 67.8; H = 4.3 per cent.). The *anilide*, m. p. 219–220°, crystallises in tufts of needles from dilute alcohol or dilute acetic acid (Found: N = 5.5. $C_{17}H_{13}O_2N$ requires N = 5.3 per cent.).

8-Hydroxy- β -naphthoic acid, m. p. 228–229°, crystallises in colourless needles from water. The sodium, potassium, or ammonium salt exhibits a dark green fluorescence in presence of excess of alkali. Ferric chloride produces a dirty red precipitate which changes to violet and finally becomes black (Found: C = 70.3; H = 4.3. $C_{11}H_8O_3$ requires C = 70.2; H = 4.2 per cent.). The *acetyl* derivative, m. p. 176–177°, crystallises in clusters of this

needles from dilute alcohol or dilute acetic acid (Found : C = 68.0; H = 4.5. $C_{13}H_{10}O_4$ requires C = 67.8; H = 4.3 per cent.). The *ethyl* ester, m. p. 135–137°, crystallises in clusters of needles from dilute alcohol. Ferric chloride gives a yellow coloration which becomes successively dirty orange and green; a bluish-black precipitate is finally deposited (Found : C = 72.2; H = 5.6. $C_{13}H_{12}O_3$ requires C = 72.2; H = 5.5 per cent.). The *anilide*, m. p. 239–240°, crystallises in needles from dilute acetic acid. It is less soluble in alcohol or acetic acid than the previously described anilides. With ferric chloride, a pronounced greenish-yellow tinge is developed (Found : N = 5.4. $C_{17}H_{13}O_2N$ requires N = 5.3 per cent.).

Sulphonation of β -Naphthoic Acid.

The conditions were those under which α -naphthoic acid was sulphonated (preceding paper); the time of sulphonation may be extended to twelve hours without appreciable effect.

The mixture of neutral barium salts prepared from the sulphonic acids was fractionally crystallised, twelve fractions in all being obtained; these were arranged in six groups each containing crystals of an obviously similar nature. Recrystallisation of these groups from water readily furnished a large quantity of glistening needles of a neutral barium salt as described by Stumpf (*loc. cit.*), but it was always contaminated with a salt which refused to show definite form. This salt seemed abundant in the first two groups, but recrystallisation did not cause much separation.

The salts contained in the various groups were then converted into acid barium salts by addition of hydrochloric acid to their boiling aqueous solutions.

Groups I and II.—The acid barium salts consisted mainly of two salts, one of which crystallised from water in hard, elongated tetrahedra containing three molecules of water of crystallisation, whilst the other separated from more dilute solution in long, pointed needles of an octahydrate. Both these on analysis gave results which agreed with those required for the acid barium salts of the desired acids. The two salts were converted into the corresponding acid potassium salts, both of which crystallised in clusters of needles closely resembling the crystals of the acid potassium salt of 8-sulpho- β -naphthoic acid described on page 1652. Each acid potassium salt, when fused with potassium hydroxide, gave a hydroxy- β -naphthoic acid melting at 227–229°, which yielded an acetyl derivative melting at 175–176°, and an aqueous solution of which gave, with ferric chloride, a red precipitate, changing to violet and then black. There was no doubt that the two acids

and 8-hydroxy- β -naphthoic acid were all identical; heated alone or in admixture, they all melted at the same temperature.

Groups III, IV, V, and VI.—The main constituent of these groups was a neutral barium salt which crystallised in hard tufts of needles. When converted into the acid barium salt, it gave a product which was readily soluble in hot water but almost insoluble in cold, from which it crystallised in long, silky needles. The analyses of these two salts agreed with those recorded by Stumpf. The acid potassium salt also had every property of the acid potassium salt of 8-sulpho- β -naphthoic acid (see p. 1652), and fusion with potassium hydroxide furnished a hydroxy- β -naphthoic acid, which crystallised from water in tufts of needles, m. p. 209–210°, and yielded an acetyl derivative melting at 213–215°. Stumpf's α -hydroxyisonaphthoic acid was thus conclusively proved to be 5-hydroxy- β -naphthoic acid.

All the mother-liquors were carefully searched, and although no further salts were detected, a hydroxy- β -naphthoic acid was prepared which began to melt at about 200° and was completely fluid at 235°. This substance was acetylated and the product fractionally crystallised. Hydrolysis of these fractions and re-formation of acetyl derivatives enabled us to isolate an acetyl compound, which melted at 206–209° and gave on hydrolysis an acid melting at 268–271°. This was readily identified as 7-hydroxy- β -naphthoic acid.

The other acid present in this fraction was shown to be 5-hydroxy- β -naphthoic acid.

Sulphonation of β -Naphthoic Acid at 160°.— β -Naphthoic acid (1 mol.) was sulphonated with 98 per cent. sulphuric acid (5 mols.) at 160° for six hours. The liquid was poured into water and the solution kept over-night, but no unchanged β -naphthoic acid separated. The sulphonic acids were converted into neutral barium salts, which were fractionally crystallised. The four fractions collected were converted into acid barium salts by the addition of hydrochloric acid to the boiling solutions.

When treated with a moderate bulk of water, before conversion into the acid barium salt, the first fraction was not entirely undissolved. The portion that went into solution, the whole of fractions II and III, and the first portion of fraction IV consisted of the pure normal barium salt of a sulpho- β -naphthoic acid. The acid barium salt of this main product crystallised like that of 5-sulpho- β -naphthoic acid and also resembled it in its solubility in water. When converted into the acid potassium salt, however, it suggested the 7-sulpho-derivative.

The acid potassium salt on fusion with potassium hydroxide gave

a crude hydroxy- β -naphthoic acid which crystallised from dilute alcohol in glistening tufts of needles, m. p. 268–269°. The acetyl derivative melted at 209–210°. The acid was thus identified as 7-hydroxy- β -naphthoic acid.

Small quantities of the 5- and 8-hydroxy- β -naphthoic acids were isolated, but no trace of 6-hydroxy- β -naphthoic acid could be detected.

Summary.

1. The 4-, 5-, 6-, and 8-hydroxy- β -naphthoic acids have been prepared and characterised.

2. 7-Hydroxy- β -naphthoic acid, which had previously been prepared by other workers, has been further studied.

3. The sulphonation of β -naphthoic acid at 100° by means of 98 per cent. sulphuric acid gives rise to 5-, 7-, and 8-sulpho- β -naphthoic acids, the first predominating. If the temperature of sulphonation is raised to 160°, the main product will be 7-sulpho- β -naphthoic acid, accompanied by small quantities of the 5- and 8-sulpho- β -naphthoic acids. 6-Sulpho- β -naphthoic acid could not be detected in the above sulphonations.

4. The hydroxy- β -naphthoic acid melting at 210–212° prepared by Battershall and Stumpf has been shown to be 5-hydroxy- β -naphthoic acid.

The authors again express their thanks to Professor Lapworth for his continued interest. They also acknowledge the receipt of a generous grant from the Department of Scientific and Industrial Research.

THE UNIVERSITY, MANCHESTER.

CLXXXVI.—*Researches on Phellandrenes. Part I.*

By HENRY GEORGE SMITH, ERIC HURST, and JOHN READ.

ALTHOUGH the *l*- α -phellandrene of eucalyptus oils, the *d*- α -phellandrene of bitter fennel oil, elemi oil, etc., and the *d*- β -phellandrene of water fennel oil have formed the subject of so many investigations by Wallach, Semmler, and others, it is noteworthy that such work has been directed largely towards elucidating constitutional problems, and that other interesting aspects of the study of these important substances still await attention. Little work appears to have been carried out, for example, with the object of isolating specimens of the phellandrenes of high physical purity; considerable confusion exists with regard to certain of their natural

sources; and, as we show below, even common methods of diagnosis utilised in the phellandrene chemistry involve the preparation and physical examination of derivatives which are imperfectly known.

As an example of the inexact nature of the information available in such directions, reference may be made to the description of eucalyptus oils in which *l*- α -phellandrene was originally found (Wallach, *Annalen*, 1888, **246**, 233, 278; 1895, **287**, 371; etc.). The species quoted, *Eucalyptus amygdalina*, is endemic in Tasmania, but does not appear to occur on the mainland of Australia (Baker and Smith, *J. Proc. Roy. Soc. Tasmania*, 1912, 62; Maiden, *J. Proc. Roy. Soc. Victoria*, 1922, **34**, 80, 83); it is therefore doubtful whether the oil of this species has reached Europe at any time. Owing largely to the lack of chemical information, many closely related species—such as *E. dives*, *E. linearis*, *E. radiata*, *E. regnans*, and *E. vitrea*—have been from time to time synonymised with *E. amygdalina*, which was first described and figured by Labillardier ("Plants of New Holland," 1806). It may be added that, in spite of its deficiency in piperitone, the chemical and physical characteristics of the essential oil of *E. amygdalina*, of Tasmania, indicate a closer relationship of this species to *E. dives*, of the mainland, than to any other member of the "peppermint group" of eucalypts.

What particular species, or combination of species, of *Eucalyptus* furnished the oil in which *l*- α -phellandrene was originally found, in 1888, cannot now be determined; but as the oil apparently contained appreciable amounts of cineole, it may have been derived from the species now known in Australia as *E. phellandra*, but which for many years prior to 1912 was commonly known in Eastern Australia as *E. amygdalina* (Baker and Smith, "A Research on the Eucalypts," 2nd ed., Sydney, 1920). The apparent presence of cineole in quantity indicates that the oil did not originate from *E. dives*. The oil was levorotatory, and if the specific rotatory power and other physical constants of the crude oil had been recorded the species could probably have been identified. The importance of quoting data of this kind is, indeed, strikingly demonstrated in this instance, not only in view of the historic interest, but further in connexion with certain conflicting statements which appear in the literature of the phellandrene of "eucalyptus oil."

It is well-known that α -phellandrene is commonly detected in essential oils by dissolving a portion of the appropriate fraction in light petroleum and submitting the solution to the action of nitrous anhydride at 0°. Schreiner (*Arch. Pharm.*, 1901, **239**, 90) showed that whereas the highest melting point at that time recorded for phellandrene nitrosite was 105°, the crystalline material obtained

from "eucalyptus oil" phellandrene could be separated by fractional crystallisation into components differing in melting point and rotatory power. One of these melted at 120—121° and had $[\alpha]_D + 123.5^\circ$, whilst the other melted at 100—101° and had $[\alpha]_D - 36^\circ$. In repeating this work, Wallach isolated an α -nitrosite, melting at 113—114° and having $[\alpha]_D + 142.6^\circ$ and $+ 135.93^\circ$ in chloroform solution, and a β -nitrosite, melting at 105° and having $[\alpha]_D - 40.817^\circ$ and $- 40.287^\circ$. These results were furnished by "eucalyptus oil" phellandrene, whilst corresponding values were observed for the derivatives prepared from the *d*- α -phellandrene of bitter fennel oil, the rotations being, of course, in the opposite sense (Wallach, *Annalen*, 1904, 336, 9; "Terpene und Campher," 1914, 486).

In the present communication, it is sufficient to note that an appreciable discrepancy exists in the values given by Wallach and Schreiner for the melting point of the α -nitrosite of α -phellandrene, and that in view of the somewhat unsatisfactory criterion afforded by determining the melting points of these nitrosites, emphasis has been laid on observing their optical rotatory powers (Wallach, *Annalen*, 1904, 336, 16).

In repeating the preparation of the α -nitrosite from specimens of *l*- α -phellandrene isolated from the oil of *E. dives*, we experienced no difficulty in obtaining numerous specimens melting at 121—122°, and exhibiting the highest specific rotation recorded by Wallach. At the same time, the discrepancies in the latter values quoted by the above observers found a ready interpretation in the marked mutarotation displayed by the substance when dissolved in organic solvents. An explanation was sought for the diverse melting points of the specimens of α -nitrosite, prepared by Wallach and Schreiner from eucalyptus oils, in the possible use of phellandrene fractions from distinct species of *Eucalyptus*, possessing different optical rotatory powers. Preparations made from *l*- α -phellandrene of low rotatory power, isolated from the oil of the above-mentioned *E. phellandra*, yielded, however, the same α -nitrosite, melting at 121—122°. It is thus to be concluded that the method of purification adopted by Wallach (*loc. cit.*) was unsatisfactory.

The experimental part of the present paper deals only with the isolation and examination of pure specimens of *l*- α -phellandrene and of its α -nitrosite; although the last-named substance is obtained with equal readiness from the oils of *E. dives* and *E. phellandra*, here are indications that the associated substances exhibit certain differences in the two cases. The further examination of these and related derivatives will form the subject of future investigations (compare *J. Proc. Roy. Soc. New South Wales*, 1922, 56, 179).

That the mutarotation observed in solutions of the α -nitrosite is not occasioned by any chemical change of a simple order is evident from a study of the data recorded below. The striking changes of which the rapidly fluctuating optical rotation is an index are probably to be associated in a large degree with the presence in the molecule of three asymmetric carbon atoms (compare Wallach, *loc. cit.*, p. 39), two of which would appear to be peculiarly susceptible to modification as centres of optical activity through tautomeric change.

It is evident that such changes must be taken into account in any accurate diagnosis of phellandrene in essential oils, and in observations of this kind it will be found convenient to refer to graphical representations of the mutarotation, such as those recorded below.

Since the specimens of *l*- α -phellandrene now described are probably the purest which have been isolated, it is of interest to summarise the physical constants determined for the three preparations in question

Source.	B. p.	D_4^{20} (vac.).	n_D^{20} .	$[R_L]$.	$[\alpha]_D^{20}$.
Crude "8-hour oil" of <i>E. dives</i> ...	58—59°/16 mm.	0.8410	1.4732	45.45	—112.00°
Residual oil of <i>E.</i> <i>dives</i>	67—68°/22 mm.	0.8425	—	45.51	—112.76°
Crude oil of <i>E.</i> <i>phellandra</i> ...	62.5—63.5°/15.5 mm.	0.8421	1.4744	45.48	—36.76°

The mean observed value of $[R_L]$ is 45.48, and the calculated value being 45.24, the exaltation for the conjugated linkages is 0.24 unit. The high optical rotation of the specimens from *E. dives* is noteworthy: assuming this *l*- α -phellandrene to be optically pure, the specimen from *E. phellandra* would contain 66.3 per cent. of the *l*-form associated with 33.7 per cent. of the *d*-form.

Specimens of *l*- α -phellandrene which have hitherto been prepared from eucalyptus oils have probably contained appreciable quantities of cineole and other impurities, and although the point is still under investigation it may be stated here that phosphoric acid could not be used in eliminating the cineole, owing to an apparent isomerisation of the phellandrene during the process. Further, the phellandrene could not be isolated in anything approaching quantitative yields, owing to its tendency to polymerise, even when distilled cautiously under diminished pressure.

EXPERIMENTAL.

The Isolation of l- α -Phellandrene from the Essential Oil of Eucalyptus dives.

1. The first sample of oil utilised was obtained by the steam distillation, for eight hours ("8-hour oil"), of leaves and twigs of

E. dives collected in the Braidwood district of N. S. Wales, in October. The crude oil contained about 46 per cent. of *l*-piperitone, by volume, and when dried over sodium sulphate and filtered, gave the following physical constants: D_4^{20} 0.9042 (vac.), n_D^{20} 1.4802, $\alpha_D^{20} - 56.72^\circ$,* $[\alpha]_D^{20} - 82.73^\circ$. The oil (1363 grams) was distilled under diminished pressure, in portions of about 500 c.c., from a Claisen flask immersed in an oil-bath, with the object of obtaining two main fractions, rich in phellandrene and piperitone, respectively. These fractions are numbered 2 and 6 in the appended summary of the result of the first distillation, which was conducted at 18 mm. pressure:

Fraction.	Boiling point.	Bath temperature (limit).	Weight (grams).
1	to 62°	100°	12
2	62—72	115	230
3	72—79	120	236
4	79—100	130	250
5	100—108	140	85
6	108—120	160	490
7	120—130	170	20
8	above 130	—	25

By systematic redistillation, repeated three times, fractions 2 and 6 were augmented to 540 and 494 grams, respectively. Fraction 2 when redistilled then yielded 230 grams of b. p. 63—65°/18 mm., the temperature of the bath being 95°. It proved impracticable to purify the phellandrene further by distillation, and accordingly the last-named fraction was shaken continuously with 140 grams of a 50 per cent. aqueous solution of resorcinol for thirty minutes. The cineole was subsequently recovered from the aqueous extract by steam distillation. After washing with water and drying over plaster of Paris, the residual oil yielded the following fractions when distilled at 16 mm. pressure:

Fraction.	Boiling point.	Bath temperature (limit).	Weight (grams).
1	to 57°	80°	15
2	57—58	83	30
3	58—59	85	50
4	residue	—	110

The third fraction, representing only 3.7 per cent. of the original crude oil, contained no cineole and was regarded as pure *l*- α -phellandrene. It gave the following physical constants: b. p. 58—59°/16 mm., D_4^{20} 0.8410 (vac.), n_D^{20} 1.4732, $[R_L]$ 45.45, $\alpha_D^{20} - 94.19^\circ$, $[\alpha]_D^{20} - 112.00^\circ$; D_4^{20} 0.8372 (vac.), n_D^{20} 1.4710. The second fraction (b. p. 57—58°/16 mm.) gave $\alpha_D^{20} - 83.80^\circ$.

All the values of α_D in this paper are recorded for a 1-dem. tube.

2. A similar method was applied in isolating *l*- α -phellandrene from the residues remaining after the extraction of piperitone from various samples of the crude oil of *E. dives*. Hot aqueous solutions of sodium sulphite and sodium bisulphite were used in these operations, which will be described in a later communication. A typical mixture of residual oils obtained in this manner contained about 3 per cent. (vol.) of piperitone, and had D_4^{20} 0.870 and α_D^{20} - 67.54°. When distilled under 24 mm. pressure, a sample of this material (1305.grams) gave the appended results :

Fraction.	Boiling point.	Bath temperature (limit).	Weight (grams).
1	to 69°	100°	20
2	69—73	115	375
3	73—78	130	370
4	78—100	130	285
5	100—130	190	195
6	residue	—	60

After three systematic redistillations, a second fraction of b. p. 67—71°/22 mm. (bath temperature, 110°), weighing 875 grams, was obtained. This gave 490 grams of b. p. 68.5—70.5°/22 mm., which after a thorough extraction with resorcinol solution yielded 250 grams of b. p. 67—68°/22 mm. (bath temperature, 97°).

The yield of pure *l*- α -phellandrene, calculated on the crude residual oil, was thus 19.2 per cent. The following physical constants were determined : b. p. 67—68°/22 mm., 171—172°/758.2 mm., D_4^{20} 0.8425 (vac.), D_4^{25} 0.8387 (vac.), n_D^{20} 1.4725, $[R_L]$ 45.51, α_D^{20} - 95.00°, $[\alpha]_D^{20}$ - 112.76°. Another preparation from the same material gave practically identical values.

Other residues furnished as much as 25 per cent. of purified phellandrene.

The Isolation of l- α -Phellandrene from the Essential Oil of Eucalyptus phellandra.

A sample of the crude essential oil of *E. phellandra* was distilled expressly for the work now described, the material being collected at Mongarlowe, N. S. Wales, in May, 1922. When dried over sodium sulphate and filtered, the crude oil exhibited the following physical constants : D_4^{20} 0.8980 (vac.), n_D^{20} 1.4680, α_D^{20} - 11.61°, $[\alpha]_D^{20}$ - 12.93°.

The crude oil (2475 grams) was fractionally distilled under diminished pressure, as described above, in portions of about 250 c.c. The fractions obtained in the original fractionation and three successive refractionations, all of which were conducted under 18 mm. pressure, are summarised in the appended table :

Fraction.	Boiling point.	Weight (grams) after			
		Original fractionation.	1st refractionation.	2nd ditto.	3rd ditto.
1	to 62°	78	56	34	13
2	62—72	1700	1820	1950	2049
3	72—79	254	173	97	35
4	79—100	159	118	73	45
5	100—108	147	149	146	145
6	108—113	91	107	119	129
7	residue	44	50	55	58

Fraction 2, unlike the corresponding fraction from the oil of *E. dires*, proved to consist mainly of cineole, and the elimination of the latter substance by using a 50 per cent. aqueous solution of resorcinol, as described above, presented considerable difficulty, owing to the separation of a bulky precipitate of the cineole-resorcinol compound. Repeated filtration with suction was thus necessary after the first treatment with resorcinol solution, and, in all, five additional extractions with fresh quantities of the solution were required in order to render the phellandrene irresponsive to the bromine test for cineole. In this way, 425 grams of fraction 2 yielded 27 grams of phellandrene, possessing the following physical constants: b. p. 62.5—63.5°/15.5 mm., D_4^{20} 0.8421 (vac.), n_D^{20} 1.4744, $[R_L]$ 45.48, α_D^{20} —30.95°, $[\alpha]_D^{20}$ —36.75°.

Of the 230 grams of cineole recovered by steam distilling the combined extracts, 212 grams passed over at 90—91.5°/55 mm., and the specimen possessed a noticeable purple fluorescence. It was not pure, and had α_D^{20} —4.84°.

Specimens of phellandrene practically identical with that just described were isolated in a similar way from a second fraction (b. p. 69—73°/20 mm.) obtained after the first refractionation indicated above; this fraction formed about 75 per cent. of the original oil, and prior to the extraction of the cineole had α_D^{20} —11.97°.

Preparation of 1- α -Phellandrene α -Nitrosite.

As a result of numerous preliminary experiments, the following method was elaborated for the preparation of this derivative:

A solution of purified 1- α -phellandrene (25 c.c.) in light petroleum (150 c.c.) was poured into a vessel immersed in a freezing mixture and containing an aqueous solution of sodium nitrite of about 44 per cent. concentration (53 c.c.). When the temperature of the solutions had fallen to 0°, or slightly lower, glacial acetic acid (25 c.c.) was added, and after thorough admixture the vessel was left in the freezing mixture until the contents appeared to have become practically solid. By collection on a filter with suction,

a sticky, yellow mass was obtained. When rapidly digested and washed with rectified spirit, this yielded a colourless, crystalline product, whilst the filtrate appeared to contain a yellow oily material in solution. The solid product was washed on the filter successively with water and rectified spirit, and at once digested with boiling acetone for a few minutes only. Rectified spirit was added in excess to the clear solution and the resulting crystalline solid collected on a filter with suction. A second crop of crystalline material was usually obtained from the filtrate and alcohol washings. The melting point of the preparation at this stage was usually from 105° to 108° , with decomposition.

The product was completely purified by recrystallisation from boiling acetone, this process being repeated from two to five times until the maximum melting point, $121-122^{\circ}$, was attained (Found : $N = 13.33$. Calc. for $C_{10}H_{16}O_2N_2$, $N = 13.20$ per cent.). In a typical example, the following intermediate melting points were observed : $110-112^{\circ}$, $113-114^{\circ}$, $117-118^{\circ}$, $119-120^{\circ}$. In all instances, the substance melted with decomposition.

It is important to carry out the preparation and purification of the substance without undue delay. The crude product decomposes rapidly at the ordinary temperature, yielding a yellow oil. After one or two recrystallisations, however, a much more stable product is obtained. The pure substance, which forms long, fine needles, may be kept in the open air for some weeks without any apparent decomposition taking place, but after several months the melting point declines and becomes less definite.

The yield of the pure product varied in different preparations, but was always quite small, less than 5 grams being obtained from 25 c.c. of phellandrene. Acetic acid gave better results than sulphuric acid in this preparation. The passage of nitrous fumes into solutions of phellandrene in organic solvents resulted in the formation of still larger proportions of the yellow oil mentioned above.

Specimens of phellandrene prepared from the two sources indicated above appeared to behave identically in these preparations.

The Mutarotation of 1- α -Phellandrene α -Nitrosite at 20° .

In the three appended series of observations, the pure α -nitrosite (m. p. $121-122^{\circ}$) was dissolved to give solutions of the same approximate concentration in chloroform, benzene, and acetone, respectively; these were maintained at 20° and examined polarimetrically at measured intervals after the first contact with the solvent :

1. 0.3765 Gram dissolved in chloroform and made up to 30.0 c.c. at 20°.

Time.	$[\alpha]_D^{20}$.	Time.	$[\alpha]_D^{20}$.
5 mins.	+ 142.6°	72 hours	- 54.3°
29 "	+ 132.3 "	121 "	- 67.3
49 "	+ 123.9 "	194 "	- 80.1
372 "	+ 78.1	237 "	- 80.1

2. 0.3762 Gram dissolved in benzene and made up to 30.0 c.c. at 20°.

Time.	$[\alpha]_D^{20}$.	Time.	$[\alpha]_D^{20}$.
5 mins.	+ 234.4°	95 hours	- 42.7°
20 "	+ 220.9	308 "	- 101.7
40 "	+ 209.7	333 "	- 103.3
75 "	+ 189.0	356 "	- 103.3

3. 0.2515 Gram dissolved in acetone and made up to 20.0 c.c. at 20°.

Time.	$[\alpha]_D^{20}$.	Time.	$[\alpha]_D^{20}$.
5 mins.	+ 165.9°	102 hours	+ 4.8°
80 "	+ 147.1	148 "	- 19.9
133 "	+ 140.4	338 "	- 49.3
353 "	+ 110.1	360 "	- 49.3

Altogether, about fifteen readings were taken in each series, and from the graphical representation (Fig. 1) it is evident that the general character of the change is the same. Although the initial stage of the mutarotation is most marked in benzene solution, it is in chloroform that the zero and equilibrium values are first attained. In accordance with the characteristics of the curves illustrated in Fig. 1, acetone appears to be the best solvent available for purifying the substance. In each instance, the downward mutarotation leads ultimately to optical inversion.

In more concentrated solutions than those just described, the mutarotation was more sluggish and less complete, whilst in more dilute solutions the reverse was the case, a result which may be connected with the reported bimolecular constitution of the α -nitrosite (*Annalen*, 1900, 313, 346). The following table summarises values of $[\alpha]_D^{20}$ obtained for chloroform solutions having, respectively, about one-half and twice the concentration of the chloroform solution denoted in (1) above. In each case, the weight stated was dissolved in chloroform and made up to 30.0 c.c. at 20°:

Weight (grams).	10 mins.	20 mins.	150 mins.	48 hours.	Equilibrium value.
0.1883	+ 138.6°	+ 133.0°	+ 92.7°	- 63.7°	- 104.4° (555 hrs.)
0.3765	+ 137.4	+ 134.0	+ 97.7	- 38.0	- 80.1 (194 ")
0.7517	+ 137.4	+ 135.1	+ 101.7	- 24.0	- 70.0 (120 ")

Very similar data were obtained by the examination of acetone solutions of different concentrations. In both solvents, the initial reading was not markedly affected by the concentration.

In all cases, the originally colourless solution developed a pale yellow colour during the course of the mutarotation; and with chloroform or acetone, especially in the more concentrated solutions, the ultimate colour was a deep orange-red. When the solvent was allowed to evaporate from the equilibrated solutions, an orange-red oil was invariably left, but as a rule no crystalline material could be obtained. On the other hand, by allowing the solvent to evaporate before the attainment of equilibrium it was often possible

FIG. 1.

to isolate small quantities of crystalline material from the oily residue. In such cases, the residue was washed successively with alcohol and ether, the solid being then recrystallised from warm acetone. As specific examples, an acetone solution having $[\alpha]_D^{20} + 11.4^\circ$ and a chloroform solution having $[\alpha]_D^{20} - 46.4^\circ$ each yielded a small amount of the original α -nitrosite (m. p. $121-122^\circ$) when treated in this way; in addition, from a chloroform solution which had been kept for a week was isolated in small amount a product melting at $112-113^\circ$ and having $[\alpha]_D^{20} + 14.0^\circ$ in chloroform solution.

The data recorded above were obtained by the use of *l*- α -phellandrene from *E. dives*, but specimens of phellandrene obtained from

E. phellandra readily yielded a nitrosite melting at 121–122° by the application of the same method. Such preparations, when dissolved in chloroform, benzene, or acetone, gave initial rotatory values practically identical with those recorded above, whilst the mutarotation proceeded similarly: for example, 0.2503 gram, dissolved in chloroform and made up to 20.0 c.c. at 20°, gave $[\alpha]_D^{20} + 142.2^\circ$ after 5 minutes, $+ 132.2^\circ$ after 30 minutes, $- 63.1^\circ$ after 75 hours, and $- 75.5^\circ$ after 121 hours.

Effect of Temperature on the Mutarotation.

The mutarotation was greatly accelerated by warming the solutions, and it is important to bear this fact in mind when purifying specimens of the substance. In one series of experiments, weighed quantities of 0.2500 gram of the pure α -nitrosite (m. p. 121–122°) were dissolved severally in chloroform, benzene, and acetone at 60°, the three solutions being made up to 20.0 c.c. and maintained at that temperature for polarimetric examination at intervals. In acetone there was a rapid downward mutarotation from $[\alpha]_D^{60} + 49.6^\circ$ after 5 minutes to a constant value of $[\alpha]_D^{60} - 12.8^\circ$ after 3.75 hours. In chloroform, the reading after 5 minutes had already reached the negative value of $[\alpha]_D^{60} - 27.2^\circ$; after declining to $[\alpha]_D^{60} - 50.4^\circ$ in 10 minutes, the rotation then rose to $[\alpha]_D^{60} - 28.8^\circ$ after 45 minutes, and eventually declined without further interruption to a constant value of $[\alpha]_D^{60} - 58.4^\circ$ after 2.75 hours. No alteration was observed in this instance after keeping the solution for 14 days at the ordinary temperature. Somewhat similar irregularities were observed in benzene solution, the initial and final values being, respectively, $[\alpha]_D^{60} - 10.4^\circ$ after 5 minutes, and $[\alpha]_D^{60} - 82.5^\circ$ after 7 hours. The equilibrium values were thus always less, in the *laevo*-sense, at the higher temperature.

These results are recorded graphically in Fig. 2.

Effect of Piperidine on the Mutarotation.

In all the observations recorded in this section, 0.2500 gram of the pure α -nitrosite (m. p. 121–122°) was dissolved in the solvent stated and made up to 20.0 c.c. at 20°.

With a *N*/1000-solution of piperidine in chloroform, the following values of $[\alpha]_D^{20}$ were observed: $+ 138.2^\circ$ (9 minutes), $+ 126.2^\circ$ (36 minutes), $- 41.5^\circ$ (147 hours), $- 51.5^\circ$ (363 hours). The mutarotation was thus almost unaffected in the early stages, although subsequently it became more sluggish and no definite equilibrium appeared to be reached. As in all similar observations, the solution eventually became dark red.

A *N*/100-solution of piperidine in chloroform gave very similar

results, some of the values of $[\alpha]_D^{25}$ being: $+141.4^\circ$ (17 minutes), $+116.7^\circ$ (31 minutes), $+1.6^\circ$ (15 hours), -7.2° (16 hours), -16.8° (508 hours), -20.8° (530 hours).

In a $N/100$ -solution of piperidine in benzene the effect was very similar to that observed in chloroform, as is evident from the following values of $[\alpha]_D^{25}$: $+223.6^\circ$ (8 minutes), $+145.6^\circ$ (1 hour), -24.0° (7 hours), -24.8° (53 hours), -92.8° (336 hours).

In a $N/100$ -solution of piperidine in acetone the influence of the piperidine was more marked, as indicated by the appended values of $[\alpha]_D^{25}$: $+63.1^\circ$ (8 minutes), $+20.4^\circ$ (15 minutes), -16.0° (25 minutes), -84.3° (65 minutes), -99.8° (85 minutes), -91.1°

FIG. 2.

(200 minutes), -51.9° (24 hours), -39.9° (149 hours), -39.9° (197 hours).

The three complete series of observations with $N/100$ -solutions of piperidine are represented graphically in Fig. 3.

With $N/10$ -solutions of piperidine, the influence was still more marked. In chloroform, the value for $[\alpha]_D^{25}$ declined from $+27.2^\circ$ (8 minutes) to -25.2° (25 minutes), then rose to $+38.4^\circ$ (4.5 hours), and again declined to $+3.2^\circ$ (47 hours) and -8.0° (72 hours). In benzene, the value declined from $+22.4^\circ$ (8 minutes) to $+2.8^\circ$ (15 minutes), and then rose slowly to $+84.8^\circ$ (24 hours) and $+91.2^\circ$ (48 hours). In acetone, the initial downward mutarotation observed in every other instance was absent, the value rising rapidly from

+ 21.1° (6 minutes) to + 104.0° (61 minutes) and then remaining constant at + 100.4° (3 hours, 24 hours, 172 hours). These results are represented in Fig. 4.

FIG. 3.

Thus, in all three solvents, in the absence of piperidine, there was a continuous downward mutarotation at 20°, whilst at 60° considerable oscillation occurred, suggesting the simultaneous

FIG. 4.

progress of various changes at different velocities. The presence of piperidine up to a concentration of $N/100$ appeared to effect no fundamental alteration in the character of the mutarotation, except that in the case of acetone a slow upward change succeeded the

initial downward progress. With *N*/10-solutions of piperidine, however, the predominant mutarotation was upward, whilst in chloroform solution the initial changes were very similar in general character to those produced by maintaining the solution at 60° in the absence of piperidine. It is hoped to discuss these results more fully after making similar examinations of the reported β -nitrosite and related derivatives.

Optical Rotatory Powers of Specimens of Nitrosite prepared from 1- α -Phellandrene and melting below 121°.

During the course of the work described above, numerous specimens of nitrosite were prepared, which, although identical in appearance with the material melting at 121–122°, possessed appreciably lower melting points. In general, such specimens on recrystallisation yielded the pure α -nitrosite, and possibly consisted sometimes of mixtures of α -nitrosite with the β -nitrosite described by other authors. This question is receiving further attention, but it is of interest to record in this place certain results of the polarimetric examination of such specimens. The observations concerned are summarised in the following table:

M. p. of specimen.	Source.	$[\alpha]_D^{20}$ (chloroform).	$[\alpha]_D^{20}$ for the pure α -nitrosite under similar conditions.
119–120°	<i>E. dives</i>	+ 141.3° (5 mins.)	+ 142.6°
118–119	"	+ 94.5 (60 mins.)	+ 120.0
115–118	"	+ 71.9 (60 mins.)	+ 120.0
113–114	"	– 18.5 (60 mins.)	+ 120.0
112–113	"	+ 14.0 (5 mins.)	+ 142.6
111–113	"	– 17.5 (60 mins.)	+ 120.0
108–109	<i>E. phellandra</i>	– 83.1 (6 mins.)	+ 138.5

These results emphasise the importance of careful polarimetric control in the diagnosis of phellandrenes by the nitrosite method.

We are continuing the detailed examination of the whole field of work indicated in this paper. We express our indebtedness to the McCaughey Research Fund of the University of Sydney for a grant in aid of the investigation, and to Messrs. W. B. S. Bishop, B.Sc., and P. G. Carter, B.Sc., for assistance in distilling the crude oils.

CLXXXVII.—*Investigations on the Dependence of Rotatory Power on Chemical Constitution. Part XX. The Rational Study of Optical Properties including Refraction.*

By HAROLD HUNTER.

AN intimate connexion between refractive index and rotatory power has been suspected for a considerable time, and several attempts have been made to elucidate it. A recent investigation (Part XIX, this vol., p. 434) appears to indicate that the study of dispersion, both refractive and rotatory, is of fundamental importance in this direction, and it is possible that the partial or complete failure of the earlier attempts to correlate optical properties of organic compounds is to be attributed to the neglect of this study. The importance of dispersion has been pointed out and repeatedly urged by many investigators, but up to the present, no satisfactory method for attacking the problem has been proposed. It is the object of the present paper to indicate the pressing need for dealing with the question of dispersion in an adequate manner, and to suggest and correlate some dispersion equations in an attempt to prepare the way for a satisfactory solution of the problem of optical dispersion as applied to natural rotatory power, refractive index, and magnetic rotatory power. Experimental difficulties attendant upon the study of dispersion are diminished by the modern improvements in the construction and accuracy of optical instruments, by the introduction of photographic methods of measurement, and, above all, by the availability of cheap and easy methods of producing monochromatic illumination of almost any desired wave-length.

The theoretical difficulties, unfortunately, are not so easily overcome. For the rational study of optical dispersion, it is not sufficient to measure the numerical value of a particular property—refractive power or rotatory power, as the case may be—for light of two arbitrarily chosen wave-lengths, and to express the dispersion as the difference or as the ratio of these two quantities. It is necessary, as Lowry has already pointed out in connexion with rotatory power (T., 1913, 103, 1062), to determine the form of the function connecting the numerical value of the property with wave-length. Many forms of dispersion equation have been suggested from time to time, but the ones which appear most suitable for application to organic compounds are :

(a) The Sellmeier equation for refractive dispersion,

$$n^2 = a^2 + \sum \frac{b_0 \lambda^2}{\lambda^2 - \lambda_0^2} \quad \dots \quad (1)$$

as adopted by Pickard and Hunter (Part XIX, *loc. cit.*).

(b) The Drude equation for natural rotatory dispersion,

$$\alpha = \sum \frac{k_0}{\lambda^2 - \lambda_0^2} \quad \dots \quad (2)$$

as adopted by Lowry and Dickson (T., 1913, 103, 1067).

(c) The Drude equation for magnetic rotatory dispersion, not as used by Lowry (T., 1914, 105, 81), but modified by the addition of a term independent of the absorption,

$$\delta = \frac{A}{\lambda^2} + \sum \frac{B_0}{\lambda^2 - \lambda_0^2} \quad \dots \quad (3)$$

where a , A , b_0 , B_0 , k_0 , λ_0 , etc., are respectively constants characteristic of the substance under investigation.

It will be observed that the equations have a common dispersion parameter, λ_0^2 . But λ_0^2 has a wider significance than this. It is the square of the wave-length of an absorption band in the spectrum of the substance, and has, in general, the same value in all three equations for any one substance under a given set of experimental conditions. It thus becomes possible to a certain extent to co-ordinate these three properties, and to correlate them with absorption spectra. It does not appear possible, until more experimental figures have been accumulated, to give a precise physical significance to the other constants in the dispersion equations, but at all events they have the merit of being independent of the wave-length of the light used to measure the different properties. A knowledge of the dispersion curves of organic compounds at least gives us the opportunity of comparing refractive indices of different substances at what may be considered corresponding conditions of wave-length, such as, for example, points of equal slope on their refractive or rotatory dispersion curves, thus enabling us to dispense with the arbitrarily chosen wave-length. It is now possible to discuss these three optical properties rather more in detail.

Refractive Power.

The universal custom hitherto has been to study refractive power without regard to dispersion, the *C* or *D* lines of the solar spectrum being employed as illuminants because they can be produced readily and cheaply in the laboratory. As a result of more than thirty years of investigation, it has come to be very generally accepted that the property of refractive power is the most additive, with the exception of molecular mass, of all physical properties studied by the chemist. Whilst refractive power can be taken to be additive within very broad limits when the dominant absorption bands of the substances considered are sufficiently far removed in the ultra-violet region of the spectrum, or when all the substances considered have the same

or nearly the same dominant absorption band, it must now be admitted that many discrepancies between theory and practice have been found. It is submitted that the older wide view must now be abandoned, that the effect of constitution upon refractive power is much more complex than is commonly supposed, that the present formulæ for the calculation of refractive power, together with the values of atomic refractive powers associated with them, are inadequate for their purpose and powerless as instruments for further research, and that the study of refractive power must be approached from an entirely new point if results of value are to be obtained.

The formulæ in common use at the present time are those due to Gladstone and Dale and to Lorenz and Lorentz. The earliest values of the atomic refractive powers of the various elements for use with these formulæ were those proposed by Conrady and Zecchini. These values remained the accepted standards for more than twenty years, but although they are still used to a certain extent, they are by no means to be relied upon, the list of figures which appears in nearly all the text-books of the present time containing many obvious inconsistencies.

The values of the atomic refractive powers of the common elements were recalculated by Eisenlohr (*Z. physikal. Chem.*, 1910, 75, 585) for the Lorenz and Lorentz formula. The values are calculated for four lines of the spectrum, and the values of the atomic refractive power for any one element or group decrease in a regular manner with increasing wave-length of light. It must be pointed out, however, that the figures are not nearly accurate enough for their purpose. If we consider the equation

$$R = (n^2 - 1)/(n^2 + 2),$$

then by simple differentiation,

$$\frac{dR}{R} = \frac{6n^2}{(n^2 - 1)(n^2 + 2)} \cdot \frac{dn}{n},$$

and when $n = 1.414$ (a sufficiently representative value for organic compounds),

$$dR/R = 3dn/n.$$

Refractive indices of organic liquids are often quoted to six significant figures. We will not pause to consider how far this practice is justified, but in such a case the present author can scarcely be accused of undue severity if he regards the fifth significant figure as absolute. It will be taken, then, that refractive indices can be measured to one part in 15,000—experimental error does not affect the fourth decimal place. It then follows that the expression R above can be measured to one part in 5,000. As densities can be measured with an accuracy of two units in the

fourth decimal place, any discrepancy between observed and calculated values of molecular refractive power which amounts to more than 0.02 per cent. is evidence that this property is not additive. For the purpose of obtaining the refractive powers of the methylene group and of hydrogen, Eisenlohr (*loc. cit.*) quotes the following figures for the *D* line:

Methylene group.		Hydrogen.	
n hydrocarbons	4.6247	In paraffins	1.1352
In polymethylenes	4.6324	In alcohols	1.0646
In aldehydes and ketones ...	4.6265	Mean	1.0999
In acids	4.6137		
In alcohols	4.6343		
In esters	4.6056		
Mean	4.6178		

It is obvious that with figures such as these, refractive power cannot legitimately be regarded as an additive property. With such large variations, there can be no justification for the assumption that the values for the same atom or group in different compounds are substantially identical and are best represented by their "mean." The result of these discrepancies is that it is impossible to obtain satisfactory values for the calculated molecular refractive power of a compound. For a simple and straightforward compound like *n*-hexane, for instance, we get—

from Eisenlohr's mean figures, $[R_L]_D = 29.908$

from Eisenlohr's actual figures, $[R_L]_D = 30.019$

values which differ by 18 parts in 5,000, corresponding to a difference of nearly two units in the third decimal place in the refractive index.

It is thus apparent that refractive power as calculated at the present time is not of much value for confirming constitutional formulæ assigned to organic compounds. The "standard" values differ amongst themselves by far more than the allowable experimental error.

In 1920, Eisenlohr and Wöhlisch (*Ber.*, 1920, 53, [B], 1746) abandoned all formulæ for refractive power which involve a function of the refractive index together with the inverse of the density. They point out that high refractive index is in nearly all cases associated with high density, so that changes in the values of these properties will tend to neutralise each other in any formula of the Gladstone or the Lorenz type. Consequently, they propose a formula for molecular refractive power which does not involve the density— $MR = \text{Mol.Wt.} \times n_D^2$. This formula requires that all isomerides should have the same refractive index, which is in conflict with much experimental evidence. In order to get over this difficulty, these authors are forced to recognise that chain branching, and, in particular, the presence of a *gem*-dimethyl group in the

molecule, has a constitutional effect on the refractive power. Apart from this, however, they consider that refractive power, at all events in aliphatic compounds and monosubstituted benzene derivatives, is sufficiently additive in character to allow them to assign atomic refractive powers to the various elements and ring formations. Up to the present, they have quoted values only for carbon, hydrogen, and oxygen—it is remarkable that the value for hydrogen is negative—so that an examination of the proposal is restricted practically to aliphatic compounds containing only these three elements. Yet another restriction is imposed by the fact that their figures apply only to refractive indices determined for the *D* line at 20°. A few figures are, however, available, and are collected in Table I.

TABLE I.*

* Many of these values are taken from the list compiled by Fieser and himself (*Z. physikal. Chem.*, 1910, 75, 585). The remainder are from the published work of other investigators in this field.

It will be noticed that observed and calculated refractive indices are compared, so that the differences in the fourth decimal place of the refractive index recorded in the fourth column represent the departure from additivity of the property of refractive power calculated in this manner. A few ring and branched-chain compounds are included at the end of the list. In all cases allowance has been made as indicated by Eisenlohr and Wöhlisch for unsaturation and ring formation, but not for chain branching. It will be observed that in most cases the differences are too serious to be neglected, while in many of them they are very large indeed. Furthermore, it is to be expected that when compounds containing other elements such as nitrogen or sulphur, are considered, the discrepancies will become even greater. With the Lorenz and Lorentz formula Eisenlohr distinguished three kinds of oxygen linking in the molecule and assigned a different value to the atomic refractivity of each one. Similarly, he distinguished thirty different kinds of nitrogen ("Spektrochemie organische Verbindungen," 1913, p. 62). In his new method, he recognises six different kinds of oxygen; one awaits with considerable interest the list of atomic refractive powers of nitrogen in different states of combination.

None of these methods of calculating refractive power takes account of dispersion. There is no *a priori* reason why the *D* line alone should be used in a rational method for the study of refractive index. Up to the present, a certain amount of success has attended the efforts of investigators who have employed this illuminant to the exclusion of all others, but it is submitted that this success is merely superficial and has no real significance. It is due largely to two facts:

- (a) The relative crudity of the formulae employed. The accepted standard figures are not sufficiently accurate for their purpose, and the method of calculating and expressing refractive power encourages investigators to ignore differences between calculated and experimental figures of many times the experimental error.
- (b) The transparency of the substances investigated. The greater part of the material examined refractometrically in the past was transparent in the visible and the near ultra-violet regions of the spectrum. It thus becomes obvious that the earlier workers could afford with impunity to ignore the effects of dispersion. The light rays with which they worked had wave-lengths which were so very far removed from those of the characteristic absorption bands of the substances they had to deal with that it was really a matter of indifference which line of the spectrum they chose as a standard. The dispersion curves of the substances used in the visible region of the spectrum were flat, and their absorption asymptotes were very far away in the remote ultra-violet, so that the slight changes in the

refraction introduced by small alterations in the position of the absorption asymptote from substance to substance were completely masked by the insensitive nature of the formulæ employed.

With the refinement of experimental method, however, and, what is more important, with the ever-widening scope of the investigation to include substances of more complicated chemical structure, the accepted method has begun to break down. So long as the empiricist has to deal with simple organic compounds containing only carbon, hydrogen, and oxygen, his formulæ serve him well enough—especially when they are so effective in concealing the true magnitude of the discrepancies involved—because the absorption band controlling the dispersion is far removed from the region of observation. It now becomes clear why it is impossible to assign any one value to the atomic refractive power of elements of variable valency like nitrogen, sulphur, and phosphorus; why special values have to be introduced to account for the effect of double and triple bonds; why special values have to be assigned to the refractive effect of ring closure, and why still further modifications have to be introduced into the figures for conjugated systems of double bonds, or of ketonic groups, or of one with the other. All these effects tend to produce colour in the molecule, that is to say that they bring the dominant absorption band in the spectrum of the substance nearer to the visible region, and thus cause the effects of dispersion to become more and more marked. The inadequacy of the formulæ for the calculation of refractive power is now no longer a sufficient cloak for concealing the neglect of dispersion, and the method obviously breaks down. It is therefore suggested that a new method be adopted: that the form of the refractive dispersion curves for organic compounds be studied. If the constants of the dispersion equations are used for the purposes of comparison of one compound with another, the question of a standard wave-length will not arise, and, provided that no attempt is made to obscure the real scientific issue by the use of formulæ such as those of Gladstone and Dale or of Lorenz and Lorentz, it may reasonably be hoped that the true nature of refractive power, showing in all probability strongly marked constitutive character, will be revealed. It is suggested that the Sellmeier equation (1) will prove very suitable for this purpose.

Natural Rotatory Power.

The Drude equation (2) has already been used with marked success to express the natural rotatory dispersion of organic compounds, mainly by Lowry and Pickard and their collaborators. Pickard and the present author have shown, further, that in the case of *d*- γ -nonyl nitrite (*loc. cit.*), λ_0 has the same value in both the

Sellmeier equation (1) and the Drude equation (2), and also that it is identical with the wave-length of the head of an absorption band in the spectrum of that substance.

Recent work in these laboratories points to the fact that this is probably a general rule for all organic compounds, and perhaps for all optically active substances, thus affording welcome evidence of the validity of both these dispersion equations. *d*-sec.-Octyl alcohol may be quoted as one example.

Refractive Dispersion of d-sec.-Octyl Alcohol.

The refractive dispersion of this compound at 20° can be expressed by the equation

$$n^2 = 1.6013 + 0.313\lambda^2/(\lambda^2 - 0.0283^*),$$

where λ denotes the wave-length in microns. The agreement between the observed and calculated figures for values of λ between 6438 and 4358 Å.U. is within the limit of experimental error (Table II).

TABLE II.

λ in Å.U.	n_D^{20} obs.	n_D^{20} calc.	Difference.
6438	1.4238	1.4238	\pm
5896	1.4256	1.4256	\pm
5461	1.4273	1.4273	\pm
5086	1.4292	1.4293	+0.0001
4800	1.4311	1.4312	+0.0001
4678	1.4320	1.4320	\pm
4358	1.4349	1.4350	+0.0001

Rotatory Dispersion of d-sec.-Octyl Alcohol.

The rotatory dispersion of this compound at 16° can be expressed by the equation

$$[\alpha]_D^{16} = 3.14/(\lambda^2 - 0.0283)$$

with λ in microns as before. The observed and calculated figures for values of λ between 6438 and 3650 are collected in Table III.

TABLE III.

λ in Å.U.	$[\alpha]$ obs.	$[\alpha]$ calc.	Difference.	
6438	8.12	8.13	+0.01	Visual readings.
5893	9.86	9.85	-0.01	
5461	11.65	11.64	-0.01	
5086	13.58	13.63	+0.05	
4800	15.46	15.54	+0.08	
4678	16.42	16.47	+0.05	
4358	19.49	19.43	-0.06	Photographic measurements.
4251	20.6	20.0	0.6	
3969	24.2	24.2	\pm	
3790	27.5	27.3	\pm	
3650	29.9	30.7	+0.8	

* This figure was determined from the measurements of rotatory power recorded in Table III.

In the case of quartz, the agreement is very striking indeed. Using figures for λ_1 and λ_2 calculated from early refractometric determinations, Lowry (*Phil. Trans.*, 1912, [A], 212, 261) has shown that the natural rotatory dispersion of quartz can be expressed by the equation

$$\alpha_{\text{degrees per min.}} = \frac{11.6064}{\lambda^2 - 0.010627} + \frac{13.42}{\lambda^2 - 78.22} - \frac{4.3865}{\lambda^2}$$

throughout the visible spectrum from λ 4358 to λ 6708 Å.U. with an accuracy of about 1 part in 25,000. The accuracy of the early determinations of the refractive index of quartz is open to question, but the author has had occasion to fit a Sellmeier equation to Gifford's later, and much more trustworthy figures (*Proc. Roy. Soc.*, 1902, 70, 239; 1910, 84, 193), and finds that the equation

$$n_{\text{ordinary ray}}^2 = 1.35375 + \frac{1.00317\lambda^2}{\lambda^2 - 0.010627} + \frac{0.8275\lambda^2}{\lambda^2 - 78.22}$$

with the same dispersion constants, expresses the refractive index throughout the spectrum from λ 7950 to λ 3303 Å.U. with an accuracy of about 1 part in 150,000.

Magnetic Rotatory Power.

The study of magnetic rotatory dispersion is at present in an undeveloped and unsatisfactory state. Wiedemann's law of the proportionality of natural and magnetic rotatory powers has been shown to be invalid for organic compounds (Lowry, Pickard, and Kenyon, T., 1914, 105, 94). Lowry has proposed (*ibid.*, p. 81) an equation of the Drude type (2) to express the magnetic rotatory dispersion of organic compounds, and has found that, in every case so far examined, one term only of such an equation is required. It appears to the author, however, that this proposal is somewhat unfortunate, and he would prefer, for two reasons, to regard it as a first approximation only.

First, it is quite conceivable that a substance should exhibit simple natural rotatory dispersion, but complex magnetic rotatory dispersion. The converse case, however, seems much less likely. Natural rotatory dispersion is affected only by those electrons within the molecule which move in asymmetric paths; refractive dispersion, on the other hand, is influenced by all the vibrating electrons in the molecule (provided, of course, that their periods are sufficiently small) whether they move in asymmetric paths or not. It would seem legitimate, too, to assume that the phenomenon of magnetic rotatory dispersion is due to the fact that the magnetic

field imposes an element of asymmetry upon the paths of all the electrons controlling refractive dispersion. Unless, therefore, it is assumed that the magnetic field acts selectively and influences certain electrons rather than others, which seems at present an unnecessary multiplication of hypotheses, it would appear impossible for fewer electrons to influence magnetic than natural rotatory power. Further, because of the great similarity between the physical mechanism of refractive and magnetic rotatory dispersion, it would appear desirable to adopt dispersion equations for both these properties which indicate this similarity of mechanism by a similarity of form. It is claimed that the dispersion equations (1) and (3) fulfil this condition.

Secondly, if we consider a substance which exhibits both simple magnetic and simple natural rotatory dispersion, we should expect its natural and magnetic rotatory dispersion ratios for two given wave-lengths to be identical, unless it is assumed that a magnetic field alters the position of the dominant absorption band. In other words, it would seem that Lowry, Pickard, and Kenyon (*loc. cit.*) have made two contradictory statements—

(i) That a Drude equation (2) with one term can be applied to the magnetic rotatory powers of many organic liquids.

(ii) That Wiedemann's law is not valid for any of these liquids. These investigators attempt to reconcile the two statements by assuming that λ_0 is not the same in the two dispersion equations. There appear to be two ways in which this could occur. The magnetic field might alter the position of the absorption band—a Zeeman effect on a hitherto unprecedented scale. Were this the case, we should expect the shift to be proportional to the strength of the field, so that the dispersion would vary with the field strength, and it would be futile to propose a dispersion equation which does not take account of this fact. The only other way out of the difficulty appears to be to assume that the effect of the magnetic field is to suppress one band entirely and to bring another into prominence. In view of the considerations brought forward in this communication and in Part XIX, it is very difficult to accept this hypothesis.

The Natural and Magnetic Rotatory Dispersions of Ethyl Tartrate.

The points discussed above are well illustrated by the optical properties of ethyl tartrate. It is well known that the natural rotatory dispersion of this compound cannot be represented by a Drude equation with one term. Lowry and Cutter (T., 1922, 121, 532) have recently shown that its natural rotatory power can be

expressed, at least in the visible and the near ultra-violet regions of the spectrum, by the equation

$$[\alpha] = \frac{25.005}{\lambda^2 - 0.03} - \frac{20.678}{\lambda^2 - 0.056}$$

which predicts the presence of absorption bands at $\lambda = \sqrt{0.03}$ and $\lambda = \sqrt{0.056}$, that is, at $\lambda 1730$ and $\lambda 2370$ Å.U. Its magnetic rotatory power can be expressed, according to Lowry, Pickard, and Kenyon (*loc. cit.*), by a one-term Drude equation of type (2), and its magnetic rotatory dispersion ratio, $\delta_{4358}/\delta_{5461}$, is 1.630. This gives a value for λ_0 of 1350 Å.U. The discrepancy is far too great to be ascribed to experimental error, even if we could explain the fact that the natural rotatory dispersion equation requires two terms, whilst the magnetic rotatory dispersion equation requires only one. It is inconceivable, too, that the position of the dominant absorption band can have been moved at least 400 Å.U. merely by the application of a magnetic field.

It appears far more probable that the magnetic rotatory dispersion of ethyl tartrate is represented by the equation

$$\delta = \frac{A}{\lambda^2} + \frac{B}{\lambda^2 - 0.03} + \frac{C}{\lambda^2 - 0.056}.$$

Then, with measurements confined to the visible spectrum, the form of the equation would appear to be

$$\delta = D/(\lambda^2 - \lambda_0^2), \text{ where } \lambda_0^2 \text{ is less than } 0.03.$$

The adoption of the magnetic rotatory dispersion equation,

$$\delta = \frac{A}{\lambda^2} + \sum \frac{B_0}{\lambda^2 - \lambda_0^2},$$

could also explain the fact that, in general, magnetic rotatory dispersion ratios are smaller than the corresponding natural rotatory dispersion ratios. Where the converse is the case, notably in aromatic compounds, it is probable that the substance in question possesses a refractive absorption band of less refrangibility than its rotatory absorption band. This equation also possesses the advantage that it contains a term corresponding to the dielectric constant, and thus the connexion between refraction and magnetic rotation is clearly brought out.

It is submitted, therefore, that there is no such phenomenon as simple magnetic rotatory dispersion considered in the same sense as simple natural rotatory dispersion: the dispersion equation must always contain at least two terms. But because of the fact that the individual terms are all positive (negative magnetic rotatory power

is unknown at present amongst organic compounds, so that anomalous magnetic rotatory dispersion similar in type to the anomalous natural rotatory dispersion of ethyl tartrate has not yet been observed) and because some of them may be small, an average term can, and often does, replace the actual ones with little loss of accuracy as far as measurements in the visible region of the spectrum, remote from the absorption bands, are concerned.

Quite recently, measurements of magnetic rotatory dispersion of some organic compounds have been made in the near infra-red spectrum by Ingersoll (*J. Opt. Soc. Amer.*, 1922, 6, 663). This investigator is inclined to prefer the dispersion equation $\delta = k\lambda \cdot dn/d\lambda$, to express his results, but an inspection of his experimental curves shows clearly that this formula is not the one best fitted for his purpose. The deviations which he ascribes to experimental error are nearly all in one direction, and appear to point definitely to equation (3) as being more suitable.

Summary.

1. Emphasis is again laid on the importance of dispersion effects in the study of optical properties.
2. Dispersion equations are adopted for natural rotatory power, refractive index, and magnetic rotatory power, which can easily be applied to organic compounds.
3. It is shown that refractive power is much more constitutive than has hitherto been supposed. The accepted methods of calculation are shown to be inadequate and even harmful, because they have conferred on this property an appearance of additivity which is as misleading as it is false.
4. The proposed dispersion equations demonstrate clearly the connexion between the four optical properties, natural and magnetic rotatory powers, refractive index, and absorption spectrum.
5. From the magnetic rotatory dispersion formula suggested, becomes clear why Wiedemann's law is not obeyed by organic compounds.

In conclusion, the author wishes to thank Drs. R. H. Pickard and J. Kenyon for their assistance and interest; and he has to acknowledge the receipt of a personal grant from the Department of Scientific and Industrial Research.

CLXXXVIII.—*Ring-chain Tautomerism. Part VI.*
The Mechanism of the Keto-cyclol Change in the
Propane Series.

By ERIC WILLIAM LANFAR and JOCELYN FIELD THORPE.

It has been proved hitherto that tautomerism occurs between the two forms (I) and (II) when R = ethyl (Deshapande and Thorpe, T., 1922, 121, 1430) or *n*-propyl (Bains and Thorpe, this vol.,

p. 1206), but that when R = methyl or R₂ = methyl ethyl (Singh and Thorpe, this vol., p. 113) the hydroxy-ring form (I) is incapable of existence and the open-chain keto-form (II) is alone stable. This follows from the fact that the dibromo-esters of type (III), when treated with methyl-alcoholic potash or aqueous potassium hydroxide, yield mixtures of the hydroxy-ring acid (I) and the keto-acid (II) when R = ethyl or *n*-propyl, but give only the methoxy-derivative (IV) and the keto-acid (II) when R = methyl and R₂ = methyl ethyl.

The discovery (Singh and Thorpe, *loc. cit.*) that both the *cis*- and *trans*-forms of the methoxy-derivative (IV) in the dimethyl and methyl ethyl series passed quantitatively into the open-chain keto-acid (II) on hydrolysis showed conclusively that the hydroxy-ring acids (I) in these series were incapable of existence and that when a hydrogen atom was introduced in place of the methyl group in the methoxy-compound it passed at once to the neighbouring α -carbon atom, leading to fission of the ring and to the formation of the keto-acid.

On the other hand, in sharp contrast with this behaviour, it was found (Beesley, Ingold, and Thorpe, T., 1915, 107, 1103) that when R₂ represents a cyclohexane ring the sole product formed from the dibromo-ester of type (III), or its lactone, was the hydroxy-ring acid (I). This acid was found to be quite stable towards strong aqueous potash and it is evident, therefore, that there is no tendency for the cyclopropane complex to undergo fission in a compound of this type.

The general hypothesis which was suggested to explain these phenomena assumed that the angle at which two of the valencies of a carbon atom emerged from the nucleus could be profoundly

affected, and that two of the causes leading to the change were (a) the volume of the groups attached to the other two valencies, and (b) the inclusion of these two other valencies in a ring complex, the internal angles of which can be assumed to be fixed.

The following table shows how far this hypothesis is supported by the experimental facts already discovered:

R ₂ .	Calculated angle $R_2 > C < x$.	Equilibrium.	
		Keto-acid. Per cent.	Hydroxy- ring acid. Per cent.
2 Hydrogens	115.3°	100	0
2 Methyls	109.5°	100	0
Methyl ethyl	—*	100	0
2 Ethyls	—*	38	62
2 n-Propyls	—*	29	71
cycloHexane	107.2°	0	100

* We have no means at present of determining the volume effect of these groups.

It has been suggested that the effect produced in the manner described above may not be due, as we suppose, to an alteration in the valency direction, but may be brought about by some other cause, for example, the induced polarities of the carbon atom forming the grouping R₂. In order to meet this criticism we have now subjected the compounds in which R₂ represents a *cyclopentane* complex to a close experimental study, because it is evident that if the alteration of the tetrahedral angle is the determining cause of the observed phenomena the *cyclopentane* ring, which gives rise to a calculated angle of 109.4°, ought to exert an influence very similar to that of the dimethyl group. If, on the other hand, polarity is the cause, the effect produced by the *cyclopentane* ring ought to be similar to that observed in the case of the diethyl derivative. The experiments described in this paper show conclusively that the *cyclopentane* derivatives are similar to the dimethyl derivatives in their reactions and behave quite differently from those based on diethyl. Hence the hypothesis advanced by us is fully substantiated.

During the course of these experiments we were able to discover facts which clearly show the mechanism of the tautomeric change between the keto-acid and the hydroxy-ring acid. From the first, it has always been a matter of wonder that the slight variation in angle shown by the table should bring about the great difference in chemical properties indicated in the right-hand column, especially when it was remembered that, under normal conditions, the *cyclopropane* ring is not easily formed. The present experiments provide a complete explanation of this, for it has been found that

when the *cyclopentane* dibromo-ester (V) is treated with aqueous potash there is formed mainly the keto-acid (VI), but that when methyl-alcoholic potash is used a mixture of the hydroxy-ring acid (VII) and the methoxy-derivative (VIII) is produced.

Both the hydroxy-ring acid (VII) and the keto-acid (VI) are stable towards aqueous potash, but the former is completely converted into the latter by hydrobromic acid. Moreover, the methoxy-derivative (VIII) yields the keto-acid (VI) on hydrolysis with hydrobromic acid.

At first it seemed difficult* to reconcile the existence of the hydroxy-ring acid (VII) with our general hypothesis. Indeed, had it not been for the isolation of the methoxy-derivative and its hydrolysis to the keto-acid, it would have appeared as if the *cyclopentane* derivatives were simulating the diethyl compounds and not those containing the dimethyl group, in spite of the fact that the keto-acid and the hydroxy-ring acid could not be shown to be tautomeric. The problem of bringing these results into line presented many difficulties, until it was discovered that the hydroxy-ring acid, unlike any other compound of the type prepared hitherto, readily gave an anhydride (IX). It is evidently, therefore, a *cis*-acid, with the carboxyl groups on the same side of the plane of the ring, whereas all the other hydroxy-ring acids which have been isolated are *trans*-forms and do not give anhydrides. Moreover, it is evidently only the *trans*-modifications which undergo fission, for the fact that the *cyclopentane* hydroxy-ring acid (VII) passes into the keto-acid on treatment with hydrobromic acid can readily be explained on the assumption that conversion from the *cis*- into the *trans*-form precedes fission. Hitherto, in one instance only, has the methoxy-derivative of type (IV) been isolated in *cis*- and *trans*-forms and that was in the case of the methyl ethyl derivative (Singh and Thorpe, *loc. cit.*). The fact that both forms gave the same keto-acid with hydrobromic acid is, however, clear evidence that the *cis*-form passes into the *trans* under the experimental conditions employed.

It follows that the two stereoisomeric hydroxy-ring acids must

behave differently, the one (*cis*) being stable and the other (*trans*) at once undergoing fission to form the open-chain keto-acid, where this form is stable. The only explanation which is adequate to meet this remarkable fact removes also the difficulty regarding ring formation mentioned above, because it is evident that if the *trans*-form is the unstable form the instability must be due to interaction between the hydroxyl and the carboxyl group which, in this modification, are on the same side of the plane of the ring. Consequently, the mechanism of the change can be represented as follows:

Tautomerism takes place, therefore (in the diethyl and di-*n*-propyl series) between the two forms A and B (potassium salts) and not directly between the cyclopropane ring and the open-chain ketone.

EXPERIMENTAL.

Bromination of cyclopentane-1:1-diacetic Acid.—The bromination was carried out in exactly the same way as in the case of cyclohexane-1:1-diacetic acid (Beesley, Ingold, and Thorpe, T., 1915, 107, 1093). The product consisted almost entirely of ethyl $\alpha\alpha'$ -dibromocyclopentane-1:1-diacetate (V).

Hydrolysis of the Bromo-ester. *cis*-cyclopentanespiro-1-hydroxycyclopropane-1:2-dicarboxylic Acid (VII).—One hundred grams of the dibromo-ester (V) were added, as quickly as was consistent with safety, to a boiling solution of 200 grams of potassium hydroxide in 600 c.c. of methyl alcohol, and the mixture was boiled for a further twenty minutes. The alcohol was then evaporated off entirely, and the filtered, aqueous solution of the dry residue was acidified with hydrochloric acid and extracted five times with its own volume of ether. The ethereal solution, partly dried with calcium chloride and evaporated nearly to dryness, deposited crystals of *cis*-cyclopentanespiro-1-hydroxycyclopropane-1:2-dicarboxylic acid. These were collected—the filtrate being kept—and dried in an evacuated desiccator for two days. The acid was triturated with sodium-dried ether, in which it is insoluble, and recrystallised from chloroform, separating in crystals melting at 163°. Yield

23 grams (Found: C = 54.0; H = 6.2. $C_9H_{12}O_5$ requires C = 54.0; H = 6.0 per cent.).

The *disilver* salt was prepared from silver nitrate and the ammonium salt in aqueous solution (Found: Ag = 52.1. $C_9H_{10}O_5Ag_2$ requires Ag = 52.2 per cent.).

Anhydride of cis-cycloPentanespiro-1-hydroxycyclopropane-1:2-dicarboxylic Acid (XI).—The *cis*-hydroxy-ring acid (2 grams) and acetyl chloride (10 grams) were heated together for two hours, and the excess of acetyl chloride was evaporated. The viscous residue solidified on keeping over potassium hydroxide in a vacuum. The *anhydride* separated from ether in large crystals melting at 71°. On treatment with dilute alkali and subsequent acidification, it yielded the original *cis*-hydroxy-ring acid. Yield 1.7 grams (Found: C = 59.6; H = 5.7. $C_9H_{10}O_4$ requires C = 59.4; H = 5.5 per cent.).

The *dianilide* was prepared by heating the anhydride with excess of aniline at 190° for three hours. It was recrystallised from ether, forming colourless needles melting at 107° (Found: N = 8.2. $C_{21}H_{22}O_3N_2$ requires N = 8.0 per cent.).

cis- and trans-cycloPentanespiro-1-methoxycyclopropane-1:2-dicarboxylic Acid (VIII).—The ethereal filtrate obtained in the preparation of the ring-hydroxy-acid having been evaporated, and the residual gum made to solidify by keeping in an evacuated desiccator for a week, the solid was ground with sodium-dried ether, in which the methoxy-acids dissolved, the insoluble ring-hydroxy-acid was removed, and the filtrate evaporated to dryness, when 18 grams of a mixture of the *cis*- and *trans*-methoxy-acids, melting at 108–120°, were obtained.

Attempts to separate these acids by fractional crystallisation were fruitless, owing to their extreme solubility in all solvents except light petroleum, which, when added to the solution in another solvent, precipitated the two acids together as an oil. The solid was therefore treated with a mixture of acetyl chloride and a small quantity of light petroleum in the cold. The *cis*-acid was converted into the anhydride, which dissolved, whilst the *trans*-acid was unattacked. The latter was removed, and recrystallised from dry ether, small crystals melting at 175° being obtained (Found: C = 55.8; H = 6.5. $C_{10}H_{14}O_5$ requires C = 56.1; H = 6.5 per cent.).

The *disilver* salt was obtained by treating the acid with silver nitrate and ammonia in aqueous solution (Found: Ag = 50.3. $C_{10}H_{12}O_5Ag_2$ requires Ag = 50.4 per cent.).

To obtain the *cis*-acid, the filtrate containing the anhydride was evaporated and the residue dissolved in dilute potassium

hydroxide solution, which was then filtered, acidified, and extracted with ether. The solvent was evaporated and the residue crystallised from a mixture of ether and light petroleum. The crystals obtained melted at 160° (Found: C = 55.9; H = 6.62. $C_{10}H_{14}O_5$ requires C = 56.1; H = 6.54 per cent.).

The *disilver* salt was prepared from the ammonium salt and silver nitrate in aqueous solution (Found: Ag = 50.5. $C_{10}H_{12}O_5Ag_2$ requires Ag = 50.4 per cent.).

α -Ketocyclopentane-1:1-diacetic Acid (VI).—This acid was obtained by the action of boiling strong hydrobromic acid on either the ring-hydroxy-acid (VII) or the ring-methoxy-acid (VIII).

A solution of the ring-hydroxy-acid (5 grams) in 50 c.c. of hydrobromic acid (d 1.49) was boiled under reflux for two hours, the hydrobromic acid then evaporated, and the residue dissolved in a large quantity of ether. The solution was filtered, as some charring had occurred, and evaporated as completely as possible on the water-bath. The residue was dissolved in a large quantity of ether, and the small quantity of water which remained was removed. The ether was evaporated, and the viscous residue kept for three weeks in an evacuated desiccator containing potassium hydroxide. The crystals that separated were pressed on a porous tile and recrystallised from a mixture of ether and light petroleum: the product melted at 112° (Found: C = 53.7; H = 6.1. $C_9H_{12}O_5$ requires C = 54.0; H = 6.0 per cent.).

A *quinoxaline* derivative was prepared by heating the keto-acid and *o*-phenylenediamine in glacial acetic acid, and separated as a crystalline precipitate, melting at 222° , on diluting the solution with water (Found: C = 66.01; H = 5.90; N = 10.02. $C_{15}H_{16}O_3N_2$ requires C = 66.24; H = 5.88; N = 10.29 per cent.).

The keto-acid was also obtained by hydrolysis of the bromo-ester (V) with aqueous potassium hydroxide. Two grams of the dibromo-ester were added drop by drop to 15 c.c. of boiling 64 per cent. aqueous potassium hydroxide (b. p. 150°). The boiling was continued for twenty minutes. When cold, the solution was diluted to 100 c.c., acidified with dilute hydrochloric acid, and extracted five times with its own volume of ether. The extract was evaporated and the residue, having been seeded with a crystal of the keto-acid, was placed in an evacuated desiccator, where it slowly solidified. The solid was moistened with ether, pressed on a porous tile, and recrystallised from a mixture of ether and light petroleum. Yield 0.6 gram.

A *silver* salt was prepared by adding silver nitrate to the ammonium salt in aqueous solution (Found: Ag = 52.1. $C_9H_{10}O_5Ag_2$ requires Ag = 52.2 per cent.).

The thanks of the authors are due to the Research Fund Committee of the Chemical Society for a grant which has partly defrayed the expenses of this investigation.

(LXXXIX.—*The Conditions of Reaction of Hydrogen with Sulphur. Part II. The Catalytic Effect of Oxygen. Part III. The Mechanism of the Reaction of Hydrogen with Sulphur and its Catalysis by Oxygen.*

By RONALD GEORGE WREYFORD NORRISH and ERIC KEIGHTLEY RIDEAL.

Part II. The Catalytic Effect of Oxygen on the Direct Combination of Hydrogen and Sulphur.

IN carrying out the experiments on the direct union of hydrogen and sulphur described in Part I (this vol., p. 704), hydrogen, diluted to give various partial pressures by admixture with nitrogen, was passed over the heated sulphur. In the preliminary experiments, the interesting fact was discovered that hydrogen so diluted was far more active in the formation of hydrogen sulphide than pure hydrogen, pointing to the fact that either the nitrogen or some contained impurity was catalysing the reaction. The most obvious impurity to look for was oxygen, and analysis showed that the gas delivered by the cylinder contained 7.0 per cent. of oxygen. When this oxygen impurity was removed by passing the hydrogen-nitrogen mixture over hot palladised copper, all trace of catalysis disappeared, the union of hydrogen and sulphur proceeding with a smaller velocity than when pure hydrogen was used. The catalytic agent must therefore have been oxygen, and this fact was finally proved by the observation that the addition of about 3 per cent. of oxygen to pure hydrogen increased the rate of formation of hydrogen sulphide about six times at 265°. In the present paper, experiments are described dealing with the catalytic activity of the oxygen as a function of its concentration in the hydrogen, for three temperatures 265°, 285°, and 340°, by a dynamic flow method similar to that described in Part I (*loc. cit.*). It is found that at the lower temperatures the catalytic activity passes through a maximum for certain concentrations of oxygen, and then falls off, finally producing a poisoning effect. At the higher temperature the oxygen appears to

act as a poison at all concentrations. At the same time, a quantity of sulphur dioxide is formed, at a rate proportional to the oxygen concentration in the gas mixture.

The presence of this sulphur dioxide in the gas stream made it impossible to estimate the hydrogen sulphide colorimetrically as colloidal lead sulphide, owing to the fact that although the concentration in the gas stream was too low for interaction between hydrogen sulphide and sulphur dioxide to take place, sulphur was immediately precipitated when the potash solution in which the gases had been collected was acidified with acetic acid.

The difficulty of estimating both gases separately was eventually overcome by passing the effluent gases into standard iodine solution, when the following reactions occur:

The amount of iodine neutralised by the mixed gases was obtained by titration with standard potassium thiosulphate solution, whilst the acid produced was estimated by a back titration with standard soda. Since in reacting with a molecule of iodine, a molecule of sulphur dioxide produces twice as much acid as a molecule of hydrogen sulphide, two equations are obtained which enable us to calculate the two unknown concentrations of these substances.

EXPERIMENTAL.

The mixtures of hydrogen and oxygen were prepared by adding the calculated quantity of oxygen to a given volume of hydrogen by means of a gas burette. The reaction chamber containing the sulphur was the same vessel as that used in Part I (*loc. cit.*), consisting of a Claisen flask of about 75 c.c. capacity, immersed in a constant-temperature bath of mixed potassium and sodium nitrates kept well stirred. The effluent gases were made to bubble at a constant slow rate through the iodine solution, contained in a deep test-tube. The absorption by this method was shown to be complete by a control experiment, in which the effluent gases were bubbled through alkaline hypobromite solution contained in potash bulbs, the total sulphur collected being estimated gravimetrically as sulphate.

As a result of two runs of one hundred minutes each with hydrogen containing 5 per cent. of oxygen at 285°, the following results were obtained by the two methods of estimation:

Total weight of sulphur collected per second:

estimated by alkaline hypobromite-BaSO₄ method, 54.89×10^{-5} gram.

estimated by iodine method, 54.76×10^{-5} gram.

It will thus be seen that the absorption and the estimation of the gases by iodine give trustworthy results.

The results obtained are shown in Table I.

TABLE I.

Reaction of hydrogen-oxygen mixtures with sulphur. Rate of flow of gas in all cases 136 c.c. per hour.

Percentage oxygen content.	Temperature 265°.		Temperature 285°.		Temperature 340°.	
	Gram of H ₂ S formed per sec. $\times 10^3$.	Gram of SO ₂ formed per sec. $\times 10^3$.	Gram of H ₂ S formed per sec. $\times 10^3$.	Gram of SO ₂ formed per sec. $\times 10^3$.	Gram of H ₂ S formed per sec. $\times 10^3$.	Gram of SO ₂ formed per sec. $\times 10^3$.
0	1.08	0.0	3.63	0.0	189.7	0.0
1			7.05	16.9	114.5	56.9
3	5.91	16.0	10.13	43.5		
5	7.77	27.5	9.86	90.8	37.46	289.4
7	7.74	36.0	3.30	121.8		
10	2.11	64.0	0.0	179.0		

Before proceeding to a discussion of these results, it is necessary to make a correction to obtain the pressure of oxygen in the reaction chamber. Column 1 of Table I gives the oxygen content of the gas flowing into the bulb. The effluent gas is poorer in oxygen by an amount equivalent to the sulphur dioxide formed, and the oxygen pressure in the reaction chamber may be taken as a mean between the pressures in the inflowing and the outflowing gas stream. The volume of gas passing over per hour after absorption of the sulphur dioxide was in all cases 136 c.c. If x is the velocity of formation of sulphur dioxide in grams per second, then $60 \times 60 \times x \times 22400/64$ c.c. = $126 \times 10^4 \times x$ c.c. is the volume of sulphur dioxide absorbed per hour.

The total volume of gas (V) passing through the reaction vessel is thus $V = 136 + 126 \times 10^4 x$ c.c.

If p is the percentage oxygen content of the inflowing gas, this volume contained $(136 + 126 \times 10^4 x) \times p/100$ c.c. of oxygen. This in the outflowing gas has been reduced to

$$\frac{(136 + 126 \times 10^4 x \times p - 126 \times 10^4 x)}{100} \text{ c.c. of oxygen.}$$

The percentage oxygen content in the outflowing gas has thus fallen to

$$\begin{aligned} & \frac{(136 + 126 \times 10^4 x) p - 126 \times 10^4 x}{(136 + 126 \times 10^4 x)} \times 100 \\ &= p - \frac{126 \times 10^4 x}{136 + 126 \times 10^4 x} \\ & \quad \quad \quad 3 \text{ m}^2 \end{aligned}$$

The percentage oxygen content of the gas in the reaction bulb is the mean between those of the inflowing and outflowing gas streams, that is,

$$p + \frac{\left\{ p - \frac{126 \times 10^6 x}{136 + 126 \times 10^4 x} \right\}}{2} = p - \frac{63 \times 10^6 x}{136 + 126 \times 10^4 x}$$

Column 3 in Tables II and III shows the true pressures of oxygen in the reaction vessel obtained in this way.

The experimental results contain four salient features which must be explained by any interpretation put upon them, namely—

- (1) The existence of a maximum in the catalytic power of the oxygen at 265° and 285°.
- (2) The change from catalytic effect to poisoning effect as the concentration of oxygen increases at these temperatures.
- (3) The fact that the velocity of formation of sulphur dioxide is approximately proportional to the concentration of the oxygen in the gas mixture.
- (4) The fact that at 340° only a poisoning effect by the oxygen is observed.

It has already been demonstrated in Part I of this paper that the interaction of hydrogen and sulphur takes place by way of two reactions, surface and gaseous, the former extending over the whole glass surface of the reaction vessel, and being predominant below 300°, whilst the latter predominates above that temperature. If it be assumed in addition, first that the presence of oxygen in the gaseous phase exerts a strong inhibiting action in the gaseous formation of hydrogen sulphide, and secondly that its presence on the surface of the sulphur exerts a catalytic action in the surface formation of hydrogen sulphide, changing to a poisoning effect for higher concentrations in the gaseous phase, as the surface becomes more and more completely covered with oxygen, all the points enumerated above will find complete explanation.

It is believed by the authors that the above hypothesis is the only one which will explain the experimental facts, and in what follows it has been developed to give a physical picture of the process and a quantitative explanation of the experimental data. The gaseous reaction will be considered first.

It was demonstrated in Part I that the velocity of formation of hydrogen sulphide in the gaseous reaction at 340° for a pressure of 0.81 atm. was 142.6×10^{-8} gram per second,* whilst the surface

* The experimental data of this paper are directly comparable with those of Part I, since the same reaction vessel was used throughout the two series of experiments.

reaction was only 14.35×10^{-8} gram per second. By scaling the gaseous reaction up to 1 atmosphere pressure, its magnitude is found to be 176×10^{-8} gram per second, compared with the surface reaction of 14.35×10^{-8} gram per second.

It is thus evident that the anticatalytic action of oxygen at 340° must operate mainly in the gaseous reaction. This being so at 340° , it is reasonable to assume that it is also a fact at the lower temperatures of 265° and 285° , where the gas reaction is relatively less important than the surface action, and that the high catalysis observed there is the result of the effect of the oxygen on the surface reaction.

If we assume further with Bodenstein (*Z. physikal. Chem.*, 1899, 29, 315) that in the gaseous phase sulphur atoms are removed to form hydrogen sulphide or sulphur dioxide as rapidly as they are formed by the dissociation of S_2 molecules—in other words, that at each temperature there is a constant active mass of sulphur atoms in the gaseous phase, then in the two competing reactions

it follows that the sulphur atoms will be divided between the hydrogen and the oxygen present in the ratio of the velocities of the two reactions. In other words, the velocity of formation of hydrogen sulphide in gram-molecules per second (W) is given by

$$W = \frac{k_h P_h}{k_h P_h + k_o P_o} \times C,$$

where P_h and P_o refer to the partial pressures of hydrogen and oxygen respectively, measured as percentages of the total pressure, k_h and k_o are the respective velocity coefficients of hydrogen sulphide and sulphur dioxide formation, and C represents the total number of gram-molecules of hydrogen sulphide and sulphur dioxide formed per second, constant for any given temperature.

We have, further, from the conditions of experiment, $P_h + P_o = 100$ and therefore

$$W = \frac{k_h P_h}{k_h P_h + k_o (100 - P_h)} \times C \quad \dots (1)$$

At 340° , from the figures given for the gaseous reaction above, when $P_o = 0$, we have $C = \frac{176}{34} \times 10^{-8} = 5.18 \times 10^{-8}$ gram-molecule per second.

Therefore
$$W = \frac{P_h}{P_h + \frac{k_o}{k_h} (100 - P_h)} \times 5.18 \times 10^{-8} \quad (1a)$$

In order to obtain W for any value of P_H , we must evaluate the ratio k_0/k , and this can be done if we make the further assumption that at 340° , when $P_0 = 3.7$ per cent. in the reaction bulb (see Table III), the surface action is completely poisoned. It will be shown, when dealing with the surface reaction, that this assumption is likely to a high degree of probability. The figure 37.46×10^{-8} is thus taken to refer only to the gaseous formation of hydrogen sulphide, giving W for 3.7 per cent. of oxygen concentration equal to $\frac{37.46}{34} \times 10^{-8} = 1.1 \times 10^{-8}$ gram-molecule per second; and substituting for W in equation (1a), we thus obtain $k_0/k_H = 120.0$.

Having obtained the ratio k_0/k_H for the temperature 340° , we may assume that at 265° and 285° it remains sensibly the same* and use it to calculate by equation (1) the magnitude of the gaseous H_2S and SO_2 reactions at those temperatures, for the various concentrations of oxygen employed, evaluating C as before from the known gaseous reaction when the gas phase is constituted by pure hydrogen. In this way we obtain W , the number of gram-molecules of hydrogen sulphide formed in the gas phase for various concentrations of oxygen. Further, if Y represents the number of gram-molecules of sulphur dioxide formed in the gas phase, then the relation $W + Y = C$ enables us to calculate Y .

In Table II, Y and W are transformed from gram-molecules per second to grams per second, and tabulated in columns 4 and 5, respectively. Finally, by subtraction of these figures from the corresponding total SO_2 and H_2S reactions given in Table I, we obtain the "observed" velocities of formation of sulphur dioxide and hydrogen sulphide on the surface, tabulated in columns 6 and 7 of Table II.

It will be seen that the velocity of formation of sulphur dioxide in the gaseous phase at the lower temperatures is in general very small compared with the velocity of formation on the sulphur surface, and thus, on plotting the total formation of sulphur dioxide against oxygen content of the gas phase, the form of the curve within the limits of experimental error, is determined by the surface

* Since the above reactions both take place between the diatomic hydrogen or oxygen molecule on the one hand and sulphur atoms on the other, the assumption of the approximate constancy of this ratio over the comparatively small range of temperature involved is probably not seriously in error.

Any error in the magnitude of k_0/k_H cannot affect the magnitude of the total gaseous sulphur reaction, but only the ratio in which this reaction is divided between the formation of hydrogen sulphide and sulphur dioxide, and considering the smallness of these quantities compared with the total reaction, any error in their absolute magnitude would not affect seriously the computation of the "observed" surface reaction.

reaction, the velocity of which, as will be shown theoretically below, is directly proportional to the oxygen pressure. We thus obtain practically a straight line on plotting the velocity of formation of sulphur dioxide against the oxygen percentage at 265° and 285°; at 340°, the form of the curve is determined both by the surface and gaseous reactions, and is again nearly a straight line over the range of pressures investigated.

The data of Tables II and III are plotted in Figs. 1 and 2.

Curves I and II (Fig. 1) show the variation of the velocity of formation of hydrogen sulphide in the surface reaction with the concentration of oxygen in the gas phase. It will be seen that the catalytic effect of the oxygen first rises to a maximum and finally falls off until the surface becomes completely poisoned. With rising temperature, it will be observed that the point of maximum catalysis occurs at lower and lower oxygen concentrations in the

gas phase. Thus, at 265° the maximum occurs at an oxygen concentration of 5.8 per cent., whilst at 285° the maximum occurs at an oxygen concentration of 3.7 per cent. of oxygen. It follows that at 340°, if a maximum exists, it will occur at a very low oxygen concentration, probably less than .1 per cent. At the same time, the point at which the surface is completely poisoned shifts from an oxygen concentration of 10.3 per cent. at 265° to a concentration of 7 per cent. at 285°, and it is thus highly probable, as assumed above, that at 340° the surface is completely poisoned for oxygen concentrations of 3–4 per cent.

FIG. 1.

To account for this surface catalysis and subsequent poisoning, it is necessary to assume that oxygen molecules are preferentially adsorbed on the surface of the sulphur, so that, as the concentration of oxygen in the gas mixture increases, the area occupied by adsorbed hydrogen grows less and less, while that occupied by oxygen increases. At a concentration of about 7 per cent. of oxygen, the surface is completely covered with oxygen at 285° and thus completely poisoned as far as the formation of hydrogen sulphide is concerned. For lower concentrations of oxygen in the gas mixture, hydrogen and oxygen molecules exist side by side in the surface, and the whole of the observed effects can be explained by ascribing a catalytic activity to these oxygen molecules. A discussion of the mechanism of

catalysis will not be entered into at this point, but reserved for a later section of this paper.

In developing the quantitative expression for the catalysis of the surface reaction, it is necessary to make certain very probable assumptions which will be shown later to have a definite physical significance when the mechanism of the reaction is considered.

Let the velocity of the interaction of hydrogen and sulphur be proportional both to the number of adsorbed oxygen molecules and to the number of adsorbed hydrogen molecules per square centimetre. Denoting these numbers by m_1 and m_2 , respectively, for a given gas mixture and temperature, and if V_1 represent the velocity of the catalysed reaction, and V_2 that of the uncatalysed reaction, we have

$$V_1 \propto m_1 m_2 \text{ and } V_2 \propto m_2.$$

Thus the total surface reaction velocity (V) may be written

$$V = V_1 + V_2 = k_1 m_1 m_2 + k_2 m_2 \dots \dots (2)$$

where k_1 and k_2 are constants.

The chance of a vacant sulphur atom in the surface being occupied by an oxygen atom is directly proportional to the number of oxygen molecules, and inversely proportional to the number of hydrogen molecules hitting the surface per second. These numbers are, however, in the ratio of the partial pressures of the two gases, and thus we have $m_1 \propto P_o/P_H$, where P_o and P_H are the partial pressures of the oxygen and hydrogen respectively.

Now it has been demonstrated in Part I of this paper that the adsorption capacity of the surface of sulphur in contact with an atmosphere of pure hydrogen gas is completely saturated. Furthermore, we know from the experiments detailed above that at 285° the surface is completely poisoned when the hydrogen atmosphere contains 7 per cent. of oxygen, and therefore must be completely covered by oxygen. It is thus clear that surfaces in contact with hydrogen atmospheres containing less oxygen than this must be completely saturated by the adsorption of a mixture of hydrogen and oxygen molecules. Thus, if n is the total number of sulphur atoms per square centimetre of surface, capable of adsorbing hydrogen and oxygen molecules, then, at any moment, we have

$$n = m_1 + m_2.$$

$$\text{Wherefore } m_1 = k_o P_o / P_H \dots \dots \dots (3)$$

$$\text{and } m_2 = n - k_o P_o / P_H \dots \dots \dots (4)$$

where k_o is a constant.

Thus substituting for m_1 and m_2 in equation (2), we have

$$V = k_1 \cdot k_0 \frac{P_o}{P_H} \left(n - k_0 \frac{P_o}{P_H} \right) + k_2 \left(n - k_0 \frac{P_o}{P_H} \right)$$

Therefore $V = \left(k_1 k_0 \frac{P_o}{P_H} + k_2 \right) \left(n - k_0 \frac{P_o}{P_H} \right) \quad \dots \quad (5)$

or $V = \left(a \frac{P_o}{P_H} + b \right) \left(1 - c \frac{P_o}{P_H} \right) \quad \dots \quad (6)$

where a , b , and c are constants to be evaluated.

The experiments having all been carried out at atmospheric pressure, we may substitute the partial pressures as percentages of the whole in equation (6), that is,

$$V = \left(a \frac{P_o}{100 - P_o} + b \right) \left(1 - c \frac{P_o}{100 - P_o} \right) \quad \dots \quad (7)$$

The constants may be obtained as follows:

(1) where $P_o = 0$, $V = b$,

that is, for b we may write the velocity of the reaction when catalysis is absent, obtained from Part I (*loc. cit.*, Fig. 2, curve 6).

(2) $V = 0$ when $cP_o/(100 - P_o) = 1$.

The corresponding value of P_o may be obtained from the experimental curve at the point where it cuts the abscissa, giving c .

(3) a is obtained by differentiating equation (7), putting $d^2V/dP_o^2 = 0$, and inserting the values found for P_o when V is a maximum, and b and c as found above.

Proceeding in this way, we obtain the following values:

Temperature 265°: $a = 2.60 \times 10^{-4}$; $b = 0.75 \times 10^{-6}$; $c = 8.6$.

Temperature 285°: $a = 5.00 \times 10^{-6}$; $b = 1.66 \times 10^{-8}$; $c = 13.2$.

In the last two columns of Table II are shown the surface reaction velocities observed, and calculated with the above constants according to equation (7), corresponding to various percentages of oxygen in the reaction bulb. It will be seen that the agreement is in general good, and lends support to the view of surface catalysis adopted.

The rate of production of sulphur dioxide on the sulphur surface will be proportional at any moment to the number of adsorbed oxygen molecules per square centimetre.

This quantity according to equation (3) is $m_1 = k_0 P_o/P_H$.

Thus we can write $V_{so_2} = K' P_o/P_H$, where V_{so_2} is the rate of formation of sulphur dioxide on the surface and K' is a constant.

Now over the range of oxygen pressures investigated, P_o varies from 1 to 10, whilst P_H varies only from 90 to 100. Thus the velocity of formation of sulphur dioxide will be very nearly directly proportional to the partial pressure of the oxygen as found experimentally.

FIG. 2.

Concentration of Surface Phase in Equilibrium with a Given Gas Phase.

On dividing equation (4) by n , we obtain

$$\frac{m_2}{n} = \left(1 - c \frac{P_o}{P_H}\right) = 1 - \theta,$$

where θ is the fraction of each square centimetre of sulphur surface occupied by oxygen.

Hence

$$\theta = cP_o/P_H \quad . \quad . \quad . \quad . \quad . \quad (8)$$

In this way it is possible to give for the first time a table based on experimental results showing how the surface concentration of adsorbed gases varies with the composition of the gaseous atmosphere

in equilibrium with it. Table IV has been calculated from equation (8), giving to the constant c the values found for it above for the two temperatures 265° and 285°.

Part III. The Mechanism of the Reaction of Hydrogen with Sulphur and its Catalysis by Oxygen.

The data obtained in the experimental sections of Parts I and II of this paper, and also certain thermochemical data relating to sulphur published by Budde and Pollitzer, make it possible to study in detail the mechanism of the reaction.

It has already been shown (Part I, *loc. cit.*) that the temperature coefficients of the gaseous and surface reactions lead to critical increments of 52,400 cal. per gram-atom of sulphur and 26,200 cal. per gram-atom of sulphur for the two reactions, respectively, the value for the gas reaction being exactly double that for the surface reaction.

Now the interaction of hydrogen and sulphur in the gaseous phase undoubtedly depends on a chain of linked reactions, such as

and, other things being equal, its velocity will be fixed by the slowest reaction in this series. The actual velocity temperature coefficient measured, therefore, is that of the slowest reaction in some such series as the above, and the critical increment, 52,400 cal., calculated therefrom will be the critical increment necessary to activate the molecule taking part in that reaction.

In view of the extremely small fraction of sulphur dissociated into atoms at these temperatures (Preuner and Schupp, *Z. physikal. Chem.*, 1909, 68, 129), it is highly probable that the reaction

$S_8 \rightleftharpoons 2S$ is by far the slowest stage in the dissociation of sulphur molecules into atoms, and thus that the critical increment measured is that required to dissociate the S_8 molecule into its component atoms. Budde (*Z. anorg. Chem.*, 1912, **58**, 169; also von Wartenberg, *ibid.*, 1907, **56**, 320) has obtained a value 103,800 cal. at constant volume, or 100,000 cal. at constant pressure at 300° as the heat of dissociation per gram-molecule of S_8 , that is, 50,000 cal. per gram-atom, a value in very good accord with that calculated above from the temperature coefficient.

Turning now to the surface reaction, we have to explain why the critical increment of the surface reaction is exactly half that of the gas reaction, and the idea at once suggests itself that in this case we are measuring only the energy increment necessary to break one of the $S=S$ linkages, whilst that for the gas reaction is a measure of the energy required to break both bonds. It is obvious, however, inasmuch as we start with hydrogen and sulphur, and finish with hydrogen sulphide, that the net energy change in the two reactions—surface and gas—must have been the same, and thus to bring the surface reaction into line with the gaseous reaction, in which two bonds are broken, it must be supposed that the former takes place in two successive stages, each involving the rupture of a linkage.

These two stages must be :

- (1) Adsorption of the hydrogen to form a surface layer involving breaking of the first bond.
- (2) Final rupture of the sulphur atoms from the surface and formation of the hydrogen sulphide molecule.

It is unlikely that both these reactions would take place with the same velocity, and the temperature coefficient would thus apply only to the slower, the critical increment calculated therefrom thus applying only to one or other of the above processes.

It has been shown by Pollitzer (*Z. anorg. Chem.*, 1909, **64**, 121) that the heat of sublimation of diatomic sulphur molecules from the surface of sulphur is 28,000 calories, a value in such good agreement with our value of 26,000 calories for the removal of a molecule of hydrogen sulphide from the surface as to suggest that we are here again dealing with the same phenomenon, namely, the breaking of a single sulphur bond.

Since the vapour in equilibrium with a sulphur surface at the temperatures we are concerned with consists almost entirely (about 95 per cent.) of S_8 molecules (Preuner and Schupp, *loc. cit.*; Roscoe and Schorlemmer, Vol. I, 5th edn., p. 386), it follows that the molecules in the surface must also be mainly of the formula S_8 . The system S_8 is apparently formed by the association of S_2 molecules, and is one of considerable stability. We should therefore expect it to have a

very small external field, since in it sulphur exhibits its maximum degree of saturation. In the absence of any data by which the spatial structure of the molecule may be fixed, we may picture it as some type of closed system, such as a ring, or a cube with a sulphur atom at each corner. Such molecules, in view of their high degree of saturation, would probably be incapable of forming adsorption compounds by association with molecules of hydrogen or oxygen, and we must assume that at any instant a small fraction of them is opened up by the rupture of a bond. By virtue of their highly

FIG. 3.

Dotted line indicates surface of separation between liquid and gas phases.

unsaturated and polar condition, these ruptured S_8 molecules would be capable of adsorbing gas molecules when they exist in the surface, by the exercise of their unused bonds. These ideas may be rendered clearer by the help of the diagrammatic representations shown in Fig. 3, in which a ring structure for the S_8 molecules is assumed for simplicity, but it is by no means essential.

A, B, C, D, E, F, G, and H represent various S_8 molecules, existing in the surface, in various stages of unsaturation.

A is an unbroken molecule, its affinity saturated to the maximum extent, and incapable of adsorbing either hydrogen or oxygen.

B is an S_8 molecule which has become opened up, free polarity being developed at the two ends of the chain, rendering it capable of attracting molecules of hydrogen or oxygen. C, D, E, and F represent various adsorption compounds—C with oxygen attached to the two ends of the chain, D and E with hydrogen and oxygen attached at opposite ends of the chain, F with hydrogen attached to the two ends.

It will be seen that from B, C, and F, molecules of S_2 , SO_2 , and H_2S can be detached, respectively, by the breakage of one linkage between two sulphur atoms, and it follows that the heat of sublimation of S_2 and the heats of evaporation of hydrogen sulphide and sulphur dioxide from a sulphur surface should be the same. That this is true for H_2S and S_2 molecules has already been shown, the rupture of a bond involving the expenditure of 26,000 to 28,000 calories per gram-atom of sulphur, and it is hoped to investigate in a later paper the case of sulphur dioxide.

If hydrogen and oxygen are adsorbed at opposite ends of a sulphur chain, it is to be expected that the strong attraction of the oxygen for the sulphur at one end of the chain will cause a weakening of the force by which the sulphur at the other end is held (as shown by the alternate strong and weak bonds in D and E) and thus lower the critical energy increment necessary to remove the end sulphur atom as hydrogen sulphide. To this we can therefore attribute the catalytic effect of adsorbed oxygen on the surface combination of hydrogen and sulphur, and it follows from this view that catalysis should be at a maximum when the surface is approximately half covered with oxygen and half with hydrogen. That this fact has been demonstrated experimentally will be seen by comparing Table II with Table III (Part II).

The mechanism of attachment of hydrogen and oxygen molecules in their adsorbed compounds with sulphur molecules calls for some further comment. It has already been postulated that for adsorption to take place the sulphur molecules must be rendered polar by the rupture of a bond, thus developing a positive and a negative end. In order that a hydrogen or oxygen molecule may be attached to the ends of this chain, it also must develop a polarity (for example, by induction on approaching closely to an open sulphur molecule) and adsorption may then take place between oppositely charged ends of oxygen or hydrogen molecules and sulphur chains. In view of the preferential adsorption of oxygen, it follows that this polarity can be induced more easily in the oxygen molecule than in the hydrogen molecule. At very low pressures, we may suppose that hydrogen or oxygen molecules may be adsorbed by the unsaturated sulphur molecules as in G and H (Fig. 3), that is, by

occupying "two spaces" per molecule, as we know is the case in their adsorption on the much more polar palladium and platinum surfaces at atmospheric pressure. In view of the weaker attraction of the sulphur surface, however, the effect would rapidly disappear at ordinary pressures, such doubly adsorbed molecules tending to give way to singly adsorbed molecules as the effect of crowding increased.

As to the critical increment required to bring about the necessary displacement of electrons and nuclei in the hydrogen and the oxygen molecule to produce polarisation, these experiments tell us nothing, the temperature coefficients merely indicating the critical increment required to break one sulphur bond in removing the molecules of hydrogen sulphide and sulphur dioxide from the surface, this being the slowest process in the chain of reactions making up the surface reaction.

It might be expected that the juxtaposition of polarised oxygen and hydrogen molecules would lead to the catalytic formation of water vapour by the sulphur surface, as is the case on the surface of palladium. That this is not so was experimentally demonstrated by passing the effluent gases from the reaction chamber over anhydrous copper sulphate. No trace of water was obtained. It thus follows that the degree of polarity induced in the oxygen and the hydrogen molecules is not sufficient to cause them to combine together, or it may be that the tendency for the oxygen to form sulphur dioxide is much greater than its tendency to form water. The molecules on the surface of the metal palladium, however, are known to be highly polar, and in activating hydrogen and oxygen molecules they probably induce a much higher degree of polarity than is the case on the sulphur surface, thus enabling adjacent molecules of hydrogen and oxygen to react. This high polarisation reaches the extreme case of complete dissociation in the cases of oxygen adsorbed on platinum, and hydrogen on tungsten. The strong tendency of either of the reactants, hydrogen or oxygen, to react preferentially with the catalyst is also here absent.

Summary.

Part II.

The catalytic action of oxygen on the interaction of hydrogen and sulphur has been investigated. It has been found that this catalytic action becomes a poisoning action with rise of temperature and increase of oxygen concentration beyond 10 per cent. at a temperature of 265° and 7 per cent. at 285°. The effects observed have been separated into a strong poisoning effect in the gaseous reaction between hydrogen and sulphur at all temperatures, and a catalytic

effect on the surface reaction which only becomes observable at low temperatures (265° and 285°), where the surface reaction is of greater relative importance. This surface catalytic action rises to a maximum with increase of oxygen concentration in the hydrogen and then falls off, finally becoming a poisoning action for concentrations of oxygen beyond 10 per cent. At the same time, sulphur dioxide is formed at a rate directly proportional to the concentration of the oxygen.

The effects observed have been shown to be quantitatively explained by postulating a gradual preferential adsorption of oxygen by the sulphur surface, all the hydrogen being displaced when the gaseous concentration of oxygen has exceeded 10 per cent., and ascribing to the oxygen a catalytic activity proportional to the number of molecules adsorbed per sq. cm. of surface.

It has been found possible to calculate for the first time the composition of the adsorbed gas film in equilibrium with a given gaseous atmosphere.

Part III.

The mechanism of the interaction of hydrogen and sulphur and its catalysis by oxygen have been considered in the light of the experimental data of Parts I and II, and the thermochemical data furnished by Budde and Pollitzer.

The critical increment of the gaseous reaction has been found to be in agreement with Budde's value for the heat of dissociation of S_8 molecules into atoms, and thus corresponds to the energy required to sever two sulphur bonds.

The critical increment of the surface reaction similarly corresponds to the breaking of one sulphur bond, and is equal to that required to sublime a molecule of S_2 from the surface, which also involves the breaking of one bond.

The surface reaction is considered to take place in two stages—(1) adsorption of the molecule, involving breaking of one bond, and (2) removal of the molecule of hydrogen sulphide, involving breaking of the second bond, the critical increment measured corresponding only to the slower of these two processes.

It is shown how, by assuming a small percentage of the stable and saturated S_8 molecules of which the surface is mainly composed to be opened by the rupture of one linkage and thus polarised, we can account for the adsorption of hydrogen and oxygen and for the catalytic action of the latter.

LABORATORY OF PHYSICAL CHEMISTRY,
CAMBRIDGE UNIVERSITY.

[Received, April 19th, 1923.]

*CXC.—The Mechanism of the Pinacol-Pinacolin and
Wagner-Meerwein Transformations.*

By CHRISTOPHER, KELK INGOLD.

THE investigation of that rearrangement of carbon skeleton which so frequently accompanies the dehydration of *tert.*-alkylcarbinols has long been actively pursued, and of recent years has derived much interest and importance from the remarkable success that has attended the efforts of Meerwein and his collaborators to base many of the complex structural changes which occur in camphor chemistry on transformations of this type.

The prevalent view of the mechanism of the change appears to be that which involves the assumption of an intermediate cyclic compound, which is supposed to be formed by the elimination of the elements of water and to undergo subsequent fission in such a way as to give rise to the altered carbon skeleton. Applying this idea to the transformation of pinacol into pinacolin (compare V. v. Richter, "Organische Chemie," 11te Aufl., p. 243), we obtain the following result:

The objection to this view is that the real difficulty is merely transferred to the second stage of the hypothetical scheme, since there is no independent evidence that the intermediate ethylene oxide, if formed, would undergo the remarkable isomeric change postulated. Further, although it is possible to assume the intermediate formation of an analogous oxide in the case of certain molecular changes in the terpene series, for instance, the conversion of α -dihydroxydihydrocampholenic acid into α -pinonic acid,

other transformations, manifestly similar in general character, cannot be brought within the scheme for the reason that the initial substance, being a monohydric and not a dihydric alcohol, cannot give rise to an ethylene oxide. To account for such cases, it has been supposed (compare Ruzicka, *Helv. Chim. Acta*, 1918, 1,

110; Ruzicka and Liebl, *ibid.*, 1923, 6, 267, and others) that a cyclopropane derivative is first produced by the elimination of water, and is then disrupted by an isomeric change. Thus in the simplest possible case, namely, the dehydration of *tert.*-butylcarbinol (Robinson, private communication*), the intermediate compound would be 1:1-dimethylcyclopropane:

whilst in the conversion of isoborneol into camphene it would be tricyclene:

and so forth. Unlike the scheme for the dehydration of a dihydric alcohol, this scheme *does* suggest a plausible mechanism for the rearrangement of the carbon skeleton; but there is, nevertheless, some evidence that, in this case also, the cyclic substances which are assumed to intervene are actually too stable to undergo the subsequent isomeric change under the conditions in which this change is supposed to occur. Thus, whilst 1:1-dimethylcyclopropane *can* be converted into its isomeride, isopentene (by passage over contact material at 400°; Ipatiev and Hahn, *Ber.*, 1903, 36, 2014), the change has not been shown to occur under the usual conditions of a Wagner-Meerwein transformation; again, tricyclene *can* be converted into camphene, but the change does not take place to an appreciable extent under conditions in which isoborneol is completely converted into camphene (Meerwein and van Emster, *Ber.*, 1920, 53, [B], 1815).

Recently, an alternative explanation, embracing not only the pinacol-pinacolin change, but also the Wagner-Meerwein change (that is, the dehydration of monohydric as well as dihydric *tert.*-alkylcarbinols), has been suggested by Robinson (*Mem. Manchester*

* R. Robinson and (Miss) M. Tadman have found that the dehydration of *tert.*-butylcarbinol yields a mixture of $\text{CH}_3\text{CMe} \cdot \text{CH}_2\text{CH}_3$ and $\text{CMe}_2\text{CH} \cdot \text{CH}_3$, and that the former hydrocarbon is converted into the latter under the conditions employed to carry out the reaction. Hence they regard the former hydrocarbon as the primary product of the dehydration.

Phil. Soc., 1920, 64, No. 4), whose view is expressed by the following general symbols*:

In these expressions, R^1 , R^2 , R^3 , and R^4 represent alkyl groups, A a bivalent atom or group ($O<$ in the pinacol-pinacolin change, and $CH_2<$ in the Wagner-Meerwein change) and $x-y$ a compound (usually $H-OH$ or $H-Br$) such that there is a strong tendency to its formation. The initial stage of the process, which leads ultimately to the elimination of $x-y$, consists in the formation of a ring of six atoms held by partial or complete valencies. Thus the group R^2 becomes involved, and a continuation of the process to the point at which the molecule $x-y$ separates leads to the transference of R^2 to the adjoining carbon atom.

It will at once be observed that, quite apart from detail regarding the intermediate stages, there is a very real distinction between this view and the older one. Considering the simple case of the dehydration of *tert.*-butylcarbinol by way of example, it will be seen that, on the older view, the methyl group (numbered 1 in the formulæ below) which supplies the hydrogen atom eliminated as water is the one which becomes transferred to the adjacent carbon atom during dehydration, whilst, on Robinson's view, it is not this methyl group but one of the others which becomes so transferred:

Of course it is not possible to distinguish experimentally between the two possibilities, either in this case, or, for that matter, in most others in which a molecule of the type HX is eliminated, because the product is the same whatever the mechanism. It is, however, possible to imagine certain transformations, similar in all essential respects to the Wagner-Meerwein change, which would give rise to different products according to the mechanism, and would thus serve as a means for deciding whether the older view or Robinson's is closer to the truth.

* These formulæ differ slightly from those given by Robinson owing to the fact that, apparently, in his formulæ the symbol \cdots invariably represents exactly half a valency.

An example of this kind has now been studied and has yielded decisive evidence in favour of Robinson's mechanism as against the older one, at least so far as concerns the character of the ultimate product of the change.

It has been shown by Zelinsky (*Ber.*, 1913, 46, 160) that the elimination of bromine from *ωω*-dibromo-1:1-dimethylcyclopropane (I) proceeds with great readiness, yielding a hydrocarbon C_5H_8 . According to the view that a cyclopropane ring is closed and subsequently broken, the intermediate stage would be the spiran hydrocarbon (II), and the normal product (supposing that the intermediate cycloid is sufficiently unstable to undergo the usual isomeric change) would be ethylcyclopropene (III). However, just as in certain of Meerwein's examples, so also in this case, the normal product might undergo a further change yielding, by the migration of the double bond, either ethylenecyclopropane (IV) or vinylcyclopropane (V):

Robinson's mechanism leads to a very different result, the normal product being methylenecyclobutane (VI), which might conceivably undergo further change into either of the methylenecyclobutenes (VII and VIII):

Thus according to the older view, all the possible products are cyclopropane derivatives, whilst, according to Robinson's, they are all cyclobutane derivatives, and hence a proof of the structure of the substance actually isolated would supply evidence of the type required.

It should be stated here that Zelinsky did not oxidise, or otherwise establish the constitution of, his hydrocarbon, to which he assigned the spirane structure (II); but he supposed the substance to be identical with a hydrocarbon prepared by Gustavson (*J. pr. Chem.*, 1896, [ii], 54, 97) from the bromide of pentaerythritol. He offered no proof of this, however, beyond the determination of

density and refractive index—means scarcely adequate to distinguishing between so many closely related isomerides, even if the substances compared were known to be pure chemical individuals; and, actually, Gustavson's product is now known to be a mixture of variable composition (Philipow, *J. pr. Chem.*, 1916, [ii], 93, 162).

It is, however, readily possible to distinguish between the various isomerides by oxidation, and, as it is of value to consider the negative as well as the positive evidence, the following table of the oxidation products to be expected from the six isomeric hydrocarbons, (III)–(VIII), is given.

Series.	Hydro-carbon.	First oxidation products.	Ultimate oxidation products.
<i>cyclo</i> -Propane.	III	Propionylacetic acid.	Acetic acid + malonic acid, or propionic acid + oxalic acid.
	IV	Acetic acid + <i>cyclo</i> -propanone.	Acetic acid + malonic acid.
	V	<i>cyclo</i> Propanecarboxylic acid.	<i>cyclo</i> Propanecarboxylic acid.
<i>cyclo</i> -Butane.	VI	<i>cyclo</i> Butanone.	Succinic acid.
	VII	Laevulic acid.	Succinic acid, or acetic acid + malonic acid.
	VIII	Methylsuccinic acid.	Methylsuccinic acid.

In addition to these oxidation products, oxalic and carbonic acids are to be expected whatever the constitution of the hydrocarbon.

The actual oxidation products of the unsaturated hydrocarbon, C_5H_8 , obtained from dibromodimethyl*cyclo*propane are laevulic and succinic acids, together with small amounts of oxalic acid and carbonic acid. Acetic, propionic, malonic, *cyclo*propanecarboxylic, and methylsuccinic acids, ketones, and ketonic acids other than laevulic acid have all carefully been searched for and found absent. It follows, therefore, that the hydrocarbon must consist essentially of methyl- Δ^1 -*cyclobutene* (VII), unaccompanied by any of its isomerides of the *cyclo*propane series. The *cyclobutene* isomeride (VIII) is also excluded, but not methylenecyclobutane (VI), since the *cyclobutanone* expected from it might not have survived the conditions of the oxidation.

Therefore the main issue is plain. The structure of the hydrocarbon is that given by Robinson's mechanism [the reaction proceeding as far as the compound (VII) in the scheme outlined above] and is not that to which the older view of the process, involving the intermediate formation of the spirane hydrocarbon (II), must lead.

It may be added that by combining these results with Philipow's investigation of Gustavson's hydrocarbon the conclusion follows that, despite many statements to the contrary, the simplest possible

piro-compound (II) has never yet been isolated or even transiently formed as an unstable intermediate product.

EXPERIMENTAL.

The dibromodimethylcyclopropane required was prepared by Zelinsky and Krawetz's method (*loc. cit.*, p. 165), and converted into the hydrocarbon C_5H_8 by digestion with alcohol and zinc dust. The hydrocarbon was washed thoroughly with water, dried with calcium chloride, and carefully distilled. It boiled at $38.5-40^\circ/755$ mm. and could not be resolved into two fractions of different boiling point (compare Philipow, *loc. cit.*).

Oxidation of the Hydrocarbon C_5H_8 .—A solution containing 15 grams of the hydrocarbon in 100 c.c. of acetone was cooled to 0° , and titrated slowly with a cold solution of potassium permanganate in aqueous acetone. The permanganate solution was made up by dissolving 70 grams of potassium permanganate in a mixture of 3,400 c.c. of pure acetone and 200 c.c. of water, so that 1,200 c.c. of the solution corresponded approximately to 1 atom of available oxygen. When 2—3 atoms of oxygen had been absorbed the reduction became very slow and the process was discontinued. The solution was allowed to warm to the room temperature to destroy the small excess of permanganate, saturated with carbon dioxide, filtered, and then distilled with the aid of an efficient column. The oxides of manganese were washed with hot water, and the washings mixed with the aqueous residue from the distillation. The combined solutions were then treated with a sufficient quantity of a chromic acid solution, prepared by dissolving 90 grams of potassium dichromate and 150 grams of sulphuric acid in 1,200 c.c. of water, to supply the balance, after allowing for the absorption of permanganate, of a total of six atoms of available oxygen. The reduction of the chromic acid was completed by heating the mixture in the water-bath, and the cooled solution extracted repeatedly with a large volume of pure ether. The acid products were removed from the extract by shaking it thoroughly with aqueous sodium carbonate and then recovered by again extracting the aqueous solution thoroughly with ether after acidification with sulphuric acid. The neutral and the acid extracts were dried with sodium sulphate, and the ether was distilled off through an efficient column.

Carbon dioxide. During the oxidation with chromic acid a considerable quantity of carbon dioxide was evolved.

Oxalic acid. The aqueous solution of chromic salts was mixed with the acid sodium sulphate solution, and the whole boiled to expel carbon dioxide, made faintly alkaline with ammonia, and

then treated with a small amount of calcium chloride. The precipitate (4.2 grams) was collected, washed with dilute acetic acid and water, and identified as calcium oxalate in the usual way (Found: Ca = 31.0. Calc., Ca = 31.1 per cent.).

Glycol, $C_5H_8(OH)_2$. The residue from the neutral extract was a viscous syrup which showed no tendency to crystallise. The quantity (3.6 grams) was scarcely sufficient for a satisfactory distillation, but almost the whole boiled between 110° and $120^\circ/26$ mm. (Found: C = 58.2; H = 10.2. $C_5H_{10}O_2$ requires C = 58.8; H = 9.8 per cent.). It was not further investigated.

Succinic acid. The residue from the acid extract crystallised partly on keeping, and a further quantity of crystalline material separated after addition of dry chloroform. The crystals (2.5 grams) were collected and washed with chloroform. Without further purification, they melted at $180-182^\circ$, and after crystallisation from water, at 184° . They were identified as succinic acid (Found, by titration, $M = 117.6$. Calc., $M = 118$) by direct comparison, by the melting point of the mixture with a genuine specimen, and by conversion into succinic anhydride, which was identified similarly.

Lævulinic acid. The chloroform solution of liquid acids showed no tendency to deposit any more crystals either on keeping or on cooling to a low temperature, and therefore it was evaporated and the residue esterified with ethyl alcohol and sulphuric acid in the usual way. The esters and unchanged acids were extracted thoroughly with ether after the addition of water, and the acid products removed by aqueous sodium carbonate and recovered by re-extraction with ether after acidification. They were then re-esterified and the ester was added to the main bulk, which, after removal of ether by distillation through a column, was carefully fractionated under atmospheric pressure. No trace of ethyl acetate, ethyl propionate, or ethyl cyclopropanecarboxylate was isolated. The first drop of distillate appeared at 197° , and almost the whole was collected at $200-203^\circ$, although a few drops boiling at $210-215^\circ$ were obtained, which on hydrolysis with hydrochloric acid gave fairly pure succinic acid (0.5 gram) unaccompanied by any appreciable trace of methylsuccinic acid.

The fraction, b. p. $200-203^\circ$ (11.5 grams), on hydrolysis with hydrochloric acid yielded a liquid acid, which boiled at $147-149^\circ/18-19$ mm. and then solidified to a mass of colourless crystals, m. p. $31-32^\circ$. It was identified as lævulinic acid by analysis (Found: C = 51.7; H = 7.1; $M = 116$. Calc., C = 51.7; H = 6.9 per cent.; $M = 116$), by its m. p. and b. p., and by the m. p. of its semicarbazone ($190-191^\circ$, decomp.) and phenylhydrazone ($107-108^\circ$).

The ethyl ester was identified by its boiling point, composition (Found: C = 58.2; H = 8.4. Calc., C = 58.3; H = 8.3 per cent.), and the m. p. of its phenylhydrazone (109–110°).

Recovery of Material.—The following table shows how far the material employed was accounted for as identified products of oxidation:

Oxidation product.	Yield (grams).	Equivalent in grams of hydrocarbon oxidised.	Equivalent in grams of oxygen absorbed.
Levulinic acid	9.3	5.4	3.8
Succinic acid	3.0	1.5	2.8
Oxalic acid	3.0	2.3	7.0
Glycol, $C_2H_4(OH)_2$	3.6	2.4	0.6
		11.6	14.2
Hydrocarbon used	15.0 grams	Oxygen used	21.2 grams
„ accounted for	11.6 „	„ accounted for... ..	14.2 „
Balance	3.4 „	Balance	7.0 „

If the balance of the oxygen were employed in oxidising a portion of the hydrocarbon to carbon dioxide and water, a further 2.1 grams of hydrocarbon would be accounted for as oxidation products, leaving a net deficit of 1.3 grams out of a total of 15 grams to be explained as experimental losses and unidentified material. It seems unlikely, therefore, that any important product has been missed.

CXCI.—The Conversion of Sabinol into Thujene.

By GEORGE GERALD HENDERSON and ALEXANDER ROBERTSON.

THE experiments described in this paper were instituted with the object of examining the products formed by the hydrogenation of sabinol (I) under different conditions, and also of ascertaining if the hydrocarbon produced from dihydrosabinol (II) by the xanthate method is α -thujene (III), because if that proved to be the case, additional evidence confirmatory of the identity of dihydrosabinol with thujyl alcohol would be provided.

Semmler (*Ber.*, 1900, **33**, 1459) has shown that sabinol yields thujyl alcohol when reduced with sodium and alcohol. Wallach (*Nach. Ges. Wiss. Göt.*, 1919, **3**, 321) found that when hydrogen is passed into a mixture of sabinol with a dilute aqueous solution of palladium chloride the chief product is a saturated alcohol, dihydrosabinol (b. p. 206—208°, d_4^{20} 0.9090; n_D^{20} 1.4576) which on oxidation gives the ketone thujone; together with the alcohol a small quantity of a hydrocarbon (b. p. 161—163°, d_4^{20} 0.7950, n_D^{20} 1.4375) is produced. Further, it has been proved by Tschugaev (*Compt. rend.*, 1910, **151**, 1058) that, on reduction at the ordinary temperature with hydrogen and platinum black, α -thujene, β -thujene, and sabinene all yield the same saturated hydrocarbon thujane, $C_{10}H_{18}$ (b. p. 157—158°/760 mm.; d_4^{17} 0.8190; n_D^{17} 1.44393).

On treatment of sabinol with hydrogen in presence of active nickel at 170—175°, we obtained a product consisting chiefly of hydrocarbons, with a little unchanged sabinol. From the mixture we isolated thujane, and another saturated hydrocarbon of b. p. 161—163°, but no dihydrosabinol.

This method having proved unsuitable for the preparation of dihydrosabinol, we proceeded to reduce sabinol with hydrogen at a pressure of 2 atmospheres in presence of a palladium sol. Hydrogenation took place rapidly at the ordinary temperature, and the product proved to be a mixture of dihydrosabinol, which was the chief constituent, with some thujane and some of the saturated hydrocarbon of b. p. 161—163°. The last product was probably the same hydrocarbon as that obtained by Wallach (*loc. cit.*). The physical constants of the dihydrosabinol were found to be practically identical with those of thujyl alcohol.

The dihydrosabinol was then converted by Tschugaev's method into methyl dihydrosabinyl xanthate, a viscous liquid of a dark red colour, which did not crystallise. The xanthate was decomposed by heating at 160—165° ($C_{10}H_{17} \cdot O \cdot CS \cdot SMe \rightleftharpoons C_{10}H_{16} + MeSH + COS$), and the liquid distillate purified from traces of sulphur compounds by repeated treatment with sodium, and then distilled fractionally. The three fractions which were separated corresponded closely in physical properties with those obtained by Kondakov and Skworzow (*J. pr. Chem.*, 1903, [ii], **67**, 573) in their preparation of thujene from thujyl alcohol through methyl thujyl xanthate, which also is a viscous liquid, and the two lower fractions undoubtedly consisted of thujene—in all probability of both the α - and β -isomerides. The highest fraction was not further examined, owing to lack of material. It is therefore evident that dihydrosabinol is identical with thujyl alcohol.

EXPERIMENTAL.

Hydrogenation of Sabinol.—The sabinol used in these experiments was prepared from oil of savin, in which it occurs partly in the free state and partly as esters. The oil was heated on the water-bath for half an hour with the necessary quantity of alcoholic potassium hydroxide and then distilled in a current of steam. The volatile products were extracted from the distillate by means of light petroleum, and, after removal of the solvent, the sabinol was separated from the hydrocarbons with which it was mixed by fractional distillation in an atmosphere of carbon dioxide. It was observed that a certain amount of decomposition into a hydrocarbon and water takes place when sabinol is distilled at atmospheric pressure, and therefore the final purification was effected under diminished pressure. Sabinol (b. p. 208–210°/758 mm., d_4^{20} 0.9420, n_D 1.4874) on treatment in pyridine solution with *p*-nitrobenzoyl chloride yields a *p*-nitrobenzoate, which crystallises from alcohol in colourless needles, m. p. 76°.

An attempt was made to hydrogenate sabinol by the method of Sabatier and Senderens. A stream of carefully purified hydrogen was led through sabinol heated at about 120°, and the mixed vapours were passed through a tube filled with fragments of pumice covered with finely divided active nickel, and maintained at 170–75°. The liquid product, which contained water, was dried over anhydrous sodium sulphate and fractionally distilled, with the result that the following substances were isolated: (1) a saturated hydrocarbon, b. p. 157–160°/760 mm., d_4^{20} 0.8181, n_D 1.4440, which, from its physical constants and from its method of formation, was evidently thujane; (2) another saturated hydrocarbon, b. p. 161–163°/761 mm., d_4^{20} 0.7950, n_D 1.4300, which is probably identical with the hydrocarbon obtained by Wallach, along with dihydrosabinol, on hydrogenating sabinol in presence of palladium chloride; (3) a small quantity of unaltered sabinol. No dihydrosabinol was obtained.

It was found that the preparation of dihydrosabinol could be carried out with satisfactory results by the following process. 0.05 Gram of palladium chloride was dissolved in 5 c.c. of water, with addition of two drops of concentrated hydrochloric acid, and the solution diluted to 90 c.c. and mixed with 10 c.c. of a 10 per cent. solution of gum arabic. The liquid was then heated at 80° and the palladium chloride reduced by gradual addition of a dilute solution of hydrazine hydrate. The black, colloidal solution of palladium thus obtained was transferred to a 400 c.c. bottle fitted with a rubber stopper through which passed an inlet and an outlet

tube, the former being connected to a hydrogen container and manometer. Twenty grams of sabinol were poured into the bottle, the stopper was inserted, the air displaced by hydrogen, the outlet tube closed, the pressure of hydrogen increased to 2 atmospheres, and the bottle agitated. Under these conditions, the reaction was completed in about fifteen minutes, 20 grams of sabinol taking up 2.85 litres of hydrogen, whilst the quantity theoretically required was 2.99 litres.

It was found that a sol of platinum could be used as a catalyst instead of palladium, and with similar results, and also that the process of hydrogenation does not take place, except to a small extent, when the sabinol is dissolved in alcohol or in glacial acetic acid.

The product of hydrogenation was distilled in a current of steam and extracted from the distillate with light petroleum, the solution dried over anhydrous sodium sulphate, the solvent removed, and the residual liquid fractionally distilled. Three compounds were isolated, namely (1) thujane, (2) the same hydrocarbon of b. p. 161—163° as was produced by the action of hydrogen on sabinol in presence of active nickel, and (3) the saturated alcohol, dihydrosabinol. This alcohol is a colourless liquid, b. p. 206—208°, d_4^{20} 0.9100, n_D 1.4601. When treated with *p*-nitrobenzoyl chloride in the usual manner, it did not yield a nitrobenzoate, but appeared to undergo dehydration.

Preparation of Thujene from Dihydrosabinol.—The dihydrosabinol was first converted into sodium dihydrosabinyl xanthate $C_{10}H_{17} \cdot O \cdot CS \cdot SNa$, by treatment of its solution in toluene with sodium and then with carbon disulphide and ether, and the sodium salt was converted by means of methyl sulphate into methyl dihydrosabinyl xanthate, $C_{10}H_{17} \cdot O \cdot CS \cdot SMe$, which was obtained in the form of a dark red, viscous liquid. The xanthate was decomposed by heating at 160—165°, and finally at 180°, and the distillate purified by distillation with sodium. After six repetitions of this treatment, a colourless liquid, free from sulphur compounds, was obtained, which distilled at 152—166° and consisted of a mixture of unsaturated hydrocarbons. On fractionation of this mixture, the following products were separated: (1) a liquid, b. p. 151—152.5°, d_4^{20} 0.8230, n_D 1.4500; (2) a liquid, b. p. 152—156°, d_4^{20} 0.8260, n_D 1.4590; (3) a liquid, b. p. 156—167°, d_4^{20} 0.8231, n_D 1.4528. In physical properties, these correspond with the fractions of the thujene prepared from thujyl alcohol by the xanthate method (Kondakov and Skworzow, *loc. cit.*), and it is evident that the lower fractions consist mainly, if not altogether, of thujene, probably both the α - and the β -isomendes

being present. This was confirmed by the fact that they responded to the following test for thujene. The hydrocarbon was dissolved in chloroform, and to the cooled solution a chloroform solution of bromine (1 mol.) was added. The chloroform was evaporated under diminished pressure at the ordinary temperature, leaving a dark coloured, oily liquid. On dilution with alcohol, this liquid gave an intense red coloration.

We desire to express our thanks to the Carnegie Trust for a scholarship which enabled one of us (A. R.) to take part in this work, and for a grant which met some of the expense.

UNIVERSITY OF GLASGOW.

CXCII.—*The Correlation of Additive Reactions with Tautomeric Change. Part I. The Aldol Reaction.*

By EDITH HILDA USHERWOOD.

IN the series of papers of which this is Part I it is proposed to examine a number of typical additive reactions of the general type

in order to ascertain, in the first place, whether, as there is reason to believe, the reversibility of these reactions is an absolutely general phenomenon; further, supposing that this is the case, it is proposed to determine how the equilibria which are established between the addenda and the additive product are affected by temperature, and in how far they are conditioned by the structure of the substances involved. The present communication is concerned primarily with the aldol additive process, in which the residue A:B in the general formula is the carbonyl group, C=O, and in the ensuing parts analogous reactions involving other double-bonded groupings, such as C=N, N=N, C=C, will be examined.

The view underlying this series of communications is, briefly, as follows. In the reactions under consideration the saturated addendum is of the type (H)—X in all cases, the hydrogen atom, (H), becoming separated during the additive process from the residue to which it was previously attached. These additive reactions are therefore to be included amongst a number of apparently dissimilar types of change, which, however, possess a common feature connected in an intimate manner with the nature,

indeed the strength, of the valency joining the reactive or "mobile" hydrogen atom* to the residue of the molecule.

Of these types depending on the presence of a mobile hydrogen atom, the only one which needs to be considered here is the reversible isomeric changes which occur where the triad grouping $(H)-X-Y=Z$ possesses tautomeric mobility. Certain symmetrical systems of this class, those in which X and Z represent the same element, have recently been examined by Ingold and Piggott (T., 1922, 121, 2381), who have shown that mobility, resulting in the establishment of equilibria, $(H) \cdot X \cdot Y : Z \rightleftharpoons X : Y \cdot Z \cdot (H)$, does not always arise in systems which conform to the triad type unless certain other conditions are also satisfied; these relate only to the terminal atoms of the system and not to the central atom. Since in the establishment of an equilibrium the tautomeric hydrogen atom of each individual molecule must become detached in turn from both the terminal atoms of the system, the indications obtained by Ingold and Piggott may plausibly be interpreted on the ground that tautomeric change must necessarily be associated with the occurrence of hydrogen in the condition which has been termed "mobile."

In order that triad tautomeric change may take place, however, it is obviously necessary that the molecule contain, not only a mobile hydrogen atom, but also an appropriately situated double bond. The change may therefore be regarded as a kind of additive reaction, the residue containing mobile hydrogen "adding" to the unsaturated residue much as in the intermolecular additive process with which it is compared in the following equations:

Thus we are led to recognise a close similarity between the intra- and inter-molecular changes; and, provided certain conditions (referred to below) are satisfied, a general comparison becomes possible between additive reactions involving mobile hydrogen and each of the principal types of tautomerism (reversible isomeric change). Keto-enol tautomerism becomes the intramolecular form

* In this paper, the word "mobile," when unqualified, is intended to connote a hydrogen atom capable of becoming detached in additive processes and such other reactions as are referred to. It is, perhaps, unfortunate that the word is so frequently used without qualification to mean "tautomeric mobility," which is in reality only a particular case of "mobility" in the wider sense just explained. The author would have preferred to use the word "activated," which seems less likely to be confused with its physico-chemical meaning than "mobile" is with its ordinary organic significance.

of the aldol reaction, three-carbon tautomerism that of the Michael reaction, and so forth :

In order to complete this analogy, one important condition has to be satisfied : it must be shown that the additive processes are reversible, and to establish this forms an essential part of the general object of this series of investigations. In this paper, the aldol and retrograde aldol reactions are studied, and thus the analogy between these inverse actions and reversible keto-enol change is completed. Moreover, in view of Ingold, Perren, and Powell's experiments (T., 1922, 121, 1414 and earlier), the analogy between the Michael reaction and three-carbon tautomerism is equally complete.

Generalising these results, this fundamental point of view can be adopted : that every mobile triad system $[\text{H}]-\text{X}-\text{Y}=\text{Z}$ may be regarded as consisting of two elementary parts, $[\text{H}]-\text{X}$ and $\text{Y}=\text{Z}$, by the interunion of which tautomeric change takes place; that since this tendency towards the interaction of the two residues operates no matter whether they are in the same or in different molecules, each tautomeric change will be found to have its counterpart in a reversible additive process depending on the separation of mobile hydrogen.

It will not seem remarkable that the existence of equilibria in aldol reactions should hitherto have escaped the notice of numerous investigators, when it is recalled that the simple additive process is usually only the first stage of a more or less complex series of reactions. Since a single subsequent reaction, particularly one which is irreversible, as, for instance, the elimination of water,* would be sufficient to destroy any equilibrium which would otherwise have been reached, it is plainly a practical necessity for any detailed study of the simple additive process to preclude the possibility of subsequent reactions by employing alkylated aldols containing the group $-\text{CH}(\text{OH})-\text{CRR}'\text{CHO}$, which are incapable either of losing water or of combining with themselves to form more complex aldols. The simplest aldol of the required type is isobutaldol, $\text{CHMe}_2\text{CH}(\text{OH})\text{CMe}_2\text{CHO}$, and therefore this compound was chosen as the standard example.

In the first place, it was necessary to show that the retrograde

* Despite this and other side reactions, Koclichen (*Z. physikal. Chem.*, 1900, 23, 130) has succeeded in observing the equilibration of acetone with diacetone alcohol.

aldol reaction could be realised under the conditions in which the direct aldol reaction is usually carried out. This was readily proved to be the case, for when specimens of *isobutaldol*, which had been shown to be free from any trace of *isobutaldehyde*, were treated with aqueous potassium carbonate under conditions similar to those used in the preparation of *isobutaldol*, considerable quantities of *isobutaldehyde* were produced. A closer study of the process showed that the composition of the mixture of *isobutaldehyde* and *isobutaldol* formed under given conditions of temperature and concentration was the same, provided that sufficient time for

FIG. 1.
Temperature 60°.

equilibration was allowed, no matter whether the pure aldehyde or the pure aldol were employed as the starting material:

Fig. 1 is a graphical record of a set of experiments for the temperature 60°. The curves illustrate the attainment of the equilibrium from both sides, and the manner in which the time factor affects the composition of the mixtures obtained. It will be seen that the true equilibrium for this temperature is close to 33.2 per cent. of *isobutaldehyde* and 66.8 per cent. of *isobutaldol*, and that this value is reached to within a few units per cent. in the course of about ten hours.

It is to be expected that three conditions will contribute towards the fixing of the equilibrium between the formation and the fission of aldols, namely, concentration, temperature, and molecular structure.

The influence of concentration arises from the fact that the additive process is bimolecular, whilst the fission reaction is unimolecular; hence dilution must favour the fission reaction.

The effect to be expected from alterations of temperature must differ in sign according as heat is developed or absorbed in the additive process. Actually, as the figures recorded in the experimental portion show, the heat of formation of the aldol must have a considerable positive value, since an increase of temperature causes a marked shift in the equilibrium in the direction favouring the aldehyde. This is well illustrated by Fig. 2, from which it

will be seen that the equilibrium changes from 10 to 90 per cent. within a temperature range of less than 100°. In Fig. 2, the crosses represent the positions of equilibrium estimated from the experimental data, the arrow-heads stand for the nearest points to which the equilibria were approached in individual experiments, and the curve is the graph of an equation derived from van't Hoff's reaction isochore on the assumption that the heat of formation of the aldol from the aldehyde is 20 kilogram-calories per gram-molecule.*

* It would be interesting if some investigator possessing a combustion calorimeter would make a direct determination of this figure. No work appears to have been done hitherto on the heats of combustion of aldehydes and their aldols, or, indeed, on the thermochemistry of the Michael reaction or any other of the additive reactions discussed in this paper.

If q is the heat of formation of the aldol, it follows from van't Hoff's relation that

$$\log_{10} \frac{100-p}{p^2} = \frac{q}{2.3026 RT} + C,$$

where p is the weight per cent. of aldehyde in the equilibrium mixture. The equation approximately represents the experimental results if q is placed equal to 20 kilogram-calories and C to -14.50 :*

$$\log_{10} \frac{100-p}{p^2} + 14.50 = \frac{20,000}{4.57 T} \quad \dots \quad (2)$$

No doubt the agreement of this equation with the experimental data could be slightly improved by adjusting the constants, but the observations themselves are probably not accurate enough to warrant any such refinement.

It is interesting to note in connexion with the effect of temperature on the equilibrium that isobutaldol undergoes quantitative fission into its aldehyde on heating at atmospheric pressure. No doubt "secondary" and "primary" aldols, containing the groups $-\text{CH}(\text{OH})\cdot\text{CHR}\cdot\text{CHO}$ and $-\text{CH}(\text{OH})\cdot\text{CH}_2\cdot\text{CHO}$, respectively, would undergo similar quantitative fission at some suitable temperature were it not for the fact that the elements of water can be eliminated from these substances with the formation of stable unsaturated aldehydes; for Thalberg (*Monatsh.*, 1898, **19**, 154) noticed that propaldol on distillation under atmospheric pressure yields a mixture of propaldehyde and methylethylacetaldehyde, whilst Lilienfeld and Tauss (*ibid.*, p. 80) and Kohn (*ibid.*, 1901, **21**, 23, 311) made similar observations in other individual cases. Thermal fission of this kind does not necessarily mean that at the high temperature the equilibrium is such as to favour practically quantitative conversion into the smaller molecules, although, as Fig. 2 shows, this undoubtedly is the case for isobutaldol. The explanation appears to be that the equilibration, which at low temperatures requires the addition of catalysts, at high temperatures takes place without this aid, and that the aldehyde, formed in this way at a temperature considerably above its boiling point, is removed in the form of vapour as fast as it is produced, thus rendering the decomposition quantitative.

Experiments on the influence of structural factors on these equilibria are at present in progress.

EXPERIMENTAL.

Materials.—The isobutaldehyde was prepared from Kahlbaum's isobutyl alcohol by a method essentially the same as that described

* This figure is appropriate to the conditions of concentration actually employed, which were the same throughout the series of experiments.

by Fossek (*Monatsh.*, 1881, 2, 614; 1883, 4, 66), excepting that the theoretical quantity of potassium dichromate was used in place of the smaller amount recommended. The aldehyde was purified by conversion into its crystalline polymeride and subsequent depolymerisation (Fossek, *Monatsh.*, 1883, 4, 661). It boiled at $65^{\circ}/758$ mm.

The isobutaldol was prepared from isobutaldehyde by treatment with saturated aqueous potassium carbonate in the manner described by Brauchbar (*Monatsh.*, 1896, 17, 637).

Identity and Purity Criteria.—The specimens of isobutaldehyde and aldol obtained as products of the experiments described below were identified by their boiling points, $65^{\circ}/758$ mm. and $114\text{--}117^{\circ}/15\text{--}16$ mm., respectively, and by analysis (Found: for the aldehyde, C = 66.8; H = 11.0. Calc., C = 66.7; H = 11.1. Found: for the aldol, C = 67.1; H = 10.9. Calc., C = 66.7; H = 11.1 per cent.).

General Method of Experiment.—The pure aldehyde or aldol was mixed with an equal volume of saturated aqueous potassium carbonate, and kept in a closed vessel at a known temperature for a period of time which preliminary experiments had indicated to be sufficient to ensure equilibration to within two or three units per cent. The product was then thoroughly extracted with pure ether and washed with a little water, and the washings were again extracted with ether. The combined ethereal extracts were dried over calcium chloride, and the ether slowly distilled off through a long fractionating column, the receiver being changed when about 30 c.c. of liquid remained in the distilling flask. When nearly all the ether had passed over, the liquid was transferred to a Claisen flask (the last traces being washed in with ether), and the ether removed as far as possible by distillation through a small fractionating column. The residue was then distilled without a column until a thermometer immersed in the liquid registered 120° , the receiver being changed when a second thermometer, immersed in the vapour, recorded the boiling point of the aldehyde. (Preliminary experiments had shown that the aldol does not undergo thermal decomposition into aldehyde at 120° .) Usually a small quantity of aldehyde still remained in the residual liquid; it was removed by distillation in a current of dry carbon dioxide at 100° , and collected with the aid of an efficient condenser, fed with ice-cold water, and a receiver cooled in ice. This distillate, and that which passed over at 65° (vapour temperature), consisted of pure isobutaldehyde; the various preceding distillates proved to be solutions of isobutaldehyde in ether, and the residue in the distilling flask isobutaldol containing a small amount of octaglycol mono-isobutyrate (compare Kirchbaum, *Monatsh.*, 1904, 25, 249).

Preliminary experiments had shown that isobutaldol, on heating in a distilling flask fitted with a fractionating column and condenser, decomposes smoothly and quantitatively into isobutaldehyde; octaglycol monoisobutyrate, on the other hand, was unchanged by this treatment, and therefore the process afforded a convenient means of estimating the quantity of isobutaldol in mixtures of this substance with the ester.

The liquid obtained as residue after the distillation in carbon dioxide was heated in the manner described until no more aldehyde passed over. (The aldehyde thus obtained was quite pure.) The small amount of liquid adhering to the column was then washed back into the distilling flask, and the last traces of the aldehyde formed by decomposition of the aldol, were completely removed by distillation without a column in a current of ether vapour. The almost colourless residue in the flask consisted solely of the octaglycol ester (b. p. 250°).

It was also found possible to obtain a fairly complete separation of the aldol and ester by distillation under 12 mm. pressure, but this process was not quite quantitative and was not employed in the final series of experiments.

The quantity of ester formed in these experiments was usually of the order of 2—3 grams, that is, about 6—9 per cent. of the theoretical, and this was neglected (that is, treated as material put out of action) when considering the relation between isobutaldehyde and isobutaldol. As explained above, the estimation of the isobutaldol in the product of an experiment was made to depend on its quantitative conversion (after removal of the accompanying isobutaldehyde) into isobutaldehyde by destructive distillation. The estimation of the aldehyde, whether obtained as a product of the experiment or formed by decomposition of the aldol, was complicated by the fact that in each case only a portion of the aldehyde was isolated in the pure condition, the remainder being obtained in solution in ether, from which it could not satisfactorily be separated. Therefore, in order to complete the analysis, it was necessary to find a means of estimating the aldehyde in ethereal solution.

The method ultimately employed depended on a study of the reaction between the aldehyde and anhydrous ammonia, which proceeds quantitatively according to the equation

The method of experiment was as follows: Twenty c.c. of the ethereal solution to be analysed were saturated with anhydrous ammonia, and then the ether and excess of ammonia rapidly evaporated at the ordinary temperature, and the products of the

reaction weighed. From the stoicheiometric relation, due allowance being made for the solubility of ammonia in the small amount of water formed in the reaction, the quantity of aldehyde originally present could be calculated. It was found, however, that the value obtained in this way was usually somewhat high, owing to the absorption of moisture from the atmosphere during manipulation, and although this error could be obviated by taking precautions to exclude the atmosphere, it proved to be more convenient, when carrying out a large number of estimations, to determine the error by means of a comparable series of blank experiments using known amounts of aldehyde, and correct for it.

In the case of the very dilute solution of aldehyde obtained as distillate when the original ethereal solution was concentrated to 90 c.c. (p. 1723) a further check was necessary, as, even if 50 c.c. were taken for analysis, a very small error in the actual determination became appreciable when calculated on the whole volume (about 350 c.c.). This control was applied by determining the rate of "leakage" of aldehyde through the fractionating column when employed to separate ether from known mixtures of ether, aldehyde, and aldol under standard conditions. In this series of experiments, the figures for the rate of leakage were obtained by difference, since the aldehyde retained in the distilling flask could be accurately estimated by the methods already described.

From the general concordance of the data obtained in the above experiments, and from the evidence afforded by the consistency of the final values, it may be concluded that the latter are unlikely to be in error by more than 1 or at most 2 per cent.

Results.—Whilst it is unnecessary to give in detail the numerical data obtained in the rather numerous experiments referred to above, the following figures may be quoted in illustration of the method of approaching the equilibrium from both sides (x denotes the percentage of aldehyde in the mixture of aldehyde and aldol).

Temperature 60°.		
Starting material :	Aldehyde	
Time 6.5 hours		49.5
" 10.0 hours		36.8
Starting material :	Aldol	
Time 6.5 hours		26.9
" 10.0 hours		31.8
(Estimated for infinite time		33.2)

The following table records the nearest points to which the equilibria were approached from either side at the three temperatures investigated.

Temperature.	Time.	Starting material.	Percentage of aldehyde.
13°	10 days	Aldehyde	6.7
13°	10 days	Aldol	5.4
(Estimated for infinite time			5.5)
60°	10 hours	Aldehyde	38.8
60°	10 hours	Aldol	31.8
(Estimated for infinite time			33.2)
100°	1.5 hours	Aldehyde	90.4
100°	1.5 hours	Aldol	87.4
(Estimated for infinite time			90.1)

The further reduction of these data and the calculation of the heat of reaction have already been described in the introduction.

The author wishes to thank the Chemical Society for a grant with the aid of which the expenses incurred in this research have been met.

CXCIII.—*The Polysulphides of the Alkali Metals.* *Part IV. The Polysulphides of Ammonium.*

By JOHN SMEATH THOMAS and RICHARD WILLIAM RIDING.

SEVERAL polysulphides of ammonium have been described, but the accounts are contradictory and untrustworthy. In some cases, it is highly improbable that the methods of preparation employed could have yielded the compounds described in anything but a very impure state.

It has long been known that aqueous solutions of these polysulphides can be obtained by dissolving sulphur in ammonium hydroxide. These solutions are, however, complicated mixtures and they invariably contain free ammonium hydroxide. Attempts have been made from time to time to determine the true nature of these solutions and also to prepare specimens of the polysulphides in a state of purity. Thus, Fritsche (*J. pr. Chem.*, 1841, 24, 400; 1844, 32, 313) acted on solutions of ammonium hydroxide with hydrogen sulphide and sulphur under a variety of conditions. From these solutions, solids crystallised which Fritsche considered to be polysulphides, but which must have contained free sulphur. In this way he claimed to have isolated a tetra-, a penta-, and a hepta-sulphide. He was, however, unable to prepare either a di- or a tri-sulphide.

Similar methods were employed by Bloxam (*T.*, 1895, 67, 277) in a very thorough investigation of the preparation of these com-

pounds from aqueous solutions. He too succeeded in isolating hydrated tetra-, penta-, and hepta-sulphides and, in addition, he described compounds having the formulae $(\text{NH}_4)_4\text{S}_8$ and $(\text{NH}_4)_2\text{S}_8$, which he called tetra-ammonium enneasulphide and ammonium enneasulphide, respectively. To the first of these compounds Bloxam attached peculiar importance. In his view, this substance is the parent from which all the other ammonium polysulphides are derived by decomposition. This point is of interest inasmuch as he assigned a similar importance to so-called enneasulphides of sodium and potassium (T., 1900, 77, 753), of the existence of which Thomas and Rule (T., 1917, 111, 1063) could find no evidence.

Like Fritsche, Bloxam was unable to prepare either a di- or a tri-sulphide, though he described a solution which he considered to be a solution of the latter compound. Evidence in favour of this was obtained by Hofmann and Hochten (*Ber.*, 1903, 36, 3090; 1904, 37, 245), who, on adding auric chloride to Bloxam's solution, obtained crystals having the composition NH_4AuS_3 in which the gold was believed to be univalent.

The experiments of both Fritsche and Bloxam were conducted in aqueous solutions, and their preparations were doubtless rendered impure to a considerable extent by the hydrolysis of these solutions. Unfortunately, too, Bloxam's view of the mechanism by which polysulphides are formed was incorrect. In his opinion, direct addition of sulphur to the monosulphide took place thus, $(\text{NH}_4)_2\text{S} + 4\text{S} \rightarrow (\text{NH}_4)_2\text{S}_8$, and in his preparations he always used as his starting point solutions approximating in composition to the monosulphide, sulphur being then added in amount corresponding to the above, and to similar equations for the lower compounds. The reaction between sulphur and the monosulphide, however, takes place but slowly, whereas sulphur reacts rapidly with the hydrosulphide, hydrogen sulphide being evolved:

In this case, only half the quantity of sulphur is required to convert a solution of the same sulphur content into polysulphide. Since Bloxam's solutions almost certainly contained both monosulphide and hydrosulphide in equilibrium, the evolution of considerable quantities of hydrogen sulphide was observed by him. Instead of having added the amounts of sulphur theoretically required, he always had a large excess, and therefore free sulphur must often have been present in his final products.

In view of these circumstances the present authors determined to reinvestigate these compounds. None of the previous workers had attempted to prepare them by using non-aqueous solvents, a method which offers obvious advantages. In earlier papers

of this series (T., 1914, 105, 177, 2819; 1917, 111, 1063), the action of sulphur on alcoholic solutions of the hydrosulphides of sodium and potassium was described. This reaction was found to result in the formation of sodium tetrasulphide and potassium pentasulphide, respectively, in the anhydrous condition, and by the application of a similar method it seemed probable that polysulphides of ammonium could also be obtained.

In a previous paper (this vol., p. 1181), it has been shown that solutions consisting mainly of ammonium hydrosulphide are obtained when hydrogen sulphide is slowly passed into moderately dilute alcoholic solutions of ammonia at 0°. These solutions were made the starting point of this investigation.

EXPERIMENTAL.

Action of Sulphur on Alcoholic Solutions of Ammonium Hydrosulphide. Ammonium Pentasulphide.

The ammonium hydrosulphide solutions were prepared in the manner described by Thomas and Riding (*loc. cit.*). They were found to contain but small quantities of the monosulphide. The sulphur employed was roll sulphur. It was purified by twice recrystallising it from carbon disulphide, reducing the crystals to a fine powder, and keeping the powder for several hours at 80° to remove the last traces of solvent.

In an experiment, 100 c.c. of ammonium hydrosulphide solution, containing 14.4 grams of NH_4SH , were treated with 18 grams of finely powdered sulphur, this being the amount theoretically required to convert the hydrosulphide into pentasulphide in accordance with the equation given above. A stream of dry hydrogen was bubbled through the liquid, which was kept at 60° under reflux for several hours. The sulphur dissolved forming a deep red, almost black solution, and torrents of hydrogen sulphide were evolved. On cooling, a large quantity of beautiful yellow crystals separated. These were filtered with gentle suction, washed first with about 20 c.c. of cold alcohol, then with 20 c.c. of a mixture of carbon disulphide and ether, and finally with dry ether. The crystals appeared to decompose in the air, but they did not change appreciably when kept over paraffin wax in a desiccator containing ammonia under slight pressure. After three days they were analysed.

The ammonia was estimated by direct titration with *N*/10-acid and both the total sulphur and also the polysulphide sulphur were estimated. In the case of the total sulphur estimation, a weighed quantity of substance was treated with 50 c.c. of a 10 per cent. solution of sodium hydroxide, and bromine was then added in slight

excess. After the excess of bromine had been evaporated on the water-bath, the solution was rendered slightly acid with hydrochloric acid, and the sulphur precipitated as barium sulphate. The polysulphide sulphur was estimated by Küster and Heberlein's method (*Z. anorg. Chem.*, 1905, 43, 53). The weighed substance was added to about 100 c.c. of dilute, chlorine-free hydrochloric acid, the liquid being then heated on the water-bath for an hour. The polysulphide sulphur was thus obtained as a flocculent precipitate; it was collected in a Gooch crucible, washed, dried at 80°, and weighed directly [Found: $\text{NH}_4 = 18.18$; $(\text{S})^* = 65.68$; $\text{S}^* = 81.15$. $\text{NH}_4 : (\text{S}) : \text{S} = 2 : 4.03 : 4.98$. $(\text{NH}_4)_2\text{S}_5$ requires $\text{NH}_4 = 18.34$; $(\text{S}) = 65.33$; $\text{S} = 81.66$ per cent.; $\text{NH}_4 : (\text{S}) : \text{S} = 2 : 4 : 5$].

A series of experiments was performed in which the ratio between the amount of ammonium hydrosulphide taken and that of the sulphur added was varied. When the proportion of sulphur added was less than that required for the formation of $(\text{NH}_4)_2\text{S}_5$, clear red solutions were obtained which, if the amount of sulphur added exceeded that required for the formation of the disulphide, deposited crystals on cooling. These crystals were filtered off and analysed. In every case, they were found to consist of the pentasulphide, rendered more or less impure by the presence of hydrosulphide, and every attempt to prepare lower polysulphides by adjusting the proportions of sulphur and ammonium hydrosulphide either by crystallisation or by precipitation with ether ended in failure. The products obtained by the latter method were much more impure than those obtained by crystallisation. They were generally faintly yellow in colour and their composition was quite indefinite; they certainly contained hydrosulphide, for on treatment with sulphur much hydrogen sulphide was evolved.

This observation is in agreement with those recorded by Rule and Thomas (*loc. cit.*) in their investigation of the polysulphides of sodium and potassium. They showed that the action of sulphur on the hydrosulphides of these metals results in the formation of one polysulphide only, sodium tetrasulphide, and the pentasulphide in the case of potassium. It would appear, therefore, that this is true of the ammonium compounds also and that, inasmuch as the polysulphide obtained is the pentasulphide, they resemble the potassium compounds more closely than those of sodium, as, indeed, one would expect.

When sulphur was added to the hydrosulphide in amounts greater than would be required for the formation of the pentasulphide, solutions were obtained which were almost black in colour.

* (S) and S denote polysulphide sulphur and total sulphur, respectively.

These solutions deposited red crystals on cooling, which, on treatment with water, partly dissolved, leaving a residue of sulphur. When these crystals were treated with carbon disulphide, sulphur was removed and an orange-red substance remained. This was washed free from carbon disulphide with ether, and after standing over paraffin wax it was analysed (Found: $\text{NH}_4 = 17.74$; $(\text{S}) = 65.22$; $\text{S} = 81.24$; $\text{NH}_4 : (\text{S}) : \text{S} = 2 : 4.22 : 5.26$. $(\text{NH}_4)_2\text{S}_5$ requires $\text{NH}_4 = 18.34$; $(\text{S}) = 65.33$; $\text{S} = 81.66$ per cent.; $\text{NH}_4 : (\text{S}) : \text{S} = 2 : 4 : 5$). These figures prove that this residue consisted of practically pure ammonium pentasulphide.

The solution from which the crystals described above were deposited yielded a copious precipitate of sulphur on treatment with water, whereas when sulphur had been added in smaller amount than that required to form the pentasulphide the addition of water to the mother-liquor gave a perfectly clear solution. These results are similar to those obtained in the case of potassium. Here too there is no indication of the formation of higher polysulphides than the pentasulphide, even when quantities of sulphur far in excess of that corresponding with the pentasulphide are used.

Anhydrous ammonium pentasulphide is obtained in orange-yellow crystals by the method previously described; a microscopic examination of these crystals, suspended in Canada balsam, showed them to be quite homogeneous. When the substance is exposed to air, it changes colour, becoming deep red, and at the same time it decomposes rapidly into hydrogen sulphide, ammonia, and sulphur. This decomposition takes place more rapidly when the crystals are kept over calcium chloride, more slowly, but still at an appreciable rate, when phosphoric oxide is employed as the drying agent. In the majority of cases, it was only necessary to keep the substance for a short time, a few days at most, and it was found that this could be accomplished by placing it in a desiccator containing chips of paraffin wax to remove ether, and filled with ammonia under slight pressure; the amount of decomposition during these short periods was so small that it could safely be neglected. If, however, the crystals are stored in a solution of ammonia in dry ether they may be kept unchanged for very considerable periods.

Two explanations may be offered of the colour change which is observed when the crystals are exposed to air. In the first place, the substance may exist in two modifications, one of which is orange-yellow, the other deep red. Some support is given to this view by the fact that the change is greatly accelerated by the presence of moisture or of free ammonia, particularly the former, the weight of the substance remaining unaltered, and that, on passing a current

of dry air over a little of the substance in which the colour change has been effected by the action of ammonia, the reverse change immediately takes place and the crystals immediately become yellow.

On the other hand, Fritsche (*loc. cit.*) states that the spontaneous decomposition of ammonium pentasulphide results in the formation of ruby-red crystals of the heptasulphide, a change which he represents by the equation

Fritsche's experiment was repeated by Bloxam, who, however, considered the substance he obtained to be the enneasulphide, $(\text{NH}_4)_2\text{S}_9$. With the object of investigating this divergence of opinion, the present authors exposed 10 grams of finely divided ammonium pentasulphide to the air until its colour was deep red throughout. A considerable amount of decomposition had taken place but, on examining the mass by means of a lens, it appeared to be homogeneous. At this point, an analysis was made [Found: $\text{NH}_4 = 13.98$; $\text{S} = 85.89$; $(\text{S}) = 73.82$; $\text{NH}_4 : (\text{S}) : \text{S} = 2 : 5.98 : 6.89$. $(\text{NH}_4)_2\text{S}_7$ requires $\text{NH}_4 = 13.82$; $(\text{S}) = 73.87$; $\text{S} = 86.18$ per cent.; $\text{NH}_4 : (\text{S}) : \text{S} = 2 : 6 : 7$].

This analysis, which is typical of several others, certainly agrees with the composition theoretically required by the heptasulphide, but it is in no way conclusive. When the decomposition was allowed to proceed further than the point mentioned, quite discordant results were obtained. It should also be mentioned that on treatment with water the red crystals yielded a distinctly turbid solution. Nevertheless, in view of the evidence obtained in later experiments presently to be described, the authors are of opinion that the red colour which develops during the decomposition of the pentasulphide is due to the formation of ammonium heptasulphide.

Ammonium pentasulphide readily dissolves in water to form a yellow solution which, on warming, darkens in colour and finally becomes almost black. Bloxam's statement (*loc. cit.*) that ammonium pentasulphide is decomposed by water, sulphur being deposited, is probably to be explained by the presence of dissolved oxygen in the water used by him. When freshly boiled, distilled water is employed, perfectly clear solutions are obtained, which, if air is excluded, can be kept for weeks without any decomposition taking place. It was also noticed that the addition of a few drops of ammonia to tap water made it possible to use such water to prepare stable solutions of the pentasulphide.

The substance is much less soluble in alcohol and, like the aqueous solutions, the solutions thus obtained deposit sulphur when they

are exposed to the air. When the pentasulphide is shaken with alcohol at the ordinary temperature, bright yellow crystals are obtained on the sides of the vessel. These crystals appeared to be small, monoclinic prisms and they are probably an alcoholate similar to that formed by potassium pentasulphide when it is treated in this way (compare Rule and Thomas, T., 1914, 105, 2822).

Ether, carbon disulphide, and most other organic solvents are without action on ammonium pentasulphide in the cold, but its behaviour when treated with pyridine or nitrobenzene may perhaps be mentioned. On the addition of pure pyridine, an intense red colour is produced in the liquid, which becomes turbid. A definite reaction appears to take place, resulting possibly in the formation of an additive compound, but this point has not yet been investigated. Potassium pentasulphide and sodium tetrasulphide behave in a somewhat similar manner except that in the case of the sodium compound the colour produced is green.

When the pentasulphide is treated with nitrobenzene in the cold, the solvent becomes pink. On warming the liquid, the colour disappears, but it returns as the liquid cools. The substance itself undergoes no apparent change. Biltz and Wilke-Dörfurt (*Ber.*, 1905, 43, 53) noticed that rubidium pentasulphide gave rise to a red coloration when it was treated with nitrobenzene, and Rule and Thomas (*loc. cit.*) have observed a similar phenomenon in the case of potassium pentasulphide.

Attempts to determine the melting point of ammonium pentasulphide were not very successful. When the substance is heated in an open tube, it decomposes and a residue of sulphur melting at 115° remains. A small quantity of yellow oil was noticed in the cool portions of the tube. Finally the substance was sealed up in a small, fairly thick-walled tube, which was then slowly heated in a sulphuric acid bath. At 95°, the substance melted without apparent decomposition to a dark red liquid. This temperature is, therefore, the approximate melting point of ammonium pentasulphide under pressure.

Solubility of Sulphur in Alcoholic Solutions of Ammonium Hydro-sulphide.

It has already been mentioned that ammonium hydrosulphide solutions will take up more sulphur than is required for the formation of the pentasulphide, and this is also true of both aqueous and alcoholic solutions of the sodium and potassium compounds, as Küster and Heberlein (*Z. anorg. Chem.*, 1905, 43, 53) and Rule and Thomas (*loc. cit.*, p. 2819) have shown. The measurements of the last-mentioned authors prove that in the case of alcoholic sodium hydro-

sulphide solutions at 25° sulphur can be taken up to an extent represented by the formula $\text{Na}_2\text{S}_{6.36}$, whilst in the case of potassium the solubility at the same temperature is represented by the formula $\text{K}_2\text{S}_{6.46}$.

Similar measurements were made with ammonium hydrosulphide at 25° and at 60°, the method followed being that described by Rule and Thomas (*loc. cit.*). The ammonium hydrosulphide was approximately normal, and when saturated with sulphur at the higher temperature it became almost black in colour. As soon as equilibrium was reached, 25 c.c. of the solution were withdrawn, made up to 1 litre with water, and aliquot parts of this solution taken for analysis, ammonia and total sulphur being estimated in the usual way. The results obtained are shown in the following table, which also contains results previously obtained in the cases of sodium and potassium.

TABLE I

Substance.	Conc. of soln.	Temperature.	Ratio metal : S.
NH_4HS	Normal	25°	2 : 6.17
NH_4HS	"	60	2 : 6.41
KHS	0.25 Normal	25	2 : 6.46
NaHS	2Normal	25	2 : 6.36
NaHS	"	81	2 : 6.9

When the solution at 60° was cooled, long crystals of monoclinic sulphur were deposited together with crystals of ammonium pentasulphide. The addition of water to these solutions resulted in the precipitation of much sulphur. It is clear that the solubility of sulphur in alcoholic solutions of the hydrosulphides is influenced but slightly by the temperature over the range 25° to 80°. Küster and Heberlein (*loc. cit.*) made a similar observation in the case of aqueous solutions of sodium hydrosulphide.

Unfortunately, the solutions used in the determinations quoted above were not all of the same strength, and consequently no comparison can be made from this point of view between the different alkali metals. Nor is it possible to make any definite statement regarding the influence of concentration of the hydrosulphide solutions on the sulphur solubility. The authors feel justified, however, in concluding that, in the case of reasonably dilute solutions at any rate, the ratio $\text{NH}_4 : \text{S}$ is not affected to any great extent by differences in concentration.

Action of Heat on Ammonium Pentasulphide. Ammonium Disulphide.

It has already been mentioned that when attempts were made to determine the melting point of the pentasulphide by heating

the substance in open capillary tubes, decomposition occurred and a small quantity of yellow oil appeared in the cool portion of the tube.

This decomposition was now investigated more closely. About 10 grams of ammonium pentasulphide were sealed up in a wide glass tube bent into the shape of the tubes employed by Faraday in his experiments on the liquefaction of gases. The end of this tube containing the substance was immersed in a bath of boiling water for several hours, whilst the other end was surrounded by a freezing mixture. It was hoped that the pressure developed in the apparatus would prevent the further dissociation of any volatile products that might be formed in the course of the reaction. After a short time, a few drops of a yellow oil were observed in the cold portion of the tube; this gradually increased in quantity until about 2 c.c. had collected. When the experiment had been completed, but before the tube was opened, this oil was found to have solidified to a mass of yellow crystals. The limb of the tube which had been heated contained a pale yellow residue. The tube was now opened, the increase in the internal pressure being found to be very slight, and the contents of both limbs were examined.

The pale yellow residue, which was insoluble in water, but dissolved completely in carbon disulphide, proved to be practically pure sulphur (Found: S = 99.43 per cent.).

The yellow crystals dissolved readily in water, forming a clear yellow solution [Found: NH_4 = 35.86; (S) = 31.89; S = 65.10; NH_4 : (S) : S = 2 : 0.98 : 2.04. $(\text{NH}_4)_2\text{S}_2$ requires NH_4 = 35.97; (S) = 32.02; S = 64.03 per cent.; NH_4 : (S) : S = 2 : 1 : 2). The substance is therefore ammonium disulphide, and it does not appear previously to have been described. Fritsche (*loc. cit.*) certainly investigated the action of heat on the pentasulphide, but he states that the products are ammonium monosulphide and sulphur. This result is probably to be explained by the fact that his experiments were carried out in open vessels. Bloxam (T., 1895, 67, 277), following a method described in Watt's "Dictionary of Chemistry," attempted to prepare the disulphide by passing ammonium chloride and sulphur vapour through a hot tube, but without success. Indeed he drew the conclusion that it is extremely doubtful whether the substance exists.

A further experiment was also made in which a known weight of pentasulphide was taken and the residue of sulphur obtained was carefully weighed; in this case, the tube was heated for fourteen hours (Found: residue = 48.65 per cent.). The decomposition $(\text{NH}_4)_2\text{S}_5 \rightarrow (\text{NH}_4)_2\text{S}_2 + 3\text{S}$ would require the residue to be 48.96 per cent. of the weight of the pentasulphide taken, and it thus appears that the decomposition is quantitative in character.

Ammonium disulphide is generally obtained as a yellow oil which crystallises on standing to a mass of lemon-yellow, needle-shaped crystals. It decomposes very readily, and it was not found possible to determine its melting point. When heated in a sealed tube, it becomes liquid at about 48° . The crystals are soluble in both water and alcohol, and the solutions formed are quite stable, provided contact with air is prevented. Only on prolonged boiling is sulphur deposited. Both the aqueous and the alcoholic solutions readily dissolve sulphur, and from the solutions thus obtained the pentasulphide separates.

It was also noticed that when the pentasulphide was heated with carbon disulphide it slowly decomposed. In one experiment the substance was boiled with carbon disulphide under a reflux condenser, and a yellow oil was observed to collect in the condenser which gradually solidified to orange-yellow, needle-shaped crystals. These were dissolved out by means of water and the ratio $\text{NH}_4/(\text{S})$ in the solution determined. The value found, 0.0307 : 0.0606, is that required for a substance having the formula $(\text{NH}_4)_2\text{S}_{2.2}$. The quantity of sulphur is higher than that required for the disulphide, but taking into account the conditions under which the experiment was made, and especially the fact that the decomposition of the substance would result in loss of ammonia, whilst sulphur would accumulate, it is evident that the disulphide is formed when the pentasulphide decomposes under these conditions also.

Several attempts were made to prepare pure ammonium disulphide by modifications of this method. When the mixture of pentasulphide and carbon disulphide was distilled, the disulphide volatilised with the solvent and floated as a yellow oil on the surface of the condensed liquid. On attempting to remove the carbon disulphide by distillation under reduced pressure, the oil completely decomposed. The carbon disulphide used was examined at the end of the experiment and was found to contain no thiocarbonate. When carbon disulphide was kept in contact with ammonium pentasulphide in the cold, no decomposition could be observed.

Although alcoholic solutions of the pentasulphide can be heated at 80° without decomposition taking place, when they are heated above this temperature rapid decomposition occurs and sulphur is deposited. It was at first thought that this decomposition followed the same course as that just described in the case of carbon disulphide.

To test this view, 5 grams of ammonium pentasulphide were heated at about 80° with 100 c.c. of dry alcohol, a stream of hydrogen being passed through the boiling liquid. Several experiments were made, and in each case the sulphur remaining after the penta-

sulphide had been completely decomposed was weighed. The amount of sulphur thus obtained varied, but it was always found to lie within the limits represented by the equations

Results in accordance with equation (1) were obtained when the alcohol was boiled briskly and a rapid stream of hydrogen was passed through the liquid, thus carrying away the disulphide as fast as it was formed, whilst equation (2) represents the course of events when a slow stream of hydrogen was bubbled through the liquid and this, instead of boiling vigorously, was kept just at the boiling point.

The bearing of this reaction on the constitution of the polysulphides is of especial interest. In a previous paper of this series (T., 1917, 111, 1063), the views which have been put forward by various authors, notably by Spring and Demarteau (*Bull. Soc. chim.*, 1889, [iii], 1, 11) and by Küster and Heberlein (*Z. anorg. Chem.*, 1905, 43, 72), concerning the constitution of the polysulphides were discussed. In spite of the criticisms of Küster and Heberlein, reasons were given for preferring the general formula $\text{R}_2\text{S}_2\text{S}_x$ suggested by Spring and Demarteau to the formula R_xSS_x advocated by them.

The evidence then adduced pointed to the existence in the polysulphide molecule of two sulphur atoms in a different state of combination from the remainder, and in order to obviate the objections of Küster and Heberlein it was suggested that the disulphides should be regarded as being derived from a form of hydrogen disulphide represented by the formula $\text{R}\cdot\text{S}\cdot\text{S}\cdot\text{H}$. Higher polysulphides are then formed by the addition of sulphur to the disulphides, compounds of the type $\begin{array}{c} \text{R}\cdot\text{S}\cdot\text{S}\cdot\text{R} \\ | \\ \text{S} \end{array}$, $\begin{array}{c} \text{R}\cdot\text{S}\cdot\text{S}\cdot\text{R} \\ | \quad | \\ \text{S} \quad \text{S} \end{array}$, etc. being thus obtained.

This view is entirely confirmed by the decomposition of ammonium pentasulphide into the disulphide and free sulphur. The reaction takes place at a low temperature and is quantitative in character. It proves beyond doubt that three sulphur atoms in the molecule are differently combined from the remainder.

It would be interesting to make a complete comparison of the alkali metals from the point of view of the polysulphides to which they give rise. The investigation of the lithium compounds is, however, not yet complete, and no useful purpose would be served by anticipating the publication of this material.

Higher Polysulphides.

Measurements of the solubility of sulphur in alcoholic solutions of the hydrosulphide indicate, as has been shown, that at 25° sulphur can be taken up to an extent represented by the formula $(\text{NH}_4)_2\text{S}_{6-17}$. Attempts to obtain higher polysulphides from these solutions always resulted in the formation of mixtures of the pentasulphide with sulphur.

Mention has been made in an earlier section of the decomposition of ammonium pentasulphide in air, whereby the heptasulphide is believed to be produced. Further evidence of the existence of this compound was obtained in the following experiment, suggested by one made by Fritsche (*loc. cit.*).

A solution of ammonium pentasulphide in alcohol was prepared in the usual way and to it powdered sulphur was added. The solution was then kept in a tightly stoppered bottle for four months. At the end of this time the solid at the bottom of the bottle was observed to be red in colour and distinctly crystalline. These crystals were separated, washed, and analysed [Found: $\text{NH}_4 = 13.6$; $(\text{S}) = 73.8$; $\text{S} = 85.24$; $\text{NH}_4 : (\text{S}) : \text{S} = 2 : 6.08 : 7.04$. $(\text{NH}_4)_2\text{S}_7$ requires $\text{NH}_4 = 13.82$; $(\text{S}) = 73.87$; $\text{S} = 86.18$ per cent.; $\text{NH}_4 : (\text{S}) : \text{S} = 2 : 6 : 7$].

When powdered, the substance yields a yellow powder which decomposes much more rapidly than the crystals when exposed to air. It dissolves partly in water, but the solution obtained is always turbid. It was found impossible to determine its melting point. This is the only polysulphide of ammonium other than the penta- and the di-sulphide which the authors have succeeded in obtaining, and the existence of this compound is interesting in view of the fact that no polysulphide of so high a sulphur content has been obtained in the case of any of the alkali metals.

Conclusions.

1. Ammonium pentasulphide has been prepared by the action of sulphur on solutions of ammonium hydrosulphide in dry alcohol. Lower polysulphides are not formed in this reaction, which is analogous to the cases of sodium and potassium where the tetrasulphide and pentasulphide, respectively, are solely formed.
2. All attempts to prepare the enneasulphide described by Bloxam have failed.
3. Ammonium pentasulphide resembles sodium tetrasulphide and potassium pentasulphide in that its alcoholic solution dissolves sulphur at 25° to an extent represented by the formula $(\text{NH}_4)_2\text{S}_{6-17}$. All attempts to prepare a higher compound by crystallisation from

these solutions failed owing to decomposition. On the other hand, evidence has been found of the existence of higher polysulphides, and a heptasulphide has been isolated.

4. Ammonium disulphide has been prepared by the action of heat on the pentasulphide in a sealed tube.

The authors wish to express their thanks to Professor E. C. C. Baly for providing facilities for carrying out this work and for kindly criticism during its progress.

CXCIV.—*Hydrolysis of the Sulphoxide and the Sulphone of $\beta\beta'$ -Dichlorodiethyl Sulphide.*

By ALBERT ERIC CASHMORE.

It has been suggested that the well-known vesicant action of $\beta\beta'$ -dichlorodiethyl sulphide may be due to the oxidation of the substance in the animal system with subsequent hydrolysis of the oxidation products. In order to gain some information relevant to this suggestion, the hydrolysis of the sulphoxide and the sulphone of $\beta\beta'$ -dichlorodiethyl sulphide has been examined in some detail. The products of the reaction between the above compounds and sodium hydroxide in ethyl-alcoholic and in aqueous solution have been isolated, purified, and examined physiologically. It may be stated here that of the hydrolysis products described in this paper not one possesses a vesicant action.

Helfrich and Reid (*J. Amer. Chem. Soc.*, 1920, **42**, 1208) state that by treatment of an alcoholic solution of $\beta\beta'$ -dichlorodiethyl sulphoxide or sulphone with an alcoholic solution of sodium hydroxide the corresponding dihydroxy-derivatives are produced. No analytical figures are given and apparently the products were not isolated in a pure state. We have not been able to confirm these experiments, as under these conditions the chief products of the reaction are the corresponding diethoxy-derivatives.

The table opposite summarises the results obtained under various conditions.

It is interesting to note here that $\beta\beta'$ -dichlorodiethyl sulphide in presence of alcoholic sodium hydroxide gives divinyl sulphide and not $\beta\beta'$ -diethoxydiethyl sulphide (Bales and Nickelson, *T.*, 1922, **121**, 2137).

Products isolated.		
Solvent.	$\beta\beta'$ -Dichlorodiethyl sulphoxide.	$\beta\beta'$ -Dichlorodiethyl sulphone.
15 Per cent. ethyl alcohol.	$\beta\beta'$ -Diethoxydiethyl sulphoxide, $(\text{EtO}\cdot\text{CH}_2\cdot\text{CH}_2)_2\text{SO}$. Oil; soluble in ether. B. p. 177—179°/25 mm.	$\beta\beta'$ -Diethoxydiethyl sulphone, $(\text{EtO}\cdot\text{CH}_2\cdot\text{CH}_2)_2\text{SO}_2$. Oil; soluble in ether. B. p. 242—244°/20 mm.
Water.	Sulphoxide of 1 : 4-thioxan, $\text{O} \begin{array}{c} \text{CH}_2\cdot\text{CH}_2 \\ \diagup \quad \diagdown \\ \text{CH}_2\cdot\text{CH}_2 \end{array} \text{SO}$. Solid; m. p. 25°; b. p. 147°/15 mm.	Sulphone of 1 : 4-thioxan, $\text{O} \begin{array}{c} \text{CH}_2\cdot\text{CH}_2 \\ \diagup \quad \diagdown \\ \text{CH}_2\cdot\text{CH}_2 \end{array} \text{SO}_2$. Solid; m. p. 129°.
50 Per cent. ethyl alcohol.	(a) $\beta\beta'$ -Diethoxydiethyl sulphoxide. (b) $\beta\beta'$ -Dihydroxydiethyl sulphoxide, $(\text{HO}\cdot\text{CH}_2\cdot\text{CH}_2)_2\text{SO}$. Unstable oil which in the presence of boiling dilute alkali gives the sulphoxide of 1 : 4-thioxan. Insoluble in ether.	(a) $\beta\beta'$ -Diethoxydiethyl sulphone. (b) Unstable oil (not isolated) which on treatment with boiling dilute alkali gives the sulphone of 1 : 4-thioxan. Insoluble in ether.

The formation of thioxan derivatives on treatment of the sulphoxide or sulphone of $\beta\beta'$ -dichlorodiethyl sulphide with aqueous sodium hydroxide is unexpected. There is no evidence that thiodiglycol or $\beta\beta'$ -dichlorodiethyl sulphide gives 1 : 4-thioxan in similar circumstances.

Consideration of the three systems represented by the formulæ (A, B, and C) leads one to suggest that in the case of (B) and (C), the partial or total saturation of the quadrivalent or sexavalent sulphur atom by the oxygen atoms would cause the angle between the valencies connecting the sulphur atoms to the two side chains to become smaller than it would be in the case of (A). Thus in the case of (B) and (C) the removal of a molecule of water from the two hydroxyl groups would take place more readily than in the case of (A). This is really an application of the principles underlying Baeyer's strain theory; the cases of ring formation so exhaustively studied by Professor J. F. Thorpe and his collaborators are in some ways analogous.

It has been shown by Hilditch and Smiles (T., 1911, 99, 408, 973) that the orthosulphoxides of *p*-cresol and of *p*-chlorophenol are converted into the corresponding phenothioxin derivatives by the prolonged action of cold concentrated sulphuric acid :

The corresponding sulphides do not give the phenothioxin derivatives even in the presence of hot concentrated sulphuric acid, anhydrous zinc chloride, or phosphoryl chloride. These results would seem to be in agreement with the above considerations.

The sulphone of 1 : 4-thioxan has been isolated by Baumann and Walter (*Ber.*, 1893, 26, 1124) as a by-product of the hydrolysis of hydroxyethylsulphone-sulphinic acid. The ring compound is an extremely stable solid and resembles 1 : 4-thioxan, which Clarke (*T.*, 1912, 101, 1795) has shown to be very unreactive in comparison with such compounds as 1 : 4-dioxan, 1 : 4-dithian, pentamethylene sulphide, etc.

The sulphoxide of 1 : 4-thioxan has not at present been examined in any great detail; it is a hygroscopic solid of low melting point which is best purified by distillation under diminished pressure.

It is intended to continue investigations into the formation of heterocyclic ring compounds by reactions similar to the above in the near future, and it is hoped that the experiments may be carried out on some approximately quantitative basis.

EXPERIMENTAL.

The $\beta\beta'$ -dichlorodiethyl sulphoxide used in these experiments was supplied by the Chemical Warfare Department. After one recrystallisation from water it melted at 108—109°. The $\beta\beta'$ -dichlorodiethylsulphone was obtained from the sulphoxide by oxidation with chromic acid (Helfrich and Reid, *loc. cit.*) and was recrystallised from 50 per cent. alcohol. The purified substance melted at 57°.

Reaction between $\beta\beta'$ -Dichlorodiethyl Sulphoxide and Sodium Hydroxide in 95 per cent. Ethyl-alcoholic Solution.— $\beta\beta'$ -Dichlorodiethyl sulphoxide (20 grams), gradually added to a solution of sodium hydroxide (10 grams) in 95 per cent. ethyl alcohol (250 c.c.), dissolved with evolution of heat and precipitation of sodium chloride, the mother-liquor being coloured deep yellow. Having been maintained at the boiling point for sixteen hours, the mixture was cooled, filtered after neutralisation with alcoholic hydrogen chloride, and the main bulk of the ethyl alcohol removed by distillation. The residue consisted of a viscous, brown liquid which on being poured into a large excess of water separated as an oil. This was

extracted with ether, and the ethereal extract washed with dilute sodium carbonate solution and water and dried over anhydrous sodium sulphate. The ether was then removed and the residual oil purified by three distillations under diminished pressure. The main fraction (14 grams) boiled at $177-179^{\circ}/25$ mm., and the analytical figures corresponded to those required for $\beta\beta'$ -diethoxydiethyl sulphoxide (Found: C = 48.45; H = 9.0; S = 16.46. $C_8H_{18}O_2S$ requires C = 48.45; H = 9.3; S = 16.48 per cent.).

$\beta\beta'$ -Diethoxydiethyl sulphoxide is a pale yellow, viscous liquid, soluble in alcohol, ether, chloroform, and the usual organic solvents, but practically insoluble in water. It has an unpleasant odour somewhat resembling that of a mercaptan.

Reaction between $\beta\beta'$ -Dichlorodiethyl Sulphoxide and Sodium Hydroxide in Aqueous Solution.—Heat was evolved and a brown solution obtained when $\beta\beta'$ -dichlorodiethyl sulphoxide (20 grams) was added to sodium hydroxide (12 grams) dissolved in water (120 c.c.). The solution was maintained at the boiling point for two hours, left over-night, and neutralised with glacial acetic acid, care being taken to avoid adding excess of acid. It was then concentrated, filtered, and shaken with chloroform, and the extract washed with dilute aqueous sodium carbonate and water and finally dried over anhydrous sodium sulphate. After removal of the chloroform there remained a brown oil which would not solidify, but on distillation under diminished pressure a fraction was obtained (5 grams) which boiled at $147^{\circ}/15$ mm. and solidified in the receiver in long needles which melted at about 25° . These needles were found to be hygroscopic, and purification was best effected by distillation. The composition of the colourless solid agreed with the formula of the sulphoxide of 1:4-thioxan (Found: C = 39.7; H = 6.4; S = 26.90. $C_4H_8O_2S$ requires C = 40.0; H = 6.7; S = 26.66 per cent.).

This substance is soluble in alcohol, water, or chloroform and sparingly soluble in light petroleum, but does not crystallise well from any of these solvents. A further supply may be obtained by boiling the aqueous residues from the chloroform extract with sodium hydroxide for another three hours and thus converting some of the unstable dihydroxy-compound into the ring compound, which may then be extracted with chloroform and purified as before.

Reaction between $\beta\beta'$ -Dichlorodiethyl Sulphoxide and Sodium Hydroxide in 50 per cent. Ethyl-alcoholic Solution.— $\beta\beta'$ -Dichlorodiethyl sulphoxide (60 grams) was gradually added to a solution of sodium hydroxide (30 grams) in 50 per cent. ethyl alcohol (300 c.c.), a considerable amount of heat being evolved. The yellow solution was boiled for twelve hours, neutralised with hydrochloric acid,

the sodium chloride removed, and the filtrate concentrated by distillation under diminished pressure. The mixture was then filtered, extracted with ether, and the ethereal extract washed and dried as before. After removal of the ether there remained a viscous, brown oil which was purified by two distillations under diminished pressure. A fraction boiling at $165^{\circ}/15$ mm. (15 grams) was obtained consisting of $\beta\beta'$ -diethoxydiethyl sulphoxide (Found: C = 48.75; H = 9.3; S = 16.36 per cent.).

The aqueous residues from the ether extraction were next examined. The ethyl alcohol and the water were removed as far as possible by evaporation on the water-bath and the inorganic matter was separated by filtration, a viscous, brown oil of unpleasant odour remaining. This was insoluble in ether or chloroform, but soluble in pyridine. It was extremely soluble in water or ethyl alcohol, and from these properties it was thought to be the dihydroxy-compound. The oil, dissolved in pyridine, was dried as completely as possible with anhydrous sodium sulphate, and the pyridine removed by distillation under diminished pressure. The residue distilled between 180 – $230^{\circ}/30$ mm. with much charring. After two further distillations of this fraction, a sample was obtained which boiled with decomposition at 205 – $210^{\circ}/20$ mm. The analytical figures indicate that this substance is $\beta\beta'$ -dihydroxydiethyl sulphoxide contaminated with a small amount of the sulphoxide of 1:4-thioxan (Found: C = 37.9; H = 7.2; S = 22.1. $C_4H_{10}O_3S$ requires C = 34.7; H = 7.2; S = 22.1 per cent.).

$\beta\beta'$ -Dihydroxydiethyl sulphoxide is a dark yellow, viscous liquid, soluble in water or alcohol, but insoluble in the usual organic solvents. It resembles thiodiglycol in odour, but differs from it in not forming a benzoyl derivative either in pyridine solution or by the Schotten-Baumann reaction.

When it is boiled with dilute sodium hydroxide solution for two hours, some of the ring compound is formed, which can be isolated by extraction with chloroform in the usual way.

Reaction between $\beta\beta'$ -Dichlorodiethylsulphone and Sodium Hydroxide in 95 per cent. Ethyl-alcoholic Solution.—Helfrich and Reid state that the main product of this reaction is an oil which boils at 140 – $165^{\circ}/15$ mm., and is soluble in ether; this is stated to be the dihydroxy-derivative, but no analyses are given.

$\beta\beta'$ -Dichlorodiethylsulphone (15 grams) was added to a solution of sodium hydroxide (6 grams) in 95 per cent. ethyl alcohol (100 c.c.). The procedure was similar to that employed for the reaction with the sulphoxide; after removal of the ether a brown oil remained which decomposed to some extent on distillation under diminished pressure. A fraction was finally obtained, b. p. 242 – $244^{\circ}/20$ mm.,

consisting of $\beta\beta'$ -diethoxydiethylsulphone (Found: C = 45.7; H = 8.2; S = 15.08. $C_8H_{18}O_4S$ requires C = 45.8; H = 8.5; S = 15.23 per cent.).

$\beta\beta'$ -Diethoxydiethylsulphone is a pale yellow, viscous liquid, soluble in the usual organic solvents, but nearly insoluble in water. It boils at 242–244°/15 mm. and has an unpleasant odour recalling the corresponding sulfoxide.

$\beta\beta'$ -Dimethoxydiethylsulphone.— $\beta\beta'$ -Dichlorodiethylsulphone (20 grams) is added cautiously to a well-cooled solution of sodium hydroxide (5 grams) in methyl alcohol (100 c.c.). The reaction is violent and is completed in a few minutes. The product is an oil which may be purified by distillation under diminished pressure; it boils at 192°/25 mm. (Found: S = 17.74. $C_6H_{14}O_4S$ requires S = 17.59 per cent.). The substance has properties similar to those of the diethoxy-derivative.

$\beta\beta'$ -Diisomylorxydiethylsulphone.—This is prepared in exactly the same way by the action of $\beta\beta'$ -dichlorodiethylsulphone on sodium amyloxide. The product after two distillations under diminished pressure is a pale yellow, viscous oil which has an odour characteristic both of the isomyl group and the sulphone residue. It boils with some decomposition at 222°/15 mm. (Found: S = 10.65. $C_{14}H_{30}O_4S$ requires S = 10.87 per cent.).

Reaction between $\beta\beta'$ -Dichlorodiethylsulphone and Sodium Hydroxide in Aqueous Solution.—The brown solution obtained when $\beta\beta'$ -dichlorodiethylsulphone (100 grams) was added to a solution of sodium hydroxide (42 grams) in water (600 c.c.) was maintained at the boiling point for six hours; it was then concentrated to about 300 c.c. on the water-bath, filtered while hot, and allowed to cool. The long, colourless needles formed after some time were recrystallised from ethyl alcohol or water. The filtrate, again boiled and cooled, yielded another crop of crystals. Yield = 50 grams. These crystals are soluble in water, alcohol, chloroform, or acetone, but are nearly insoluble in ether; after recrystallisation, they melt at 129°. The substance corresponds in properties to the sulphone of 1:4-thioxan described by Baumann and Walter (*loc. cit.*), who give the melting point as 130° (Found: S = 23.38. Calc., S = 23.50 per cent.). The sulphone is an extremely stable solid which resists the action of dilute alkalis or acids and is not nitrated by the standard methods. It shows no basic properties and will not form additive compounds with such reagents as hydrogen chloride, platinic chloride, and picric acid.

The alkaline liquor from which the sulphone had crystallised was neutralised with glacial acetic acid, concentrated by evaporation on the water-bath, and filtered. The residual brown oil was insoluble

in ether, chloroform, or benzene, but soluble in alcohol or water. This substance could not be isolated in a pure state and would not give a benzoyl derivative by the usual methods. The oil (2 grams) was added to a mixture of acetic anhydride (2 grams) and a drop of concentrated sulphuric acid; a very violent reaction took place and a solid was precipitated. The mixture was poured into water, neutralised, and extracted with chloroform; after removal of the solvent from the dried extract, a solid remained which crystallised from alcohol in long needles melting at 128°. These crystals are evidently the same as those described in the above section and are produced from the brown oil (impure $\beta\beta'$ -dihydroxydiethylsulphone) by dehydration.

Reaction between $\beta\beta'$ -Dichlorodiethylsulphone and Sodium Hydroxide in 50 per cent. Ethyl-alcoholic Solution.— $\beta\beta'$ -Dichlorodiethylsulphone (45 grams) was added to a solution of sodium hydroxide (20 grams) in 50 per cent. ethyl alcohol (250 c.c.). Heat was evolved and the reaction completed by keeping the mixture at the boiling point for three hours. It was then neutralised with glacial acetic acid, filtered, the filtrate concentrated, and extracted with ether; the ethereal fraction after the usual treatment yielded an oil boiling at 225–227°/13 mm. Analysis showed it to be the diethoxy-derivative (Found: S = 14.90 per cent.).

The aqueous portion from the ethereal extraction was boiled with a dilute alkali solution for two hours and then extracted with chloroform; the chloroform extract was washed, dried, and concentrated; the pasty residue crystallised from alcohol in long needles of melting point 129°. The product is obviously the sulphone of 1:4-thioxan described above.

Action of Aqueous Sodium Hydroxide on Thiodiglycol.—After thiodiglycol had been boiled with dilute (10 per cent.) sodium hydroxide for some hours, the solution was concentrated, but no 1:4-thioxan could be isolated. The thiodiglycol was recovered and characterised through its benzoyl derivative, which after crystallisation from alcohol melted at 63.5° (Found: C = 65.30; H = 5.4. Calc., C = 65.45; H = 5.5 per cent.).

The author is indebted to Dr. W. E. Dixon for the following note on the pharmacological properties of some of the derivatives described in this communication.

Of the compounds examined, $\beta\beta'$ -diethoxydiethyl sulphoxide, $\beta\beta'$ -diethoxydiethylsulphone, and $\beta\beta'$ -dimethoxydiethylsulphone are non-irritant and for all practical purposes produce no toxic effects in the animal body. $\beta\beta'$ -Disoamyloxydiethylsulphone is also non-vesicant, but produces a very definite effect on mammals in doses

of 100 mg. per kilo. It exerts a nicotine-like action in that it paralyses the whole autonomic nervous system, but it differs from nicotine in that there is no preliminary stimulation. Death is caused by paralysis of the respiratory centre.

The sulphone of 1:4-thioxan has no physiological action of importance. One hundred to 200 milligrams are sufficient to excite the medulla to a mild extent in the dog and the cat: this is shown by a slight increase of blood-pressure due to vaso-constriction, and by increased expiration.

The author wishes to express his thanks to Dr. H. McCombie for his most helpful suggestions and criticisms.

CXCV.—*Intermittent Current Electrolysis. Part I.* *The Influence of Intermittent Current on Overvoltage.*

By SAMUEL GLASSTONE.

THE difference between the overvoltage values for a given metal obtained by the "direct" and the "commutator" method has been ascribed by some authors (Newbery, T., 1914, 105, 2419; 1916, 69, 1051; *J. Amer. Chem. Soc.*, 1920, 42, 2007; Sand, Weeks, and Worrell, this vol., p. 456) to the "transfer resistance" of a gas film situated at the surface of the electrode. The existence of such a resistance affecting the measured potential has been questioned by MacInnes (*J. Amer. Chem. Soc.*, 1920, 42, 2233) and by Dunnill (T., 1921, 119, 1081), who attribute the low results obtained in the commutator method to the very rapid fall of potential that occurs when the polarising current is switched off; the recent work of Tartar and Keyes (*J. Amer. Chem. Soc.*, 1922, 44, 557) lends some support to this view. Since, however, in the commutator method for measuring overvoltage the polarising current only flows intermittently through the cell, two other factors are operative which tend to lower the potential of the electrode. First, overvoltage may be regarded, in general, as due to the accumulation at the electrode of a gas charge, which is diffusing away continuously, but is only being renewed when the polarising current is flowing. At the same current density, therefore, the maximum concentration of gas in the electrode will be lower for intermittent than for direct current; the overvoltage in the former case will thus correspond to a lower current than that indicated

on an ammeter. Direct and commutator overvoltages are therefore not strictly comparable at the same apparent current density. Secondly, the intermittent polarising current will set up induced currents, which will act alternately in opposite directions, corresponding to the make and break of the main current; thus an oscillating discharge will be superimposed upon the polarising current. It is well known that alternating current or electric waves reduce the polarisation at an electrode from which gas is being evolved (Schlömlich, *Elektrotechn. Z.*, 1903, **24**, 959; Bennewitz, *Z. physikal. Chem.*, 1910, **72**, 216; Bürgin, *Diss.*, Berlin 1911; Reitlinger, *Z. Elektrochem.*, 1914, **20**, 261; Goodwin and Knobel, *Trans. Amer. Electrochem. Soc.*, 1920, **37**, 617; Grube and Dulk, *Z. Elektrochem.*, 1918, **24**, 237; etc.), hence it appeared possible that the alternating induced currents were responsible for at least a part of the difference in overvoltage obtained by the direct and the commutator method. The object of this work was to determine the effect of a perfectly uni-directional intermittent polarising current on the overvoltage at various electrodes measured by the direct method; any diminution in potential from that obtained with a continuous current would then be due to the sum of the two effects mentioned above.

EXPERIMENTAL.

Apparatus.—The apparatus used for obtaining the intermittent current was a Tungar rectifier (British Thomson-Houston, No. 195529), fitted with a G.E.C. bulb, No. 195528; this was supplied with alternating current of 60 amplitudes per second at 100 volts. In this way a perfectly uni-directional intermittent current was obtained without any danger of sparking during the intervals when no current flowed. The arrangement was thus almost equivalent to a commutator giving 3600 breaks per minute, and was more trustworthy in working. The direct current terminals of the rectifier were connected in series with a 1000 ohm resistance coil rheostat, a moving-coil ammeter, a hot-wire ammeter, and the electrolytic cell. The last consisted of a small beaker containing about 30 c.c. of electrolyte (*N*-sulphuric acid or *N*-sodium hydroxide). The electrodes at which the overvoltage was determined consisted of small sheets of various metals which had been cleaned with No. 0 glass paper, and then completely waxed over with the exception of an area of 1 sq. cm.; the other electrode in the cell was a thin piece of platinum wire, 5 mm. in length, sealed into a glass tube. The reference electrode was $\text{Hg}|\text{Hg}_2\text{SO}_4, \text{N} \cdot \text{H}_2\text{SO}_4$ in the acid solution and $\text{Hg}|\text{HgO}, \text{N} \cdot \text{NaOH}$ in the alkaline electrolyte;

the jet of the tube connecting the cell with the reference electrode pressed tightly against the clean area of the test electrode. By the use of switches the electrode could be polarised with continuous or intermittent current as desired, without any alteration of the apparatus.

Method of Measurement.—The general procedure was to set up the electrolytic cell with a given metal as cathode and to apply a direct current of 0.15 amp. for ten minutes; then the potential at different current densities was measured at intervals of one minute by the Poggendorf compensation method with a capillary electrometer. The direct current was then replaced immediately by an intermittent current, and the potentials were again measured with the current flowing. To make sure that no appreciable change had occurred in the electrode, the potentials were again determined with continuous current. The test electrode was then removed, cleaned with glass paper, and used as an anode in a similar series of measurements.

Results.—The overvoltage values at room temperature (15°) for a number of metals are given below; the first column gives the current density in milliamps. per sq. cm.; the columns headed D.C. and I.C. give the overvoltages with direct and with intermittent current, respectively. In the columns headed N are given average values obtained from Newbery's measurements (T., 1916, 109, 1051, 1066) by the commutator method.

Cathodic Overvoltages in N-Sulphuric Acid.

Discussion.

The effect of the intermittent current is thus, in general, to reduce the potential of an electrode at which gas is being evolved. The potential is in one case as much as 0.5 volt, and is frequently from 0.2 to 0.3 volt, lower than that measured with continuous current. The higher the current density, the larger is this decrease.

and the result is that the potentials with intermittent current vary much less with variation in the polarising current than do those with direct current. This would account for the remarkable constancy of overvoltage as measured by the commutator method, with varying current density; overvoltages measured by the direct method usually agree with the formula $E = a + b \log C$ Tafel, *Z. physikal. Chem.*, 1905, **50**, 668; Lewis and Jackson, *ibid.*, 1906, **56**, 193; Zerbe, *Z. Elektrochem.*, 1912, **18**, 627), which may be deduced theoretically (see Foerster, "Elektrochemie Wasseriger Lösungen," 1922, p. 322).

During the course of the experiments with intermittent current, it was observed that the hot-wire ammeter always gave a slightly higher reading than the moving-coil instrument; this would indicate that an appreciable induced current had been produced in the circuit. Since even small oscillatory discharges produce a diminution in overvoltage, it appears that a portion, at least, of the reduction in potential observed was due to the alternating induced current set up by the repeated make and break of the intermittent current. The actual value of the induced current will depend on the resistance and general arrangement (self-inductance) of the circuit; consequently the overvoltage values obtained by the commutator method may vary with the type of apparatus used. This point is being further investigated.

It may be suggested that the alternating induced current lowers the potential as a result of the reduction of transfer resistance at the electrodes. So far no work appears to have been done on the effect of alternating current on overvoltage, measured by the commutator method, but the results of Grube and Dulk (*loc. cit.*) indicate that there is a real reduction in the potential, since evolution of oxygen may be made to take place at potentials lower than the theoretically reversible potentials, by superposing alternating current upon direct current. Obviously, the lowering of potential produced in this way must be much greater than that which could be produced simply by the elimination of transfer resistance.

From the fact that the cathodic overvoltage of amalgamated zinc in *N*-sodium hydroxide is apparently the same for continuous and for intermittent polarising current, but varies with the current density, it appears that in general the main difference of potential will be due to the alternating induced currents; the effect of these will, of course, depend on the particular electrode being tested.

Conclusion.

The difference between the overvoltage values for a given electrode, measured by the direct and the commutator method, is

partly due to the lowering of potential caused by the alternating induced currents set up by the repeated make and break of the polarising current in the latter method. The magnitude of the effect depends on the particular electrode used, and is in general greater at higher current densities; it may also be dependent on the type of apparatus used for measurement of the overvoltage.

CXCVI.—*The Behaviour of Activated Sugar Carbon in Contact with Hydrogen Peroxide Solution.*

By JAMES BRIERLEY FIRTH and FRED SHEASBY WATSON.

A REVIEW of the literature on hydrogen peroxide reveals the fact that this compound is an exceedingly sensitive reagent, being readily decomposed by a great variety of substances with liberation of oxygen. This being so, it was considered a suitable reagent with which to study the behaviour of sugar carbon of various degrees of activity.

Filippi (*Arch. Farm. speriment.*, 1907, 6, 363) showed that all powders decompose hydrogen peroxide, the velocity of decomposition being proportional to the exposed surface of the added powder and independent of the concentration of the hydrogen peroxide. Lemoine (*Compt. rend.*, 1916, 162, 725) found that charcoal from wood, from coco-nut, and from sugar is an efficient catalyst for the decomposition of hydrogen peroxide; the catalytic effect being apparently correlative with their sorptive power for gases. Clayton (*Trans. Faraday Soc.*, 1916, 11, 164) showed that hydrogen peroxide does not volatilise appreciably from its aqueous solutions at 50–60°. The rate of decomposition is not affected by stirring.

The object of the present investigation was to determine the influence on the decomposition of hydrogen peroxide of sugar carbon of different degrees of activity and also to determine the influence of temperature.

EXPERIMENTAL.

The sugar carbon used was as supplied by Merck and gave less than 0.1 per cent. of ash. In all the experiments it was very finely powdered. One gram of the carbon was carefully weighed out into a small flask; 25 c.c. of hydrogen peroxide were measured out into a flat-bottomed tube, and the tube was placed inside the flask. The flask was then connected to a gas burette and tilted quickly, thereby causing the hydrogen peroxide to come into contact with

the carbon at the required instant. Accumulation of gas in the liquid was prevented by vigorous agitation, and the flask and contents were maintained at the required temperature by immersion to a definite level in a constant temperature bath.

In the following experiments the rate of evolution of oxygen was measured, and the reaction velocity coefficients are calculated from the equation for a unimolecular surface reaction, $dx/dt = k(a - x)$, to the Napierian base and the minute as the unit of time.

FIG. 1.

In experiment II, the value of k is calculated after each interval, and it will be observed that the value is by no means constant, but continuously decreases, becoming ultimately very small. This feature was common to all experiments, hence in subsequent experiments only the initial and final values of k are recorded. The volumes of oxygen evolved are expressed in c.c. and are corrected to *N.T.P.* In the experiments hereafter described, only the volumes of oxygen evolved in the early stages of the reaction and the final volumes are recorded, the results being completely given graphically in the figure, in which the number at the end

of each curve corresponds to the number of the experiment. In all cases, a series of blank experiments was carried out, in which the only difference was the absence of the carbon. The volume of oxygen evolved in these experiments was exceedingly small. The experimental results here recorded are typical of a large number of experiments actually carried out, and in all cases the results were repeatedly confirmed. In experiments I to V, the temperature of reaction was 18° , and the average volume of oxygen evolved in a series of blank experiments at this temperature was 0.3 c.c. in three hours.

Twenty-five c.c. of the hydrogen peroxide solution used contained, in experiments I to III, 336.8 c.c., and in IV to VIII, 427.7 c.c. of available oxygen.

Experiment I.—One gram of the original carbon, finely powdered and without previous activation, was used. In the first three minutes, 0.28 c.c. of oxygen was evolved, and after 250 minutes 1.60 c.c.

Experiment II.—The finely divided carbon was introduced into a quartz flask and heated in a vacuum for two hours at about 600° , allowed to cool in a vacuum, and then 1 gram of the carbon rapidly weighed out.

Time (mins.).	C.c. of oxygen.	$k \times 10^3$.	Time (mins.).	C.c. of oxygen.	$k \times 10^3$.	Time (mins.).	C.c. of oxygen.	$k \times 10^3$.

33	10.06	0.40	172	20.40	0.16			

Experiment III.—A quantity of carbon activated as in II was treated with $N/10$ -iodine solution in chloroform, in the proportion of 25 c.c. of the solution per gram of carbon, for twenty-four hours. The carbon was then filtered off, transferred to a porcelain dish, and gently heated until practically the whole of the iodine had been volatilised. The carbon was then shaken several times with an alcoholic solution of potassium hydroxide and boiled with distilled water, until, on filtering, the filtrate showed no opalescence with silver nitrate solution. The resulting carbon was finally heated in a vacuum in a quartz flask at about 600° for two hours, then allowed to cool in a vacuum to room temperature, and 1 gram of the carbon weighed out. (After this treatment the ash was still less than 0.1 per cent.)

In the first three minutes, 8.84 c.c. of oxygen were evolved, whilst after 591 and 1338 minutes the volumes were 77.46 c.c.

and 78.87 c.c., respectively. The initial and the final value of $k \times 10^3$ were 4.16 and 0.09, respectively.

In all subsequent experiments, the carbon was activated as described in experiment III.

Experiment IV.—The mass of carbon was 2.5 grams and the volume of the hydrogen peroxide solution 25 c.c. In the first three minutes, 27.54 c.c. of oxygen were evolved; after 1662 and 1742 minutes, the total volumes of oxygen were 349.12 and 351.47 c.c., respectively. The initial and the final value of $k \times 10^3$ were 9.96 and 0.43, respectively.

Experiment V.—The initial quantity of carbon was 1 gram. When the rate of evolution of the oxygen had become very slow, a further 0.5 gram of the carbon was rapidly introduced, and this operation was repeated until the total amount was 2.5 grams. During the first three minutes 10.81 c.c. of oxygen were evolved, the value of $k \times 10^3$ being 3.70; after 247 minutes, the volume was 82.63 c.c. and $k \times 10^3 = 0.38$. After the addition of 0.5 gram of the carbon, the oxygen evolved in the next three minutes was 5.26 c.c., and $k \times 10^3 = 2.9$, whilst after 240 minutes the additional volume was 74.90 c.c. and $k \times 10^3 = 0.26$. Subsequent additions of the carbon produced similar results. The final total volume of oxygen evolved was 343.96 c.c., and the final value of $k \times 10^3$ was 0.34 after a total time of 2178 minutes.

Experiment VI.—The temperature was 35°. 23.5 C.c. of oxygen were liberated by 1 gram of carbon in the first minute, whilst after 425 minutes the total volume of oxygen evolved was 200.4 c.c. The initial and the final value of $k \times 10^3$ were 24.5 and 0.64, respectively.

Experiment VII.—The temperature was 50°. 30.08 C.c. of oxygen were liberated by 1 gram of carbon in the first minute and 312.83 c.c. after 400 minutes. The initial and the final value of $k \times 10^3$ were 31.6 and 1.43, respectively.

Experiment VIII.—The temperature was 70°. 78.96 C.c. of oxygen were evolved in the first thirty seconds and 412.0 c.c. after 100 minutes. The initial and the final value of $k \times 10^3$ were 196.2 and 14.35, respectively.

Blank experiments at 35° and 50° gave average values for liberated oxygen of 0.5 and 0.75 c.c., respectively, in three hours and at 70° 3.2 c.c. in two hours.

Discussion of Results.

Pure sugar carbon as supplied exerts only a very slight catalytic action on the decomposition of hydrogen peroxide, and carbon which has been heated at 600° in a vacuum is only moderately

active. Carbon which has been recovered after having sorbed iodine from chloroform solution shows considerable increase in activity. The rate of decomposition of the hydrogen peroxide does not give a constant when the equation for a unimolecular surface action is applied; the value of k gradually diminishes, becoming ultimately exceedingly small. The rate of decomposition will have become almost negligible after about ten hours. At the ordinary temperature, and with the reagents in the proportion 1 gram of carbon per 25 c.c. of peroxide, only about 20 per cent. of the total available oxygen was evolved. It would appear, therefore, that the catalytic activity of the carbon is gradually and continuously decaying, that is, the catalytic action is accompanied by a simultaneous poisoning action. This view is supported by experiment V, in which it was shown that further oxygen is liberated by the periodic addition of carbon.

Experiments IV and V show that, within certain limits, the volume of oxygen liberated is proportional to the carbon added, and the result is practically the same whether the carbon be added in one or several successive portions, 0.5 gram of the carbon being equivalent to about 70 c.c. of oxygen for the given concentration of peroxide solution.

Experiments VI, VII, and VIII show that the activity of the carbon increases rapidly with rise of temperature. The activity is characterised throughout by a rapid initial phase followed by a much slower and gradual decline in activity. It is in this initial phase that the effect of temperature is most pronounced, the volumes of oxygen liberated during the first three minutes being 10.8, 43.6, 56.2, and 180.5 c.c. at 18°, 35°, 50°, and 70°, respectively.

At the ordinary temperature the reaction proceeds quite smoothly when the mixture is sufficiently agitated, but at higher temperatures, particularly at 35° and 50°, there is a great tendency to develop periods of "lag," during which the evolution of oxygen falls off and then increases again. This periodic evolution took place even from vigorously agitated mixtures and was not due to any accumulation of oxygen in the particles of the carbon, but rather indicated a periodic activity of the carbon. The periods showed no pronounced regularity; they invariably appeared, however, in several repeated experiments. The curves are not smoothed in any way, but are drawn from the actual results, and curves VI and VII show the foregoing feature.

It will be seen from the above results that the reaction differs substantially from the simple catalytic decomposition in which the value of k is constant and the decomposition of the peroxide practically complete.

Summary.

(1) Ordinary pure sugar carbon gives rise to only a very slight decomposition of hydrogen peroxide solution.

(2) Sugar carbon which has been heated at 600° in a vacuum for two hours shows appreciable activity towards hydrogen peroxide solution.

(3) A considerable increase of activity is displayed by carbon which has previously sorbed iodine from solution, and from which the iodine has been subsequently completely removed.

(4) The activity of the carbon gradually decays during the reaction.

(5) Within the limits of the experiments, the decomposition of a given volume of hydrogen peroxide solution is proportional to the mass of carbon used.

(6) The activity of the carbon increases rapidly with rise of temperature.

UNIVERSITY COLLEGE, NOTTINGHAM. [Received, February 3rd, 1923.]

CXCVII.—*The Formation of Derivatives of Tetrahydronaphthalene from γ -Phenyl Fatty Acids. Part III. The Influence of Substituents on Ring Closure.*

By ARTHUR JOHN ATTWOOD, ARNOLD STEVENSON, and JOCELYN FIELD THORPE.

THE work which has been carried out in these laboratories during the past years has proved that the ease with which a second ring closes is largely influenced by the groups attached to the side chain chains extending from the primary ring. Although most of this work has been carried out on fully saturated carbon ring systems, evidence has been brought forward to show that in the formation of derivatives of tetrahydronaphthalene from compounds having a benzene nucleus to which is attached a side chain of four carbon atoms, substitution in the β -position is apparently an important factor in bringing about the closing of the second or hydrogenated ring. Thus in the first part of this series (Kon and Stevenson, T., 1921, 119, 88) it was shown that β -benzylglutaric acids of type I (R = Me or Et), which should have been obtained by the hydrolysis

3 O*2

of the corresponding Guareschi imides, could not be isolated, as they passed at once, in presence of the sulphuric acid used as a hydrolysing agent, into tetrahydronaphthalene derivatives of type II, whilst in the second part it was also shown (T., 1922, 121, 1717) that β -benzylglutaric acid itself ($R = H$), when treated with sulphuric acid, readily undergoes a similar change.

Now these three glutaric acids may be regarded as γ -phenylbutyric acids with the group $-\text{CH}_2\text{CO}_2\text{H}$ as a substituent in the β -position, and, to ascertain more definitely the influence on ring closure of substitution in this position, it was decided to compare the effects of other substituents, not only in the β -, but also in the α - and γ -positions. It was considered that this could best be done by testing series of isomeric substituted γ -phenylbutyric acids, each series having the same substituent introduced, if possible, successively in all three positions, and by ascertaining in which of these acids ring formation took place.

To determine under such conditions the ease with which a ring closes, it is necessary to employ a method which is selective; in other words, the agent used must be sufficiently powerful to bring about the necessary change in certain cases, but not in others. Experiment has shown that the action of concentrated sulphuric acid on substituted γ -phenylbutyric acids at room temperature fulfils this condition.

The formation of tetrahydronaphthalene derivatives of type II can be readily proved, as they give semicarbazones and pass to phthalic acid on oxidation with potassium permanganate; on the other hand, proof that the ring has not closed may have to be indirect, for although in some cases the original substance is not attacked by the sulphuric acid and can be recovered unchanged, in others action takes place and no definite compound can be isolated from the residue. In such circumstances, failure to obtain a semicarbazone and phthalic acid on oxidation may be regarded as evidence that ring closure has not taken place.

Now the simplest acid which by the loss of a molecule of water could pass into a tetrahydronaphthalene derivative is γ -phenylbutyric acid, and, as Kipping and Hill (T., 1899, 75, 144) found that the chloride of this acid in presence of aluminium chloride readily lost hydrogen chloride to form 1-ketotetrahydronaphthalene, it was thought that the acid itself when treated with sulphuric acid might give the same condensation product with loss of water. Although it has recently been shown by Krollpfeiffer and Schäfer (*Ber.*, 1923, 56, [B], 620) that condensation takes place at 100° , when the reaction was carried out at room temperature no tetrahydronaphthalene derivative could be identified.

Several substituted γ -phenylbutyric acids are mentioned in the literature under other names; thus benzylpyruvic acid (III) (Fittig and Petkow, *Annalen*, 1897, 299, 28) is the α -keto-, and β -benzoylpropionic acid (IV) (Burcker, *Ann. Chim. Phys.*, 1882, [v], 26, 435) the γ -keto-substituted acid. We have succeeded in preparing ethyl β -keto- γ -phenylbutyrate (V) by condensing ethyl phenylacetate

and ethyl acetate by means of sodium, and this we employed for the sulphuric acid test, owing to the instability of β -keto-acids. The series is thus complete, whilst, in addition, benzoylpyruvic acid (VIII) (Beyer and Claisen, *Ber.*, 1887, 20, 2184) is an example of a diketo-acid.

When treated with concentrated sulphuric acid, none of these gave tetrahydronaphthalene derivatives. Benzylpyruvic acid (III) was decomposed and β -benzoylpropionic acid (IV) remained unchanged, this being proved by the fact that the semicarbazone, which was obtained after treatment with sulphuric acid, was not the disemicarbazone which the tetrahydronaphthalene derivative would give, but a monosemicarbazone identical with that obtained from the original acid. Ethyl β -keto- γ -phenylbutyrate was found to pass into the corresponding acid (VI),* which, although it was precipitated on pouring the mixed ester and sulphuric acid on to ice, was very unstable and readily decomposed on warming, or even on exposure to air, to form benzyl methyl ketone.

Bromme and Claisen (*Ber.*, 1888, 21, 1132) showed that benzoylpyruvic acid exists in a hydrated form, to which they assigned the formula (VII). On heating at 95–100°, water is given off, the dehydrated acid being represented by (VIII). Both modifications were treated with sulphuric acid; the dehydrated acid remained unchanged, whilst the hydrated form lost its water and passed into the dehydrated acid.

The carboxyl group is a substituent which is known in all three positions. *prim*-Phenethylmalonic acid (IX) (Fischer and Schnitz,

* Bailein gives a reference to *Ber.*, 1888, 21, [2], 644—an abstract of a paper by Haller, *Compt. rend.*, 1888, 107, 104, but neither abstract nor paper mentions the acid.

Ber., 1906, 39, 2211) may be regarded as α -carboxy- γ -phenylbutyric acid, benzy succinic acid (XII) (Fittig and Röders, *Annalen*, 1890, 256, 87) as the β -carboxy-acid, and α -phenylglutaric acid (X) (Fichter and Merckens, *Ber.*, 1901, 34, 4174) as the γ -carboxy-acid, whilst, in addition, α -phenylpropane- $\beta\beta\gamma$ -tricarboxylic acid (XI) (Fittig and Röders, *Annalen*, 1890, 256, 92) furnishes an example of a γ -phenylbutyric acid with two carboxyl groups in the β -position.

(IX.) $\text{Ph}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}(\text{CO}_2\text{H})_2$ $\text{Ph}\cdot\text{CH}(\text{CO}_2\text{H})\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CO}_2\text{H}$ (X.)

Fichter and Merckens's paper is the only reference to α -phenylglutaric acid, and although they indicate two methods for its preparation, they give no details, and we have unfortunately not succeeded in repeating their work, whilst attempts which we have made to prepare the acid on other lines have also failed.

No tetrahydronaphthalene derivative could be obtained from *prim*-phenethylmalonic acid (IX), but when α -phenylpropane- $\beta\beta\gamma$ -tricarboxylic acid (XI) and benzy succinic acid (XII) were treated with sulphuric acid the corresponding tetrahydronaphthalene derivatives (XIII and XIV) were readily formed, the latter also being obtained when the dicarboxy-derivative (XIII) was heated. That a second ring was formed is proved by the fact that the compound (XIV) on oxidation with potassium permanganate gave phthalic acid; it is, however, possible that these two condensation products, instead of being tetrahydronaphthalene derivatives, might be the hydrindone derivatives (XV and XVI).

Whilst we have been unable to obtain direct proof as to which way the condensation takes place, it seems more than probable that tetrahydronaphthalene derivatives are formed, because both con-

densation products readily give semicarbazones, and whilst this is to be expected in the case of the compounds (XIII) and (XIV), the propinquity of the two carboxyl groups to the ketonic group in (XV) would render the formation of a semicarbazone extremely difficult if not impossible.

Phenylacetylmalononitrile and β -benzoylisosuccinic (XVII) (Kues and Paal, *Ber.*, 1885, **18**, 3324) are two substituted γ -phenylbutyric acids, which are of interest, as they show clearly the different effects on ring closure of substitution in the β - and γ -positions. Metzner (*Annalen*, 1897, **298**, 374) found that ethyl phenylacetylmalonate

(XVIII), when treated with sulphuric acid, passed through the tetrahydronaphthalene derivative (XIX) into ethyl 1:3-dihydroxynaphthalene-2-carboxylate (XX). Benzoylisosuccinic acid, on the other hand, under similar treatment was decomposed.

By introducing hydroxyl and methyl groups in both α - and β -positions, two isomeric acids were obtained. α -Hydroxy- γ -phenyl- α -methylbutyric acid (XXI) was prepared from benzyl-

acetone and hydrocyanic acid, although it was not found possible to isolate the intermediate cyanohydrin, and the yield of resulting acid was poor. From benzyl methyl ketone, ethyl β -hydroxy- γ -phenyl- β -methylbutyrate (XXII) was prepared by Reformatski's method, but on hydrolysis some secondary reaction apparently took place, for the yield of acid was small and it could only be obtained as an oil which could not be solidified. Neither of these acids gives tetrahydronaphthalene derivatives when treated with sulphuric acid.

Of the fifteen γ -phenylbutyric acids referred to above, six yield tetrahydronaphthalene derivatives on treatment with sulphuric acid at room temperature, namely, the three β -benzylglutaric acids of type I, the carboxy-acids (XI) and (XII), and ethyl phenylacetylmalonate (XVIII). It will be noted that all six have substituents in the β -position, which points to the fact that substitution in this position is essential for bringing about the closing of the second ring. But substitution in the β position alone is not enough, for this

condition is fulfilled by the β -keto-acid (VI) and the β -hydroxy- β -methyl acid (XXII) from which no tetrahydronaphthalene derivatives could be obtained. But it will be observed that in all cases where ring closure takes place there is in addition to a β -substituent a second carboxyl group, which group may form part of the β -substituent, as in the β -benzylglutaric acids of type I and as in the acids (XI) and (XII), or it may occupy another position, as in ethyl phenylacetylmalonate (XVIII). That the β -substituent and the second carboxyl group appear both to be essential is clearly shown when the behaviour of the β -keto- (VI), the α -carboxy- (IX), and the α -carboxy- β -keto- (XVIII) acids towards sulphuric acid is compared, for only the last forms a tetrahydronaphthalene derivative.

The mechanism of the reaction may be as follows:

(a) Sulphuric acid leads to the formation of the anhydride.

(b) The anhydride adds on sulphuric acid.

(c) Ring formation occurs owing to the production of sulphuric acid from the appropriate nuclear hydrogen atom.

This mechanism is in agreement with the fact that tetrahydronaphthalene derivatives are formed only from those acids which are capable of giving anhydrides. Indeed, it has actually been found that benzylsuccinic anhydride gives, on treatment with sulphuric acid, a tetrahydronaphthalene derivative identical with that derived from the parent acid.

The ester (XVIII) may react in a similar manner, because the second ester group remains unchanged in the final product (XX):

An alternative explanation, equally in agreement with the facts at present known, is that, under the catalytic influence of the

sulphuric acid, the nuclear hydrogen atom migrates to the carboxyl group of the anhydride or ester. This explanation brings the reaction described above into collation with a number of imino-reactions in which the nuclear hydrogen atom migrates to a cyano-group (Atkinson and Thorpe, T., 1896, 89, 1906; Thorpe, T., 1907, 91, 1004).

The apparent necessity for the intervention of an anhydride or ester is also explained, if it be assumed that the migration of the hydrogen atom to the free carboxyl group is inhibited by the dynamic structure of the latter.

Substitution in the β -position may also affect the angle between the carbon atoms in the chain and thus facilitate the closing of the second ring.

It is hoped that further evidence bearing on the mechanism of these reactions will be obtained when the work now in progress on the formation of derivatives of hydrindone from β -phenylpropionic acids is completed.

EXPERIMENTAL.

γ -Phenylbutyric Acid.—The acid was prepared by Kipping and Hill's modification (*loc. cit.*) of Jayne's method. One gram was dissolved in 5 c.c. of concentrated sulphuric acid and left over-night. The mixture was poured on to ice and extracted with ether, the ethereal extract yielding a brown oil which solidified in a vacuum. A semicarbazone could not, however, be obtained from this solid, although Kipping and Hill found that it was formed readily from the crude tetrahydronaphthalene derivative. The oxidation with potassium permanganate was carried out in acid solution, the method followed having been found to give a good yield of phthalic acid in cases where ring closure had taken place. A mixture of 2 grams of γ -phenylbutyric acid and 10 c.c. of concentrated sulphuric acid which had stood over-night was diluted and heated with a warm,

saturated solution of potassium permanganate (dilute sulphuric acid being added) until the pink colour persisted. After this had been destroyed with oxalic acid, the liquid was extracted with ether, but the ethereal extract did not yield any trace of phthalic acid.

Benzylpyruvic Acid (III).—Fittig and Petkow's (*loc. cit.*) directions for preparing the acid were followed. It was violently attacked by sulphuric acid, forming a dark residue from which nothing could be obtained.

β -Benzylpropionic Acid (IV).—The acid was prepared by Burcker's method (*loc. cit.*) and by that of Fittig and Ginsberg (*Annalen*, 1898, 299, 13). The semicarbazone was formed readily by mixing an alcoholic solution of the acid with semicarbazide acetate solution. Twice crystallised from alcohol, in which it is sparingly soluble, it separated as a mass of very fine needles, which shrank and darkened at 202° and melted and decomposed at 206° (Found: N = 17.89, $C_{11}H_{13}O_3N_3$ requires N = 17.86 per cent.).

Five c.c. of concentrated sulphuric acid and 0.75 gram of the acid were mixed and left over-night. On pouring the mixture on to ice, a precipitate formed, from which a semicarbazone was obtained readily. Analysis and the method of mixed melting points proved that this was identical with the semicarbazone described above (Found: N = 18.01 per cent.).

Ethyl β -Keto- γ -phenylbutyrate (V).—It was found advantageous to use an excess of ethyl acetate and sufficient sodium to convert this to ethyl acetoacetate. A mixture of 82 grams of ethyl phenylacetate and 132 grams of ethyl acetate was added to 300 c.c. of dry ether, in which were suspended 23 grams of fine sodium wire, and the whole was heated gently under reflux for four hours, when all the sodium had dissolved. Ice-cold water was added and then dilute sulphuric acid until the mixture was acid. The aqueous layer was separated off and shaken twice with ether, the ethereal solutions being added to the original ethereal layer. The ether was removed and the residue distilled under reduced pressure, yielding 41 grams of nearly pure ester, which on redistillation at 22 mm. boiled at 156° . It is a colourless, slightly viscous liquid with an odour somewhat resembling that of cloves, and it gives a plum colour with ferric chloride (Found: C = 69.56; H = 7.01. $C_{12}H_{14}O_3$ requires C = 69.87; H = 6.84 per cent.).

The corresponding acid (VI) was obtained as a precipitate when a mixture of 10 grams of the ester and 25 c.c. of sulphuric acid was left over-night and then poured on to ice. The precipitated acid was filtered off without delay, dried on porous earthenware, and crystallised from benzene and light petroleum, from which it separated in clusters of needles melting and decomposing at 95° .

[Found: 7.90 c.c.; * C = 67.01; H = 5.90. $C_{10}H_{10}O_3$ (monobasic) requires 7.45 c.c.: C = 67.38; H = 5.67 per cent.]. The acid is very unstable; it can be preserved in a vacuum, but on warming, or even on exposure to air, it loses carbon dioxide and passes to benzyl methyl ketone, this being proved by the fact that the decomposition product gave a semicarbazone which was identical with that from benzyl methyl ketone.

Benzoylpyruvic Acid (VII and VIII).—The acid was prepared by Beyer and Claisen's method (*loc. cit.*), and the hydrated form (VII) so obtained behaved on titration as a dibasic acid [Found: 12.05 c.c.* Calc. (dibasic), 11.80 c.c.]. Two grams were dissolved in 10 c.c. of concentrated sulphuric acid and left over-night. On pouring the mixture on to ice, a precipitate was obtained, which, crystallised from benzene and dried at room temperature, proved to be the dehydrated form (VIII) [Found: 15.55 c.c.; * C = 62.32; H = 4.19. Calc. (dibasic), 15.75 c.c.; C = 62.46; H = 4.22 per cent.].

That the dehydrated form remained unchanged when treated with sulphuric acid was shown by titration [Found: 12.75 c.c.* Calc. (dibasic), 12.40 c.c.] and by the melting point remaining the same.

prim-Phenethylmalonic Acid (IX).—Fischer and Schmitz's method (*loc. cit.*) was followed, ω -chloroethylbenzene being used instead of the bromo-compound. On twice crystallising from benzene, it was found that the acid melted at 143° and not at 130 – 131° as previously stated [Found: 11.75 c.c.; * C = 63.61; H = 6.13. Calc. (dibasic), 11.45 c.c.; C = 63.43; H = 5.82 per cent.].

One gram of acid was mixed with 5 c.c. of concentrated sulphuric acid and left over-night. The mixture was poured on to ice and extracted with ether, the ethereal extract yielding a brown residue from which no semicarbazone could be obtained. Similar residues were oxidised with potassium permanganate both in acid solution as described above and in alkaline solution as detailed below, but in neither case could phthalic acid be detected in the ethereal extract.

1-Ketotetrahydronaphthalene-3:3-dicarboxylic Acid (XIII).—The acid was precipitated on pouring on to ice a mixture of 2 grams of benzylethanetricarboxylic acid (Fittig and Röders, *loc. cit.*) and 10 c.c. of concentrated sulphuric acid which had been kept over-night. It is insoluble in benzene, but crystallises from water in fine needles which melt and decompose violently at 170° [Found: 11.80 c.c.; * C = 61.80; H = 4.50. $C_{12}H_{10}O_5$ (dibasic) requires 11.80 c.c.; C = 61.51; H = 5.31 per cent.]. The silver, lead, and

* On titration with $N/20$ -sodium hydroxide.

ferric salts form readily in the cold from the ammonium salt, and the barium and calcium salts on warming, but the copper and aluminium salts are soluble both in the cold and on warming.

The *semicarbazone* was prepared readily from an alcoholic solution of the acid and semicarbazide acetate solution. It could not be crystallised from alcohol or ethyl acetate, and therefore the crude substance, which began to darken at 240° and decomposed at 250°, was analysed (Found: N = 14.07. $C_{13}H_{13}O_3N_3$ requires N = 14.43 per cent.).

1-Ketotetrahydronaphthalene-3-carboxylic Acid (XVIII).—The crude acid was obtained on pouring on to ice a mixture of benzy succinic acid (Fittig and Röders, *loc. cit.*) (1 gram) and concentrated sulphuric acid (10 c.c.) which had been kept over-night. Twice crystallised from water, it separated as a flocculent precipitate melting at 149° [Found: 13.00 c.c.; * C = 69.55; H = 5.45. $C_{11}H_{10}O_3$ (monobasic) requires 12.85 c.c.; C = 69.43; H = 5.31 per cent.]. The salts of the heavy metals are precipitated readily in the cold from the ammonium salt, whilst the barium and calcium salts are soluble both in the cold and on heating. The acid can also be obtained by heating the dicarboxylic naphthalene derivative (XVI) above its melting point, and by treating benzy succinic anhydride with concentrated sulphuric acid, the identity of the three products being proved by their melting points.

The *semicarbazone* was formed readily from an alcoholic solution of the acid and semicarbazide acetate solution. It is very sparingly soluble in alcohol, separating as a crystalline powder which begins to shrink at 255° and decomposes at 261° (Found: N = 17.04. $C_{12}H_{13}O_3N_3$ requires N = 17.00 per cent.).

The oxidation to phthalic acid was carried out by dissolving 1.5 grams of the acid in sodium hydroxide solution, heating on the steam-bath, and adding a warm saturated solution of potassium permanganate until the colour persisted. After destroying the excess of permanganate with sulphurous acid, the solution was filtered and the filtrate acidified and extracted with ether, the ethereal extract yielding 0.7 gram of phthalic acid, which after crystallisation from water was identified by its giving fluorescein when heated with resorcinol, by the method of mixed melting points, and by titration [Found: 13.90 c.c. Calc. (dibasic), 16.95 c.c.].

Benzoylisosuccinic Acid (XVII).—The acid was prepared by Kues and Paal's method (*loc. cit.*), chloroacetophenone being used in place of bromoacetophenone. On dissolving 1 gram of the acid in 5 c.c. of concentrated sulphuric acid, the solution became red. After being kept over-night, this was poured on to ice and extracted with

* On titration with N/20-sodium hydroxide.

ether, the ethereal extract giving a dark residue which did not yield a semicarbazone. The residue from 5 grams of acid was oxidised with potassium permanganate, but did not give any phthalic acid.

α -Hydroxy- γ -phenyl- α -methylbutyric Acid (XXI).—To an ice-cooled mixture of ether and benzylacetone, prepared by Harries and Eschenbach's method (*Ber.*, 1896, 29, 383), an excess of finely powdered potassium cyanide was added and then drop by drop with constant stirring the theoretical quantity of concentrated hydrochloric acid. The mixture was left in the ice-bath for half an hour, filtered, and the residual salts were washed with ether, which was added to the filtered solution, this being then washed with water, dried, and the ether removed. The residue would not solidify on keeping in a vacuum and was hydrolysed by heating under reflux for some hours with hydrochloric acid (50 per cent. by volume). The liquid thus obtained was extracted with ether, the ethereal solution being then treated with sodium carbonate solution. On adding hydrochloric acid, the acid was precipitated, but the yield was poor, being only about 10 per cent. of the theoretical. Crystallised from water, the acid separated in glistening plates of indefinite melting point, and on recrystallisation from benzene in silky needles, melting at 102° [Found: 8.50 c.c.; * C = 68.07; H = 7.38. $C_{11}H_{14}O_3$ (monobasic) requires 8.60 c.c.; C = 68.01; H = 7.26 per cent.]. The barium and calcium salts and the salts of the heavy metals are precipitated in the cold from the ammonium salt.

The *acetyl* derivative was prepared by heating the acid with acetyl chloride under reflux for three hours. On evaporating off the excess of acetyl chloride and keeping in a vacuum for some days, the crude derivative solidified and this on crystallisation from light petroleum separated in minute prisms melting at 83° (Found: C = 66.16; H = 6.89. $C_{13}H_{16}O_4$ requires C = 66.05; H = 6.86 per cent.).

When treated with concentrated sulphuric acid, the acid was violently attacked with evolution of gas, and extraction with ether only gave a trace of dark coloured residue.

Ethyl β -Hydroxy- γ -phenyl- β -methylbutyrate (XXVI).—Sixteen grams of zinc fibre were gradually added to a mixture of 33.5 grams of benzyl methyl ketone, 27.5 c.c. of ethyl bromoacetate, and 125 c.c. of benzene, which was heated under reflux until the reaction started. The reaction products were diluted with water and acidified with sulphuric acid, the aqueous layer was separated off, and the residual layer dried and distilled under reduced pressure, when the ester was obtained as a colourless liquid boiling at 175°/23 mm., the yield

* On titration with N/20-sodium hydroxide.

being 36 grams (Found: C = 70.10; H = 8.12. $C_{13}H_{18}O_3$ requires C = 70.23; H = 8.15 per cent.).

After hydrolysis by means of alcoholic potassium hydroxide solution, a brown oil separated out when the aqueous solution was acidified. This was filtered off and the filtrate extracted with ether, the ethereal extract giving a poor yield of a stiff oil which would not solidify on keeping in a vacuum. Analysis showed that it was the crude *acid* [Found: 14.25 c.c.; * C = 67.45; H = 7.66. $C_{11}H_{14}O_3$ (monobasic) requires 14.30 c.c.; C = 68.01; H = 7.26 per cent.]. Hydrolysis by means of the theoretical quantity of methyl-alcoholic sodium methoxide gave no better result.

The crude acid was treated with concentrated sulphuric acid in the manner already described. The ethereal extract from the resulting product yielded a brown oil, from which a semicarbazone could not be obtained and from which on oxidation with potassium permanganate phthalic acid could not be isolated.

We are indebted to the Chemical Society for a grant which has partly paid for the materials used in the investigation.

CXCVIII.—*The Action of Halogens on Phenylhydrazones. Part I. The Action of Bromine.*

By JAMES ERNEST HUMPHRIES, EDWARD BLOOM, and ROY EVANS.

THE addition of halogens to Schiff's bases has been studied by James and Judd (T., 1914, 105, 1427). Part of their communication deals with the addition of bromine to a series of benzylideneanilines, from which coloured (yellow or orange), unstable, additive compounds were obtained. The additive compounds were dibromides of the Schiff's bases, and were formulated as

On hydrolysis (sodium ethoxide was chiefly used), the compounds decomposed giving the original aldehyde and either a para-brominated amine or (when the base was already substituted in the para-position) partly an ortho-brominated amine and partly the original amine. In either case, hydrogen bromide was eliminated, and titration by means of baryta of the additive compound

* On titration with N/20-sodium hydroxide.

in alcoholic solution showed that rather more than one-half of the added bromine was set free in this form.

The present communication deals with the addition of bromine under similar conditions, namely, in dry carbon tetrachloride at low temperatures, to a series of phenylhydrazones, which, as in the case of the Schiff's bases, contain a double bond between carbon and nitrogen. Typical aldehydes and ketones have been employed—acetaldehyde, acetone, acetophenone, benzaldehyde, and benzophenone—which give a variety of aliphatic and aromatic groups attached to the carbonyl group. The same reaction was also applied to acetylphenylhydrazine.

Under the conditions mentioned, bromine is readily substituted for hydrogen of the phenyl group attached to the nitrogen atom of the phenylhydrazone, the group $RR'C:N\cdot NH\cdot$ having an ortho-para-directive influence. The general reaction is therefore as follows :

The nature of the final product, however, depends on the stability of the resulting phenylhydrazone towards hydrolysis by hydrobromic acid; for example, acetaldehydephenylhydrazone yielded the hydrobromide of *p*-bromophenylhydrazine, whilst the bromination of benzophenonephenylhydrazone followed almost completely the course shown in the above equation. Further bromination of the bromophenylhydrazones of benzaldehyde and benzophenone showed that only two atoms of bromine could be introduced into the ring; the second substitution occurring in the ortho-position. In the case of benzaldehyde, however, further substitution took place at the carbon atom of the original carbonyl group, but this occurred only when the ortho- and para-positions were already occupied. Thus with the 2:4-dibromo- and 2:4:6-tribromophenylhydrazones of benzaldehyde the following reaction proceeded quantitatively :

When bromine was added to the solution of a phenylhydrazone in carbon tetrachloride, a coloured precipitate (yellow or red) appeared immediately, which was the hydrobromide of the brominated phenylhydrazone; we have no evidence of the formation of an additive compound, of the type found by James and Judd, preceding substitution. The primary product did not liberate iodine from potassium iodide, and it could also be obtained by passing dry hydrogen bromide into a solution of the brominated

phenylhydrazone in carbon tetrachloride or benzene. Further, the fact that benzophenone-2 : 4-dibromophenylhydrazone did not form an additive product with bromine (which remained free in the solution), but did form a hydrobromide with hydrogen bromide in solution in carbon tetrachloride proved that substitution, with liberation of the acid, was the course of the reaction. Similar behaviour was shown by benzophenone-2 : 4 : 6-tribromophenylhydrazone and the bromination products (equation 2) of the dibromo- and tribromo-phenylhydrazones of benzaldehyde.

Meyer (*Annalen*, 1892, 272, 215), describing the preparation of 3 : 4-dibromophenylhydrazine by the addition of one molecule of bromine to one molecule of acetonephenylhydrazone in dry chloroform at low temperature, states that the primary product is the hydrobromide of this hydrazine. It is shown in the experimental part of this paper that the primary product is the hydrobromide of acetone-*p*-bromophenylhydrazone, which decomposes giving *p*-bromophenylhydrazine having the melting point ascribed by Meyer to 3 : 4-dibromophenylhydrazine. We have prepared the latter compound by another method, and have shown that Meyer's reaction is not an exceptional one, but follows the normal course (equation 1).

EXPERIMENTAL.

The general procedure was to add gradually with stirring bromine (1 mol.), dissolved in carbon tetrachloride, to a solution of the phenylhydrazone (1 mol.) in the same solvent, both solutions being at -5° to -10° . In most cases the precipitate formed was tarry and could not be purified and analysed. In a few cases, however, dry powders were obtained, and analysis of these showed that they contained one molecule of bromine added to one molecule of the original phenylhydrazone. All the products were markedly unstable, particularly in the presence of moisture, when hydrobromic acid was evolved and a tarry residue obtained which on purification yielded brominated phenylhydrazones or the hydrobromides of brominated phenylhydrazines or a mixture of the two. It was found that the same decomposition occurred rapidly (acetonephenylhydrazone was an exception) when either the filtered unstable product, or its suspension in the carbon tetrachloride in which bromination had been carried out, was treated with cold alcohol; and in this way the products were obtained clean and in fairly quantitative yield. Titration with baryta of the acid liberated from the coloured precipitates in aqueous-alcoholic solution showed that one-half of the added bromine was eliminated as hydrogen bromide.

The constitution of the substituted phenylhydrazones has been

confirmed in all cases, after analysis, by preparation of the respective compounds from the corresponding phenylhydrazines, the simple tests employed being the appearance, melting point, and the melting point of a mixture, of the phenylhydrazones under comparison. The hydrobromides of the substituted phenylhydrazines, which were in some cases obtained, often gave a bromine content differing somewhat from that required by theory. This was doubtless due to slight traces of other brominated phenylhydrazines which would be very difficult to remove. In all cases the corresponding phenylhydrazones of benzaldehyde or of benzophenone were prepared for confirmation.

It will be noted in the table that in two cases (benzaldehyde-phenylhydrazone and acetylphenylhydrazone) the method of brominating in steps—one molecule of bromine to one molecule of hydrazone or hydrazine—was varied by adding two molecules of bromine to the original compound. The results were the same in both cases.

Acetonephenylhydrazone.—The primary product, a pale yellow powder, was easily the most stable of this type of compound and could be purified by dissolving it in warm alcohol and adding ether, when glassy crystals were formed, melting at 155° (with decomposition) (Found: Br = 52.5. $C_9H_{12}N_2Br_2$ requires Br = 51.9 per cent. Br liberated as HBr in aqueous alcohol = 26.8 per cent.) The compound decomposed on being warmed with water, yielding pale yellow plates of acetone-*p*-bromophenylhydrazone and the *p*-bromophenylhydrazine hydrobromide, the latter being the main product. This reaction furnishes a clean, quantitative method of preparing *p*-bromophenylhydrazine.

In connexion with Meyer's description of this reaction (*loc. cit.*), 3:4-dibromophenylhydrazine was prepared by the following series of reactions, the figures denoting the yields in grams:

The free base crystallised from ligroin in white needles, m. p. 74° (Found: Br = 60.25. $C_6H_6N_2Br_2$ requires Br = 60.09 per cent.).

Benzaldehyde-3:4-dibromophenylhydrazone forms pale yellow needles melting at 127° (Found: Br = 45.31. $C_{13}H_{10}N_2Br_2$ requires Br = 45.20 per cent.).

Benzophenone-3:4-dibromophenylhydrazone crystallises in yellow

needles melting at 157° (Found: Br = 37.08. $C_{19}H_{14}N_2Br_2$ requires Br = 37.21 per cent.).

Benzaldehyde-2 : 4-dibromophenylhydrazone.—Addition of alcohol to the yellow, granular precipitate in carbon tetrachloride caused immediate dissolution. When the solution was evaporated and alcohol added, white needles, m. p. 114° , quickly formed. This compound was also obtained as the main product of the addition of bromine (1 mol.) to benzaldehyde-*p*-bromophenylhydrazone (1 mol.).

Analysis (see table) showed that one atom of bromine had entered the original 2 : 4-dibromophenylhydrazone. Substitution had not occurred in either nucleus, because reduction with warm glacial acetic acid and zinc dust yielded 2 : 4-dibromoaniline, m. p. 179° , and *m*-bromobenzaldehyde-2 : 4-dibromophenylhydrazone (another possible product) is a yellow compound melting indefinitely above 150° . The possibility of intramolecular condensation (indazole formation) having occurred was precluded by the bromine content and by the fact that the yield of the compound was quantitative, calculated for the entry of one atom of bromine into one molecule of the original hydrazone. These data, coupled with the fact that benzophenone-2 : 4-dibromophenylhydrazone gave no bromination product, and that boiling with 20 per cent. hydrochloric acid effected no change, indicate that the compound has the formula $C_6H_5 \cdot CBr \cdot N \cdot NH \cdot C_6H_3Br_2(2 : 4)$.

Benzaldehyde-2 : 4 : 6-tribromophenylhydrazone, m. p. 96° , gave a similar product, m. p. 113° , in quantitative yield. (The melting point of benzaldehyde-2 : 3 : 4 : 6-tetrabromophenylhydrazone is 106° .) The primary product was fairly stable (Found: Br = 72.1; Br as HBr = 73.35. $C_{13}H_8N_2Br_4 \cdot HBr$ requires Br = 67.45; Br as HBr = 13.49 per cent.).

Acetophenonephenylhydrazone.—The products given in the table were obtained in approximately equal quantities. By bromination of the bromophenylhydrazones only very small quantities of not very markedly crystalline compounds were obtained and their investigation was not carried further. The primary products were very tarry and unstable.

Benzophenonephenylhydrazone.—The scarlet precipitate dissolved immediately in cold alcohol, forming a yellow solution from which a bulky precipitate of benzophenone-*p*-bromophenylhydrazone (pale yellow needles) separated in a few minutes.

Benzophenone-p-bromophenylhydrazone.—The red primary product was stable in dry air (Found: Br = 52.0. $C_{19}H_{15}N_2Br_3$ requires Br = 46.9 per cent.).

Benzophenone-2 : 4-dibromo- and -2 : 4 : 6-tribromophenylhydrazone.—No action with bromine.

Acetylphenylhydrazine.—The yellow primary product was stable in dry air (Found: Br = 47.9; Br as HBr = 24.5. $C_8H_{10}ON_2Br_2$ requires Br = 50.19 per cent.). The low bromine content was probably due to the fact that the acetyl compound was brominated in suspension and was not completely attacked.

The yellow compound dissolved readily in alcohol, forming a red solution which gave no precipitate with ether. When boiled, the solution turned yellow, and ether then gave a precipitate of *p*-bromophenylhydrazine hydrobromide in 70 per cent. yield. Boiling evidently caused hydrolysis of the acetyl-*p*-bromophenylhydrazine, formed from the unstable primary product by the hydrogen bromide liberated, for this acetyl compound could be obtained by treating the yellow compound with dilute sodium hydroxide solution.

Acetyl-p-bromophenylhydrazine.—This substance was brominated in suspension in carbon tetrachloride. The acetyl-2:4-dibromophenylhydrazine, obtained by the method employed above, was contaminated with the original acetyl compound.

This investigation was suggested to one of us (J. E. H.) by Professor T. Campbell James, and we desire to make grateful acknowledgment.

UNIVERSITY OF ABERDEEN.

CXCIX.—*The Constitution of the Higher Oxide of Nickel.*

By OWEN RHYS HOWELL.

DURING an investigation (this vol., p. 669) of the action of alkalis and hypochlorites on solutions of nickel sulphate, it was found that the precipitate was very unstable and evolved oxygen even in suspension at the ordinary temperature. The original object of the present investigation was to examine the rate of decomposition of the precipitate. It was found, however, that the precipitate was not homogeneous, and that at the working temperature adopted (boiling point), one part (the peroxide) decomposed very rapidly and the other (the sesquioxide) decomposed only slowly. By taking advantage of this fact, it was possible to determine the composition of the precipitate obtained under various conditions, and this forms the subject of the present communication.

EXPERIMENTAL.

Materials.—Nickel sulphate, free from iron and cobalt, was twice recrystallised from water. Sodium hydroxide was prepared by suspending metallic sodium in a cone of silver gauze over a platinum dish in a moist atmosphere free from carbon dioxide; the concentrated solution thus obtained was diluted with water free from carbon dioxide. Sodium hypochlorite was prepared by bubbling washed chlorine, prepared from potassium permanganate and concentrated hydrochloric acid, into aqueous sodium hydroxide (prepared as above) below 20°, a little free alkali being left to retard decomposition. These

FIG. 1.

two solutions were stored in bottles connected to burettes fitted with soda-lime tubes, so that any required volume could be taken with a minimum of exposure to air. The alkali and the hypochlorite were estimated as already described (this vol., p. 65). As in the previous investigations (this vol., pp. 65, 669), the quantities of alkali and hypochlorite are expressed as equivalents per equivalent of metal; that is, the quantities for complete precipitation and for complete oxidation are taken as unity. The available oxygen in the precipitate, however, is expressed as equivalents of oxygen per *atom* of metal; that is, the sesquioxide stage of oxidation is taken as unity. This method was adopted also in the previous investigations, where, however, it was stated somewhat ambiguously that the available oxygen was expressed as equivalents of oxygen per *equivalent* of metal, the term being used in a different sense. For the reason indicated above, the scale used for the available oxygen is in each case double that for the alkali and hypochlorite.

Apparatus.—The apparatus employed is shown in Fig. 1. A round-bottomed, wide-necked flask, *F*, of about 500 c.c. capacity was fitted with a rubber stopper through which passed (a) a water-cooled condenser, *C*, fitted with a soda-lime tube, *L*, (b) a tube, *T*,

fixed tangentially, through which could be introduced either a glass tube, thermometer, or pipette provided with a piece of rubber tubing which formed a vapour-tight joint, (c) a stirrer made of glass rod working through a seal, *S*. Loss of lubricant at the high working temperature caused seizing when a glass bearing was used through the stopper; a metal bearing was therefore employed with water as the sealing liquid. There was no condensation of vapour from the flask above the bearing.

Method of Experiment.—The air in the flask was freed from carbon dioxide by aspirating air by means of a water-pump through the glass tube *T* from a series of soda-lime towers connected to *L*. Fifty c.c. of an *M*/8-solution of nickel sulphate and 150 c.c. of water were pipetted into the flask. With the stirrer running, 50 c.c. of a solution containing the requisite amount of alkali and hypochlorite were introduced and *T* was then closed by means of a thermometer. The mixture was stirred at room temperature for twenty minutes to ensure completion of the reaction and it was then heated strongly by means of the ring burner *R*. The boiling point was reached in three and a half minutes and the flame was then lowered so as to keep the liquid boiling gently. Zero time was taken when the temperature reached 85°. Rapid stirring was maintained throughout the experiment.

At intervals, 10 c.c. of the suspension were taken by means of a pipette, introduced through *T* and attached to a water-pump. The available oxygen was estimated by running the suspension direct into a mixture of 100 c.c. of water, 5 c.c. of concentrated hydrochloric acid, and 5 c.c. of 5 per cent. potassium iodide solution and titrating the liberated iodine against *N*/40-sodium thiosulphate. Due allowance was made for the expansion of the liquid from room temperature to boiling point.

In those experiments with an excess of alkali the end-point of the titration was far from sharp owing to the formation of chlorate during the initial heating. Due allowance was made for this by titrating both the suspension and a filtered sample and taking the titre of each after standing for fifteen minutes.

Precipitation with One Equivalent of Alkali.

The results obtained by precipitating the nickel with one equivalent of alkali and varying amounts of hypochlorite are given in Table I (where *a* denotes the time of heating in hours) and are plotted in Fig. 2.

All the curves are of the same type and consist essentially of two parts. The initial portion shows a very rapid fall in the oxygen content, which is attributed to the decomposition of the peroxide

FIG. 2.

present in the precipitate. Since in all cases the oxygen content declines to a value less than that corresponding to the sesquioxide, it follows that the peroxide decomposes directly to the hydroxide without the formation of the sesquioxide as an intermediate stage. The second portion is a straight line. These lines are all parallel, and must represent the slow decomposition of a more stable portion of the precipitate. It is assumed that this portion is the sesquioxide. The loss of oxygen is a linear function of the time, so that its decomposition is zero-molecular, probably because the rate is determined by the rate of escape of the oxygen from the surface of the particles.

If these lines are produced back to zero time, the amount of oxygen originally present in the precipitate as sesquioxide is obtained, and thus the fraction of the nickel precipitated as sesquioxide is found. It is assumed that so long as there is any hydroxide remaining, the remainder of the oxygen available from the hypochlorite enters as peroxide. Although in these neutral solutions the existence of this compound may be transitory, it is known that with excess of alkali the whole of the oxygen supplied enters the precipitate quantitatively (this vol., p. 669). The amount of oxygen supplied by the hypochlorite is known and consequently the fraction of the nickel precipitated as peroxide is also determined. The difference represents the fraction of the nickel remaining as unchanged hydroxide.

The fraction of the nickel precipitated as peroxide, sesquioxide, and hydroxide is shown in Table II, and plotted in Fig. 3.

It is evident from the figure that with increasing amounts of hypochlorite there is a sudden break in the curves at one-quarter of an equivalent of hypochlorite. Up to this point, the oxygen enters almost quantitatively as peroxide and thereafter as sesquioxide.

It will be seen from the curve that, at half an equivalent of hypochlorite, *exactly* one-half of the nickel in the precipitate is present as sesquioxide, one-quarter as peroxide, and one-quarter

as hydroxide; at this stage, therefore, equal amounts of oxygen have entered as sesquioxide and peroxide.

With more hypochlorite, the fraction of nickel precipitated as sesquioxide and peroxide continues in the same ratio, but there is finally a brief but rapid increase in the peroxide fraction with a corresponding decrease in that of the sesquioxide.

When the whole of the hydroxide has been oxidised, there is no change in the amounts of sesquioxide and peroxide with increasing amount of hypochlorite. This shows definitely that the

FIG. 3.

Curve A shows the fraction of the nickel precipitated as hydroxide.
 " B " " " " " " sesquioxide.
 " C " " " " " " " peroxide.

sesquioxide is not oxidised to the peroxide. A limit is thus set to the oxygen content of the precipitate. The fraction of the nickel precipitated as sesquioxide with excess of hypochlorite is (approximately) 0.7; consequently the fraction precipitated as peroxide cannot exceed 0.3, and the content of available oxygen in the precipitate is limited to 1.3 equivalents of oxygen per atom of nickel (compare this vol., p. 669). The excess of hypochlorite is decomposed by the catalytic action of the peroxide.

Precipitation with Excess of Alkali.

In this series of experiments the precipitating solution contained a constant amount of hypochlorite (0.587 equivalent) with varying amounts of alkali.

The results obtained are given in Table III and are plotted in Fig. 4.

Fig. 4.

It is evident that, as in the previous series, the curves show a rapid initial loss of oxygen, which is attributed to the decomposition of the peroxide in the precipitate. The curve then becomes a straight line, and this is assumed to represent the decomposition of the sesquioxide. It is seen that the slope of the straight part of the curve increases with increasing concentration of alkali.

This is attributed to a difference in the size or nature of the particles produced in the presence of excess of alkali, the effective surface being greater and the evolution of oxygen consequently more rapid. The curves flatten out (the sooner, the greater the concentration of alkali) and become approximately parallel to that representing the decomposition in absence of alkali. This is attributed to the fact that diffusion of oxygen from the interior is too slow to meet the increased evolution at the surface and the rate of decomposition therefore decreases.

The fraction of the nickel precipitated as sesquioxide and peroxide in each case is readily found in the manner already described. The results are given in Table IV and plotted in Fig. 5, from which

1780 HOWELL: THE CONSTITUTION OF THE HIGHER OXIDE OF NICKEL.

it is evident that there is a continuous decrease in the fraction of the nickel precipitated as sesquioxide, and a corresponding increase in that as peroxide with increasing amount of alkali.

On plotting the logarithm of the fraction of the nickel precipitated as sesquioxide (F_{NiO_3}) against the logarithm of the equivalents

of alkali used (E_{NaOH}), a straight line is obtained. This is shown in Fig. 6A. The equation to the line is

$$\log_{10} F_{NiO_3} = -0.5383 \log_{10} E_{NaOH} - 0.1791,$$

and the agreement between the observed and the calculated values is seen in Table V. The decrease in the sesquioxide fraction with increasing alkali concentration therefore follows the Freundlich isotherm.

TABLE V.

Equivalents of NaOH.	Log. E_{NaOH} .	Log. of sesquioxide fraction.		Diff.
		Obs.	Calc.	
1.0	0.0000	1.8209	1.8209	±
1.1	0.0414	1.7980	1.7986	- 0.0006

2.25	0.3522	1.6304	1.6313	- 0.0009

On plotting the logarithm of the fraction of the nickel precipitated as peroxide (F_{NiO_2}) against the equivalents of alkali used, the curve shown in Fig. 6B is obtained. If, however, the logarithm of the ratio of these two factors be plotted as a function of the alkali, a straight line (Fig. 6C) will be obtained. The equation to the line is

$$\text{Log}_{10} \frac{F_{NiO_2}}{E_{NaOH}} = -0.1575 E_{NaOH} - 0.4325,$$

and the agreement between the observed and the calculated values is seen in Table VI.

TABLE VI.

Equivalents of NaOH.	Log. E_{NaOH} .	Log. of peroxide fraction.	Log. $\frac{F_{NiO_2}}{E_{NaOH}}$		Diff.
			Obs.	Calc.	
1.0	0.0000	1.4082	1.4082	1.4100	- 0.0018

2.25	0.3522	1.5723	1.2201	1.2131	+ 0.0070

It therefore appears that the function of the alkali is to stabilise the peroxide (compare this vol., p. 669). The fraction of the nickel precipitated as peroxide increases with increasing alkali in proportion to the amount adsorbed.

Discussion of Results.

It has been shown that nickel peroxide decomposes directly to the hydroxide, the sesquioxide not being produced as an intermediate stage. This is brought out strikingly in the first experiment detailed in Table I, where the black precipitate, containing peroxide and only a little sesquioxide, was completely decomposed after boiling for three hours, leaving a pure apple-green suspension of the hydroxide.

It has also been shown that the hydroxide is oxidised simultaneously to the sesquioxide and to the peroxide and that the sesquioxide is *not* an intermediate stage in the formation of the peroxide.

These facts offer a ready explanation for the decay in activity of an oxygen-carrying catalyst whose efficacy depends on the formation and reduction of a higher oxide. The higher oxide in yielding its available oxygen decomposes directly to a lower oxide, which is then reoxidised, not wholly to the higher oxide, but partly to an intermediate oxide which is ineffective in the catalysis. Since this intermediate oxide can neither be oxidised to the higher oxide, nor readily reduced to the lower oxide, the activity of the catalyst

falls. Thus during an investigation of the decomposition of sodium hypochlorite by cobalt peroxide (*Proc. Roy. Soc.*, 1923, [A], 103, in the press) it was found that the activity fell progressively with continued use. It was shown that the mechanism of the reaction consisted in the alternate reduction and oxidation of the catalyst thus:

It is now evident that the decay in activity can be accounted for by the fact that the oxidation of the monoxide does not regenerate the peroxide quantitatively, since part is oxidised to the sesquioxide, which is inactive in causing decomposition.

When a solution of nickel is precipitated with one equivalent of alkali and increasing amounts of hypochlorite, the oxygen supplied by the latter first enters almost quantitatively as peroxide and then as sesquioxide. The change in the distribution occurs at one-quarter of an equivalent of hypochlorite. This may be explained by the formation of a complex the subsequent oxidation of which proceeds in a different manner:

The fact is also explained that with half an equivalent of hypochlorite, exactly half the nickel is precipitated as sesquioxide, a quarter as peroxide, and a quarter as hydroxide. Further, that complete oxidation yields a mixture of the sesquioxide and the peroxide, and that with an excess of hypochlorite there is no increase in the amount of peroxide produced.

With increasing amount of alkali for precipitation, the fraction of nickel precipitated as peroxide is increased in proportion to the amount of alkali adsorbed. It has been found (*Proc. Roy. Soc. loc. cit.*) that the rate of decomposition of sodium hypochlorite by cobalt peroxide is retarded by alkali in proportion to the amount of alkali adsorbed, and this was attributed to adsorption of the alkali on the positive and the negative oxygen linkings of the peroxide to yield an inactive molecule. It is suggested that the stabilising effect of alkali on nickel peroxide may be attributed to a similar combination.

Summary.

(1) Nickel peroxide decomposes directly to the hydroxide; the sesquioxide is not produced as an intermediate stage.

(2) By following the rate of decomposition of the precipitate obtained by the action of alkali and hypochlorite on nickel sulphate solution, the fraction of the nickel precipitated as the sesquioxide

and as the peroxide under different conditions has been determined.

(3) The hydroxide is oxidised to the sesquioxide and to the peroxide simultaneously. In general, therefore, the precipitate consists of hydroxide, sesquioxide, and peroxide, but with sufficient hypochlorite the whole of the hydroxide may be oxidised to the other two oxides.

(4) The sesquioxide is not oxidised to the peroxide. A limit is therefore set to the oxygen content of the precipitate.

(5) With just sufficient alkali for precipitation, the oxygen supplied by the hypochlorite first enters almost wholly as peroxide and then as sesquioxide. This is attributed to the formation and subsequent oxidation of a complex.

(6) With increasing amount of alkali for precipitation, the fraction of nickel precipitated as peroxide increases and is proportional to the adsorption of the alkali. This is attributed to the stabilising effect of the alkali by adsorption.

The author would express his thanks to Prof. T. M. Lowry for giving him every facility for carrying out this work. He is also indebted to the Royal Commissioners for the Exhibition of 1851 for a scholarship grant.

CC.—*The Isomerism of the Oximes. Part XII.* *Hydrochlorides.*

By OSCAR LISLE BRADY and FREDERICK PERCY DUNN.

IN a previous communication (T., 1916, 109, 650), we gave some account of the hydrochlorides of the aromatic aldioximes. In view of the importance of these as intermediate compounds in isomeric change, but little attention has been paid to them and in 1914 a detailed study was started. Circumstances, however, interfered with the work and but a brief account of what were little more than preliminary experiments was published. Further investigations have now been made, the results of which have caused us to modify some of our previously expressed views (*loc. cit.*).

Luxmoore (T., 1896, 69, 183) pointed out that when a solution of benzantialdoxime in ether at 0° was treated with hydrogen chloride, a hydrochloride was precipitated (m. p. 105°) which on decomposition with dilute aqueous ammonia at 0° regenerated the original *anti*-oxime. When, however, no cooling was employed,

the ethereal solution became warm and a hydrochloride was precipitated which melted, when rapidly heated, at 66—67° and on decomposition with aqueous ammonia gave benzsynaldoxime. Luxmoore also states that the second hydrochloride is obtained by the action of hydrogen chloride on benzsynaldoxime in ether or by crystallising the *anti*-oxime-generating hydrochloride from chloroform. We (*loc. cit.*), however, found that, when benzsynaldoxime was treated with liquid hydrogen chloride, a hydrochloride melting at 103° was obtained which on decomposition with sodium carbonate solution gave benzsynaldoxime. It was thought, therefore, that there were three distinct hydrochlorides of benzaldoxime. At the same time, some evidence was obtained of an *anti*-oxime-generating hydrochloride from *p*-nitrobenzaldoxime.

Hantzsch (*Ber.*, 1893, 26, 930) claimed to have obtained two hydrochlorides of *p*-methoxybenzaldoxime (anisaldoxime) and of *p*-isopropylbenzaldoxime (cuminaldoxime), but he gives scanty experimental details and his results as regards *p*-methoxybenzaldoxime were contradicted by Carveth (*J. Physical Chem.*, 1899, 3, 437). The latter states that he obtained only the *syn*-oxime-generating hydrochloride when hydrogen chloride was passed into a solution of the oxime in ether, benzene, or alcohol at temperatures ranging from -20° to 60°. The fact that benzaldoxime was the only compound of this class in which there was uncontested evidence that more than one hydrochloride could be obtained was notable and further investigation seemed necessary.

Hereafter, a hydrochloride which gives *anti*-oxime on decomposition will be termed an α -hydrochloride and one which gives a *syn*-oxime a β -hydrochloride. As the constitution of the hydrochlorides is uncertain, the use of the prefixes *anti* and *syn* with reference to them is undesirable.

In connexion with other work, 3:4-methylenedioxybenzsynaldoxime was required and several attempts were made to prepare this compound (which had previously been described) by the usual methods, but invariably without success, the product of the decomposition of the hydrochloride being the unchanged *anti*-oxime. It seemed that, in this case, an unusually stable α -hydrochloride had been obtained. Since, in the case of the hydrochlorides of benzaldoxime, rise in temperature favoured the production of the β -hydrochloride, the effect of heating the hydrochloride and of passing the hydrogen chloride into a hot solution of the *anti*-oxime was investigated, when it was found that in these circumstances a β -hydrochloride was obtained.

A number of other oximes were investigated and it was found, in confirmation of the work of Hantzsch, that *p*-methoxybenz-

aldoxime also gave an α -hydrochloride when an ethereal solution of the *anti*-oxime was treated with hydrogen chloride at -14° and a β -hydrochloride when a hot chloroform solution was similarly treated. The action of dry hydrogen chloride on solutions of *p*-methoxy- and 3:4-methylenedioxy-benzsynaldoximes in dry ether was found to give a hydrochloride of the same melting point and general properties as that from the *anti*-oximes in hot solvents. Moreover, it was found in these cases and others to be mentioned later that the α - and β -hydrochlorides of any one oxime melted and decomposed at approximately the same temperature and did not depress each other's melting point on mixing. No evidence was obtained of the existence of a third hydrochloride.

Benzaldoxime, in giving three hydrochlorides, appeared to be abnormal and worth further investigation, especially as it was found that the hydrochloride obtained by passing dry hydrogen chloride into an ethereal solution of benzantialdoxime had a very irregular melting point, and frequently did not melt completely until a much higher temperature was reached than that given as the melting point by Luxmoore, namely, $66-67^{\circ}$. It was remarkable that Petraczek (*Ber.*, 1883, **16**, 826), who first described the hydrochloride of benzaldoxime obtained under these conditions, gave an analysis but no melting or decomposition point, as also did Beckmann (*Ber.*, 1889, **22**, 432), whilst Luxmoore gave a melting point but no analysis.

A method of preparation of benzsynaldoxime is described by Dunstan and Thole (*P.*, 1911, **27**, 233) in which the *anti*-oxime is ground with concentrated hydrochloric acid, and the mixture saturated with hydrogen chloride; after a time, a clear solution will be obtained which on pouring into a large excess of sodium carbonate solution gives a precipitate of benzsynaldoxime. It has now been found that if the clear solution be allowed to stand, a hydrochloride will crystallise in large, transparent crystals which sinter and wets the tube at 57° , melts at a somewhat higher temperature, and on decomposition with sodium carbonate solution gives the *syn*-oxime; the sintering temperature, 57° , is a definite one, several preparations behaving in the same way. The method of preparation suggested that this compound was a hydrate, and analysis showed that it contained one molecule of water. When the hydrochloride was left over concentrated sulphuric acid in an atmosphere of hydrogen chloride, the melting point rose to over 100° and analysis indicated that the compound was then anhydrous; it gave benzsynaldoxime on decomposition and appeared to be identical with the β -hydrochloride (m. p. 103°) which we had previously obtained by the action of liquid hydrogen

chloride on the *syn*-oxime. The same β -hydrochloride has now been obtained by the action of dry hydrogen chloride on a dry ethereal solution of benzsynaldoxime at the ordinary temperature. A hydrated compound of identical properties was precipitated by treating benzantialdoxime in ether, saturated with water, with hydrogen chloride at the ordinary temperature and by the action of concentrated hydrochloric acid on benzsynaldoxime. In the latter case, however, there was some possibility of preliminary conversion into the *anti*-isomeride. Moreover, when the α -hydrochloride of benzaldoxime was crystallised from chloroform not specially dried, as described by Luxmoore, a similar hydrated compound was obtained. The hydrate seemed to be formed very readily, and the water was possibly obtained by absorption from the atmosphere during the saturation of the ethereal solution with hydrogen chloride, for, if special precautions were taken to prevent the admission of water, a solution of benzantialdoxime in dry ether, when saturated with hydrogen chloride without cooling, gave a β -hydrochloride of the same melting point as that obtained from benzsynaldoxime. The high-melting, anhydrous β -hydrochloride was also obtained by crystallising the α -hydrochloride from dry chloroform with careful exclusion of moisture. There seems no reason to doubt, therefore, that Luxmoore's compound was a hydrate and that only two hydrochlorides of benzaldoxime exist.*

A number of other hydrochlorides have been studied and call for individual mention. The α -hydrochloride of *m*-nitrobenzaldoxime was found to be less stable than those previously described. In boiling benzene, an unusually pure β -hydrochloride was obtained; in ether at room temperature, the hydrochloride precipitated was a mixture, but consisted mainly of the β -form; in ether at -14° , more of the α -hydrochloride was produced, but it was only at the temperature of liquid hydrogen chloride that a pure α -hydrochloride was obtained. The case of *p*-nitrobenzaldoxime has already been described (Brady and Dunn, T., 1916, 109, 680) and even at the temperature of liquid hydrogen chloride the hydrochloride formed was a mixture.

In a previous communication (T., 1914, 105, 2872), the authors showed that *p*-dimethylaminobenzantialdoxime formed a monohydrochloride only, and it was suggested that the hydrogen chloride in this compound was attached to the dimethylamino-group;

* It is a strange coincidence that this is the third case in which a supposed isomeric derivative of benzaldoxime has been found to be a hydrate. Beck (*Z. physikal. Chem.*, 1904, 48, 674) showed that Beckmann and Lommel's (*Dissertation*, Leipzig, 1902) third isomeric benzaldoxime was a hydrated form of the *anti*-isomeride, and Scheiber (*Annalen*, 1909, 356, 215) showed that Luxmoore's (*loc. cit.*) second *N*-methyl ether was also a hydrate.

evidence has now been obtained of the formation of a dihydrochloride at low temperatures, but the compound is not crystalline and has but a transient existence.

The unusual stability of the α -hydrochloride of 3:4-methylenedioxybenzaldoxime suggested that previous failures to bring about conversion of a number of substituted benzaldoximes into their *syn*-isomerides (Brady and Dunn, T., 1916, 109, 667) might have been due to the same cause. We (T., 1914, 105, 2409) had been unable to obtain a *syn*-isomeride of 3:4-dimethoxybenzaldoxime (veratraldoxime) by the usual methods, but it has now been found that, by precipitating the hydrochloride from a boiling benzene solution of the *anti*-oxime, a new hydrochloride is obtained which yields the *syn*-oxime on decomposition. On the other hand, similar treatment of *o*-methoxy-, *m*-methoxy-, *o*-hydroxy-, and 3:5-dibromo-*p*-hydroxy-benzantialdoximes, which previously could not be made to give *syn*-isomerides, still failed to bring about conversion, whilst no hydrochloride could be obtained from 2:4-dinitrobenzantialdoxime even at the temperature of boiling xylene (compare Brady and Dunn, T., 1914, 105, 821; 1916, 109, 667; Wentworth and Brady, T., 1920, 117, 1040).

Swietoslawski and Papow (*Chem. Pol.*, 1916, 16, 1) have investigated the hydrochlorides of some aromatic aldoximes, but were apparently unaware of the work of Luxmoore and were unable to obtain pure α -hydrochlorides; moreover, they state that the pure β -hydrochlorides could not be obtained from the *anti*-oximes, but only from the *syn*-oximes (compare Dorabialska, *Roczniki Chemji*, 1921, 1, 424).^{*} These workers investigated benzaldoxime and *m*-nitrobenzaldoxime, but our conclusions are not entirely in agreement with theirs even as regards these two cases. The preparation of the pure α -hydrochloride is not easy, but we are of opinion that a fairly pure compound can be obtained either from benzantialdoxime in ether at -14° , provided the hydrogen chloride is passed in for only a short time and the precipitated hydrochloride immediately filtered off, or better by the action of liquid hydrogen chloride on the *anti*-oxime: the latter method is the only one effective in the case of *m*-nitrobenzantialdoxime. Pure β -hydrochlorides are probably precipitated from solutions of these oximes in warm solvents, in the case of benzaldoxime moisture being carefully excluded. It is true that these hydrochlorides on decomposition do not give a pure *syn*-oxime, but neither do the hydrochlorides obtained from the *syn*-oximes themselves, and the authors believe that a certain amount of inversion takes place during manipulation.

^{*} We are indebted to Mr. R. Truskowski, B.Sc., for translations of these papers.

To take the case of the β -hydrochloride obtained from *m*-nitrobenzantaldoxime in boiling benzene, although on decomposition a pure *syn*-oxime is not obtained, yet when the hydrochloride is dissolved in sodium hydroxide solution and treated with methyl sulphate no *O*-methyl ether of *m*-nitrobenzantaldoxime is formed, but only the *N*-ether and a smaller quantity of the *O*-methyl ether of *m*-nitrobenzsynaldoxime, as is the case when methylating the pure *syn*-oxime. The preparation of a pure α -hydrochloride of 3:4-methylenedioxybenzaldoxime is easier than in other cases and there is no doubt that the hydrochloride obtained by saturating a hot chloroform solution of *p*-methoxybenzantaldoxime with hydrogen chloride is a pure β -compound, as on decomposition it gives a crude *syn*-oxime melting at 131°, whilst the purest *syn*-oxime obtainable after recrystallisation melts at 131.5°. The purity of the *syn*-oxime obtained by decomposition of the hydrochloride depends on the method and speed of manipulation and on the relative stability of the *syn*-isomeride. *p*-Methoxybenzsynaldoxime is comparatively stable, and a sample preserved in a stoppered bottle for more than ten years had not appreciably altered; benzsynaldoxime, 3:4-methylenedioxy-, *o*-, *m*-, and *p*-nitrobenzsynaldoximes, on the other hand, change more or less rapidly (compare Brady and Dunn, T., 1913, 103, 1622).

As regards experimental difficulties, it may be pointed out that the hydrochloride is apt to be partly decomposed, during manipulation, by atmospheric moisture with the production of hydrogen chloride; in these circumstances the acid tends to convert the *syn*-oxime liberated at the same time into the *anti*-isomeride. This is particularly noticeable in the case of the β -hydrochloride of benzaldoxime which, as soon as it is filtered from the ethereal suspension saturated with hydrogen chloride, very rapidly acquires the characteristic odour of benzantaldoxime. When the hydrochloride is decomposed by sodium carbonate solution or by ice-cold, dilute ammonia in accordance with earlier practice, the insoluble oxime forms a coating round the grains of hydrochloride and it is practically impossible to obtain the necessary rapid and complete decomposition. For this reason we have adopted the method of treating the hydrochloride with excess of sodium hydroxide solution, which decomposes it, whilst the oxime formed dissolves as the sodium salt and is precipitated by the addition of a saturated solution of ammonium chloride. There is, moreover, some difficulty in completely drying the oxime before determining its melting point, especially as it is usually precipitated in a very fine form which holds water tenaciously; heating or keeping in a desiccator for any length of time is likely to bring about isomeric change,

and the only method available to dry the compound rapidly consists in pressing it repeatedly on several pieces of specially effective porous tile. On several occasions when unusually low melting points have been obtained, we have found that further treatment in this way caused a rise of sometimes as much as 15°; 3:4-methylene-dioxybenzsynaldoxime is perhaps the worst offender in this way.

In a previous paper (I., 1916, 109, 650) we tried to draw a clear picture of the mechanism of oxime change, assuming that the oximes existed in the tautomeric forms

It was suggested tentatively that addition of hydrogen chloride to the tautomeric form (II) of the *anti*-oxime could take place in two ways, either at the oxygen-nitrogen double bond, giving the α -hydrochloride (V), or at the oxygen-nitrogen and carbon-nitrogen double bonds simultaneously, giving the *syn*-oxime-generating hydrochloride described by Luxmoore (VI). The removal of hydrogen chloride from the latter involved the removal of a hydrogen atom different from that originally attached to chlorine and the re-formation of the double bond in a different place, with consequent inversion of configuration. The β -hydrochloride we obtained from the *syn*-oxime was regarded as of the ammonium type (VII).

Unfortunately, our previous paper was written at a time when experimental work was interrupted, and Luxmoore's statements were accepted without complete verification. Since our present work has shown that the low-melting hydrochloride is a hydrate, some revision of our views is necessary, as it appears that there are but two hydrochlorides obtainable from each oxime, one of which on decomposition gives the *anti*- and the other the *syn*-oxime. This difficulty can be overcome in one of two ways, either by the assumption that the intermediate compound (VI) is but transiently formed and changes to the ammonium type hydrochloride (VII), or by assigning to the β -hydrochloride the formula (VI). Neither of these, however, is entirely free from objection. In both cases it is impossible to assume, if a compound of type (VI) be formed, that the addition and the elimination of hydrogen chloride take

place in the same way in the case of both *anti*- and *syn*-oximes, as, in that event, passage through the hydrochloride should result in inversion in both cases:

This fact was overlooked in our former paper and the possibility was not tested, but it has now been found that the hydrochloride obtained from the *syn*-oxime cannot be converted by solution, etc. into an *anti*-oxime-generating hydrochloride and on decomposition invariably regenerates the *syn*-oxime. The first hypothesis being adopted, the *syn*-oxime reacts in the hydroxy-form (III), giving an ammonium type of hydrochloride (VII) which is stable to heat, whilst on the second hypothesis the oxime still reacts in the hydroxy-form and the addition of hydrogen chloride takes place at the carbon-nitrogen double bond, giving a hydrochloride of type (VI); in this case, since the same hydrogen is eliminated on the removal of hydrogen chloride, no inversion will occur. The choice between the two possible mechanisms may depend on the analogy of the action of methyl iodide; the second demands the existence of two *N*-ethers and the first provides a possible explanation that but one *N*-ether exists of the type $\text{R}\cdot\text{CH}\cdot\text{NMe}\cdot\text{O}$ (compare Brady, T., 1914, 105, 2104). Although all attempts have so far failed to obtain two *N*-ethers from the aldoximes (compare Scheiber, *Annalen*, 1909, 356, 215), the isolation of two *N*-methyl ethers of phenyl *p*-tolyl ketoxime by Semper and Lichtenstadt (*Ber.*, 1918, 51, 928) favours the second of the hypotheses.

Some objection has been made to the suggestion that the chlorine atom is added to carbon in preference to nitrogen, and Atack (T., 1921, 119, 1175) has argued that a compound of the type (VI) would not readily lose hydrogen chloride. It may be pointed out that hydrogen chloride acts upon phenylcarbimide, giving phenylcarbamyl chloride (Hentschel, *Ber.*, 1885, 18, 1178; Lengfeld and Stiegler, *Amer. Chem. J.*, 1894, 16, 70):

This compound loses hydrogen chloride at 90–100°, and we have found that it is readily decomposed by water and by sodium carbonate solution, regenerating phenylcarbimide. Moreover, benz-

hydroxamyl chloride is decomposed by sodium carbonate, giving the nitrile oxide (Werner and Buss, *Ber.*, 1894, 27, 2193) :

Recent investigations in this field have convinced us that our proviso at the end of our paper in 1916 was very necessary, and that much more experimental work is required, as the behaviour of the isomeric oximes is not nearly so simple as is generally supposed. Fortunately, we are now able to continue this work and we would have preferred to indulge in no further speculations at the moment, but we felt it was necessary, in as brief a way as possible, to call attention to some of the difficulties involved in our former theories.

Finally, one isolated observation calls for mention. Owing to the scarcity of *m*-methoxybenzaloxime a specimen of the hydrochloride of this oxime had been put aside in a stoppered bottle some nine years ago with the idea of ultimately recovering the oxime. When this oxime was required for the present work, this old specimen was examined and it was found that about half of it had been converted into *m*-methoxybenzamide. No evidence of a similar conversion could, however, be obtained in the case of the hydrochlorides of benzaloxime and *o*-nitrobenzaloxime in three months. This seems to be the first occasion on which the amide has been obtained directly from the oxime, for, although Minunni (*Gazzetta*, 1892, 22, ii, 174) obtained benzonitrile and benzamide by the action of hydrogen chloride on an ethereal solution of acetylbenzantialdoxime, Luxmoore (*loc. cit.*) has shown that the amide is formed by the action of hydrogen chloride on benzonitrile in the presence of acetic acid.

EXPERIMENTAL.

Introduction.—Some preliminary words are necessary in connexion with the technique adopted in this work. In dealing with the hydrochlorides and oximes, rapidity of work is essential in order to avoid, as much as possible, decomposition or isomeric change, and it is practically impossible for one person to carry out all the operations with sufficient speed. For this reason, in most of the experiments, we have worked together with rapidity, and most of the operations, for example the determinations of melting points, decomposition of the hydrochlorides, and weighing and decomposition of the hydrochlorides for analysis, were carried out within a few minutes of the preparation. Small quantities were generally used and the products, after filtration, freed from solvent or water

by pressing repeatedly on specially absorbent tile. As the melting points of the oximes, etc., were largely used as a means of determining which isomeride was formed, they are recorded more carefully than usual; the sintering point is the temperature at which the first sign of softening or shrinking occurs and the melting point that at which a definite meniscus appears in the capillary tube; the highest melting points obtained for the isomerides are given at the head of each section for comparison. The melting and decomposition points of the hydrochlorides in some cases vary over a range of some five degrees and depend on the rate of heating; the tubes were as a rule placed in the bath at room temperature and heated fairly rapidly at first and then more slowly as the melting point was approached. Mixed melting points with pure specimens of the oximes were taken from time to time in case a new isomeride was obtained, but with negative results. The hydrochlorides were, as a rule, decomposed by stirring them rapidly into an excess of cold 2*N*-sodium hydroxide; in some cases, when the last traces did not at once dissolve, the solution was filtered through glass-wool to avoid keeping the oxime in solution too long with the risk of isomeric change; the oxime was precipitated as soon as possible from the solution of the sodium salt by the addition of an equal volume of a cold saturated solution of ammonium chloride. This will hereafter be referred to as the standard method.

Action of Hydrogen Chloride on the Benzaldoximes (Benzantialdoxime, m. p. 35°. Benzsynaldoxime, m. p. 132°).—Pure recrystallised benzantialdoxime was dissolved in dry ether in a tightly corked vessel. Through the cork passed a tube with a wide adapter dipping under the surface of the liquid and an exit tube packed with dry calcium chloride to prevent condensation of atmospheric moisture during the reaction. The solution was cooled in a freezing mixture of ice and salt, and a rapid stream of hydrogen chloride, dried by passing over calcium chloride and then through concentrated sulphuric acid, passed in. Precipitation occurred almost at once and after one minute the precipitated α -hydrochloride was rapidly filtered off and pressed on filter-paper. The α -hydrochloride so obtained sintered at 103°, melting and decomposing at 105°; on decomposition with sodium carbonate solution or by the standard method, it gave benzantialdoxime as an oil (Found: Cl = 22.2. Calc. from anhydrous hydrochloride, Cl = 22.5 per cent.) (compare Luxmoore, *loc. cit.*).

A portion of the hydrochloride was transferred as soon as made to dry chloroform in a closed vessel with a calcium chloride guard tube, and another portion to ordinary chloroform in an open vessel. The chloroform was in both cases heated to boiling on the water-

bath for thirty seconds, when solution occurred. The solutions were rapidly cooled in ice and after standing for ten minutes the hydrochloride had crystallised. The β -hydrochloride from the dry chloroform sintered at 87° , melting and decomposing at 101° , and gave by the standard method a crude oxime sintering at 112° and melting at 115° . The hydrochloride from the undried chloroform sintered at 49° , wet the tube at 52° , and melted at 55° (Found: Cl = 19.8. Calc. for hydrate, Cl = 20.2 per cent.). On decomposing the hydrochloride by the standard method, an oxime was obtained sintering at 118° and melting at 122° .

Benzantialdoxime in dry ether in the special vessel as before was saturated at -10° with dry hydrogen chloride for an hour. The precipitated β -hydrochloride sintered at 94° , melted and decomposed at 100° , and gave by the standard method a crude *syn*-oxime sintering at 95° and melting at 102° . Benzantialdoxime in dry ether in the special vessel was saturated with dry hydrogen chloride without cooling. The solution became warm and a precipitate of β -hydrochloride rapidly formed; this, after separation, sintered at 97° , melted and decomposed at 103° , and gave by the standard method an oxime sintering at 101° and melting at 107° . A solution of 5 grams of benzantialdoxime in 50 c.c. of dry boiling chloroform was saturated with dry hydrogen chloride. No precipitate appeared, but on cooling and scratching, the β -hydrochloride separated in beautiful, shining leaflets; these sintered at 92° , melted and decomposed at 102° , and gave by the standard method an oxime sintering at 106° and melting at 111° .

Benzsynaldoxime was dissolved in dry ether and the solution treated at room temperature with dry hydrogen chloride, when there was an immediate precipitation of the β -hydrochloride; this sintered at 104° , melted and decomposed at 108° , and gave by the standard method a *syn*-oxime sintering at 114° and melting at 116° . The β -hydrochloride was dissolved in hot, dry chloroform, and, on cooling and scratching, white, plate-like crystals separated sintering at 102° and melting and decomposing at 104° ; these on decomposition by the standard method regenerated benzsynaldoxime of the usual degree of purity.

Some difficulty was experienced in deciding if a mixture of the two hydrochlorides of benzaldoxime melted at a lower temperature than the individual compounds. This was due to the instability of the hydrochlorides and the difficulty in preparing both compounds simultaneously. This was overcome by using the liquid hydrogen chloride method first described by us (T., 1916, 109, 679). The α -hydrochloride obtained melted and decomposed at 103° , and the β -hydrochloride sintered at 95° and melted and decomposed at

103°. The mixture of the two sintered at 93° and melted at 100°. It seems that there is no depression, the small lowering being probably due to the fact that, in making the mixture, the hydrochlorides were exposed to atmospheric moisture for a slightly longer time.

Both α - and β -hydrochlorides are very unstable in moist air and very rapidly acquire the odour of benzantialdoxime. For this reason, considerable dispatch is necessary when working with these compounds, as their melting points rapidly fall and the composition of the oxime which they give on decomposition alters. When the α -hydrochloride is examined under the microscope, the change from a crystalline material to oily drops can be seen to take place rapidly. In the case of the β -hydrochloride, the plates of the hydrochloride develop needle-like excrescences which in turn change to an oil; it seems, therefore, that moisture decomposes this compound with the formation of benzsynaldoxime (which crystallises in needles) and that this is then converted into benzantialdoxime in the usual way by the hydrochloric acid formed at the same time.

Five grams of finely powdered benzantialdoxime were stirred in a mortar with 15 c.c. of concentrated hydrochloric acid, when the oxime was rapidly converted into the hydrochloride, which remained as a white, crystalline suspension in the excess of acid. A small quantity of this solid was removed and found to soften at 57° and melt completely at 60°. The rest of the suspension was saturated with hydrogen chloride, when heat was liberated and the hydrochloride dissolved giving a clear solution (compare Dunstan and Thole, *loc. cit.*). This was cooled rapidly and left over-night, when large, transparent crystals separated, sintering and wetting the tube at 57°, and melting completely at 67°. The crude oxime obtained by the standard method sintered at 108° and melted at 113°. Two similar experiments gave large crystals of the hydrochloride; in each case partial melting occurred sharply at 57° and complete melting at 71–72° and 72–73°, respectively, and decomposition by the standard method gave oximes sintering at 110° and melting at 120° in one case and at 120° and 125° in the other. The large crystals of the hydrochloride were more stable than the α - and β -hydrochlorides and only slowly decomposed on exposure to moist air, but they could not be dried in a vacuum owing to loss of hydrogen chloride. Two samples were analysed. In one case, a portion of the crystals was drained on filter-paper and then rapidly crushed on a porous tile and pressed on fresh tile repeatedly until apparently free from moisture. The sample was then rapidly weighed, decomposed with alcoholic potassium hydroxide, and the halogen determined. In the second case, after drying as before, a quantity was added to a tared amount of alcoholic

potassium hydroxide in a closed weighing bottle, and the weight of the sample ascertained by the increase in weight of the solution, loss of hydrogen chloride or absorption of moisture during weighing being thus avoided [Found: Cl = (1) 20.1, (2) 20.1. $C_7H_8ONCl.H_2O$ requires Cl = 20.2 per cent.]. The anhydrous compound contains 22.5 per cent. of chlorine. In the second determination, 25 per cent. more material was used than in the first and it seems unlikely that exactly the same amount of entangled water would be present in two samples separately dried; moreover, the same method of drying applied to the hydrochloride of anisaldoxime gave satisfactory results (see below).

A quantity of the above compound was left for a week in an atmosphere of hydrogen chloride over concentrated sulphuric acid. At the end of that time the crystals had retained their shape, but broke up with great ease on slight pressure, although the original crystals had been very hard to crush. They sintered at 93° , melted and decomposed at 104 – 105° , and gave, by the standard method, an oxime sintering at 118° and melting at 120° (Found: Cl = 22.5. Calc. for the anhydrous hydrochloride, Cl = 22.5 per cent.).

Five grams of benzantialdoxime were dissolved in 75 c.c. of ether saturated with water, obtained by shaking ether with an equal volume of distilled water and separating. The solution was saturated with hydrogen chloride, and the precipitate separated and dried by pressing on a pad of filter-paper. The hydrochloride wet the tube at 57° , melted completely at 72° , and gave, by the standard method, an oxime which sintered at 109° and melted at 120° (Found: Cl = 20.8. Calc. for hydrate, Cl = 20.1 per cent.). The hydrochloride was left in an atmosphere of hydrogen chloride over concentrated sulphuric acid for twelve days. At the end of that time it sintered at 104° and melted and decomposed at 108° (Found: Cl = 22.8. Calc., Cl = 22.5 per cent.).

A solution of 2 grams of benzantialdoxime in 40 c.c. of ether was saturated with hydrogen chloride without cooling or without any special precautions to avoid the introduction of moisture being adopted. A small portion of the precipitate was removed and found to collapse at 62° , wet the tube at 75° , and melt and decompose at 80° . The rest of the solution containing the precipitate was kept in a stoppered bottle. After forty-eight hours, a portion of the hydrochloride sintered at 82° , collapsed at 92° , and melted and decomposed at 100° ; it gave, by the standard method, an oxime sintering at 97° and melting at 100° . After ninety-four hours, the hydrochloride sintered at 98° and melted and decomposed at 103° , whilst the oxime therefrom sintered at 110° and melted at 113° . After one week, the hydrochloride sintered at 104° and melted and

decomposed at 108°, whilst the oxime sintered at 100° and melted at 115°.

A portion of the hydrated hydrochloride obtained in aqueous solution was powdered, suspended in dry ether, and the suspension saturated with hydrogen chloride at room temperature. The solid was then found to sinter at 88° and melt and decompose at 104–105°. There seems no doubt that the hydrate in the presence of ether and a large excess of hydrogen chloride slowly loses its water.

Action of Hydrogen Chloride on p-Methoxybenzaldoximes (*p*-Methoxybenzantialdoxime, m. p. 64°. *p*-Methoxybenzsynaldoxime, m. p. 131.5°).—Pure *p*-methoxybenzantialdoxime was dissolved in dry ether, the solution cooled to –14° and saturated with dry hydrogen chloride, the temperature being kept below –10°. The α -hydrochloride was precipitated slowly and at first in a somewhat pasty condition, but it soon became crystalline. After separation, it melted and decomposed at 134° and, on treatment with sodium carbonate solution, or by the standard method, gave *p*-methoxybenzantialdoxime, sintering at 57° and melting at 63°, and at 64° when mixed with the original *anti*-oxime. The α -hydrochloride was boiled with chloroform until it dissolved, and on cooling and scratching, the β -hydrochloride separated which gave, by the standard method, an oxime melting at 122°. The solid α -hydrochloride was heated on the water-bath for thirty minutes, when it was converted into the β -compound, which gave *p*-methoxybenzsynaldoxime. *p*-Methoxybenzantialdoxime was dissolved in dry chloroform, the solution warmed on the water-bath, saturated with dry hydrogen chloride, again warmed, and more hydrogen chloride passed in. The precipitated β -hydrochloride melted and decomposed at 134° and, by the standard method, gave a crude oxime melting at 131°. Finely powdered *p*-methoxybenzantialdoxime was added to liquid hydrogen chloride, when it was rapidly converted into the hydrochloride, which did not dissolve in the excess of liquid. When the excess of hydrogen chloride had evaporated, the solid α -hydrochloride left melted and decomposed at 132° and, on decomposition in the standard way, gave *p*-methoxybenzantialdoxime.

Five grams of finely powdered *p*-methoxybenzantialdoxime were ground in a mortar with 15 c.c. of concentrated hydrochloric acid; the oxime dissolved and after a few seconds a white, crystalline precipitate of β -hydrochloride appeared. A portion of this compound was found to sinter at 110° and to melt and decompose at 122°; by the standard method, it gave an oxime sintering at 119° and melting at 123°. The rest of the suspension of hydrochloride was diluted with another 15 c.c. of concentrated hydrochloric acid

and saturated with hydrogen chloride during forty-five minutes, when most of the solid passed into solution, the small amount undissolved being removed by filtration through glass wool. The solution, which had acquired a purple tint, on leaving over-night deposited crystals of β -hydrochloride, melting and decomposing at 136° , and giving by the standard method an oxime sintering at 120° and melting at 128° . The hydrochloride was dried and analysed in a similar way to the benzaldoxime derivative prepared in a like manner (Found: Cl = 18.8. Calc. for anhydrous hydrochloride, Cl = 18.9 per cent.).

p-Methoxybenzsynaldoxime was dissolved in dry ether, and dry hydrogen chloride passed into the solution, when precipitation of the β -hydrochloride began immediately. The β -hydrochloride melted and decomposed at 134° and did not depress the melting point of the α -hydrochloride on admixture; by the standard method, it gave an oxime melting at 131° . The β -hydrochloride on crystallisation from chloroform, as with the α -compound, gave a hydrochloride melting and decomposing at 135° , which gave a crude *syn*-oxime melting at 128° .

Action of Hydrogen Chloride on 3:4-Methylenedioxybenzaldoximes (3:4-Methylenedioxybenzantialdoxime, m. p. 111° . 3:4-Methylenedioxybenzsynaldoxime, m. p. 146°).—Pure 3:4-Methylenedioxybenzantialdoxime was dissolved in dry ether and the solution saturated with dry hydrogen chloride at room temperature, when the α -hydrochloride was slowly precipitated; it melted and decomposed at 170 – 172° (Found: Cl = 17.4. $C_8H_8O_3NCl$ requires Cl = 17.7 per cent.). A portion on decomposition by the standard method, or by sodium carbonate solution, gave a crude oxime melting at 105° and, after crystallisation from acetone and water, at 109 – 111° , and at 109 – 111° when mixed with the *anti*-oxime. Another portion of the α -hydrochloride was boiled with benzene for five minutes, but did not dissolve; the solid β -hydrochloride thus obtained melted and decomposed at 167 – 169° and did not depress the melting point of the α -hydrochloride on admixture; decomposition by the standard method gave an oxime melting at 128 – 132° , which after crystallisation from acetone and water melted at 137 – 140° . Boiling the original α -hydrochloride with benzene for thirty minutes gave a product which on decomposition yielded a crude oxime melting at 134 – 135° . 3:4-Methylenedioxybenzsynaldoxime was dissolved in boiling benzene and the hot solution saturated with dry hydrogen chloride. The β -hydrochloride obtained melted and decomposed at 176 – 178° and gave by the standard method a crude oxime melting at 130° , which after crystallisation from acetone and water melted at 142° .

A quantity of the *anti*-oxime was ground in a mortar with concentrated hydrochloric acid for some minutes; the oxime rapidly changed to the hydrochloride, which was separated by pouring on to a porous tile. The hydrochloride melted and decomposed at 176—178° and gave an oxime sintering at 100° and melting at 103°, and when mixed with the original *anti*-oxime, at 99° and 110°. After crystallisation from acetone and water, the oxime melted at 110—111°, and at 109—111° when mixed with the *anti*-oxime. Unlike the hydrochloride of *p*-methoxybenzaloxime prepared in a similar way, the compound here obtained is the α -hydrochloride. Similar results were obtained when a solution of the *anti*-oxime in ether saturated with water was treated with hydrogen chloride at room temperature, the α -hydrochloride being precipitated with no indication of the formation of a hydrate.

3:4-Methylenedioxybenzsynaldoxime was dissolved in dry ether and hydrogen chloride passed into the solution. The instant the gas came in contact with the liquid a precipitate of the β -hydrochloride formed, which, after some time, was separated and found to melt and decompose at 176—178°; it did not depress the melting point of the α -hydrochloride on admixture. The β -hydrochloride so obtained, on decomposition by the standard method, gave a crude *syn*-oxime sintering at 121° and melting at 126°. Some conversion appears to have taken place during the operations, probably in the decomposition of the hydrochloride, as the crude oxime is of rather low melting point. It has, moreover, always been found a matter of considerable difficulty to obtain in this case a crude *syn*-oxime of high melting point when preparing it from the *anti*-oxime through the hydrochloride precipitated in organic solvents. A portion of the β -hydrochloride was boiled for fifty minutes with benzene under reflux, but no conversion was brought about, the product giving a crude *syn*-oxime melting at 125—126°.

Action of Hydrogen Chloride on m-Nitrobenzaloximes (*m*-Nitrobenzantialdoxime, m. p. 120°. *m*-Nitrobenzsynaldoxime, m. p. 123°).—*m*-Nitrobenzantialdoxime was dissolved in boiling benzene and the hot solution saturated with dry hydrogen chloride, when the β -hydrochloride was precipitated at once. It sintered at 122°, melted and decomposed at 135°, and gave by the standard method a crude oxime sintering at 104° and melting at 113°, which when admixed with *m*-nitrobenzantialdoxime melted at 95—98°. Mixed melting points are always necessary as a control when working with this oxime, as the two isomerides melt at practically the same temperature, but an admixture of one depresses the melting point of the other. The above method gives a purer *syn*-oxime than that

obtained by using ether at the ordinary temperature, when the β -hydrochloride is only slowly precipitated.

Hydrogen chloride passed into a solution of *m*-nitrobenzantialdoxime in dry ether at -15° precipitated a hydrochloride which sintered at 130° and melted and decomposed at 137° . On decomposition by the standard method, this gave an oxime sintering at 77° and melting at 98° , and at the same temperatures on admixture with the *anti*-isomeride; after crystallisation from acetone and water, the product sintered at 111° and melted at 119° , and when mixed with the *anti*-oxime, at 93° and 96° . The oxime obtained is obviously a mixture of the two isomerides produced from a mixture of hydrochlorides. On keeping a portion of the hydrochloride for fifteen hours and then decomposing it, a purer *syn*-oxime was obtained sintering at 90° and melting at 105° , and when mixed with the *anti*-oxime, at 87° and 94° .

Finely powdered *m*-nitrobenzantialdoxime was added in small portions to liquid hydrogen chloride, when a clear yellow solution was obtained. When the excess of hydrogen chloride had evaporated, the α -hydrochloride sintered at 125° and melted and decomposed at 134° ; it gave, on decomposition, an oxime sintering at 115° and melting at 120° and, admixed with *anti*-oxime, at 118° and 120° . At the low temperature, the α -hydrochloride can be obtained comparatively pure.

No evidence was obtained of the formation of a hydrate when *m*-nitrobenzantialdoxime was ground with concentrated hydrochloric acid and the suspension saturated with hydrogen chloride. The hydrochloride did not dissolve under these conditions, and gave a *syn*-oxime of rather poor quality on decomposition.

m-Nitrobenzsynaldoxime in ethereal solution gave an immediate precipitate of the β -hydrochloride when treated with hydrogen chloride. This sintered at 125° , melted and decomposed at 136° , and on decomposition by the standard method gave a crude *syn*-oxime sintering at 102° and melting at 111° alone, at 107° and 118° when mixed with *m*-nitrobenzsynaldoxime, and at 88° and 92° when mixed with *m*-nitrobenzantialdoxime.

3:4-Dimethoxybenzsynaldoxime.—Five grams of 3:4-dimethoxybenzantialdoxime were dissolved in 75 c.c. of boiling benzene, and the hot solution was saturated with hydrogen chloride. The precipitated hydrochloride melted and decomposed at 151° and, on decomposition by the standard method, gave a crude oxime melting at 102 – 108° . The oxime was dried by pressing it on a porous tile and added to 30 c.c. of boiling benzene, the solution filtered and rapidly cooled, when the *syn*-oxime crystallised in very pale pink needles melting at 119° (Found: N = 7.9. $C_9H_{11}O_3N$ requires

N = 7.7 per cent.). The orientation of the compound was determined in the usual way by dissolving it in acetic anhydride at room temperature, decomposing the excess of anhydride with sodium carbonate solution, and extracting the product with ether. On removing the solvent, an uncrystallisable oil was obtained which could not be induced to crystallise by seeding with 3:4-dimethoxybenzonitrile; it seems probable that the oil was acetyl-3:4-dimethoxybenzsynaldoxime, which is stable to sodium carbonate solution. Treatment of a portion of the oil with cold 2*N*-sodium hydroxide, followed by seeding with the nitrile resulted in its immediate solidification and the product was identified as 3:4-dimethoxybenzonitrile (compare Wentworth and Brady, T., 1920, **117**, 1045, who found that acetyl-5-bromo-3:4-dimethoxybenzsynaldoxime behaved similarly). The rest of the oil was heated for some hours with 2*N*-sodium hydroxide, when it slowly dissolved with evolution of ammonia. The solution on saturation with carbon dioxide gave no precipitate of oxime, but when acidified with hydrochloric acid gave veratric acid. The *syn*-configuration of the oxime was therefore established.

Action of Hydrogen Chloride on m-Methoxybenzantialdoxime.—The hydrochloride precipitated by saturating a solution of *m*-methoxybenzantialdoxime in boiling benzene with hydrogen chloride melted and decomposed at 108–110°. On decomposition by the standard method, an oil was obtained which, after extraction with ether and removal of the solvent, refused to crystallise. In order to determine whether this was a *syn*-oxime or a mixture of the two isomerides, it was dissolved at once in acetic anhydride at room temperature, the excess of anhydride decomposed with sodium carbonate solution, and the product extracted with ether. After removal of the solvent, an uncrystallisable oil was again obtained, which was hydrolysed by heating on the water-bath with 2*N*-sodium hydroxide, when the oil dissolved and ammonia was evolved. The solution was diluted somewhat, shaken with ether to remove traces of unchanged material, saturated with carbon dioxide, and again shaken with ether. On evaporating the second ethereal extract, an oil was obtained which slowly solidified and was identified as *m*-methoxybenzantialdoxime. The aqueous sodium bicarbonate solution was acidified with dilute hydrochloric acid and extracted with ether, when, on removing the solvent, a small amount of solid was obtained which was found to be *m*-methoxybenzoic acid. The relative amounts of oxime and acid obtained were, roughly, as three to one; it appears, therefore, that no better conversion had been obtained than by the ordinary methods (compare Brady and Dunn, T., 1914, **105**, 2413).

Action of Hydrogen Chloride on o-Methoxy-, o-Hydroxy-, 2:4-Dinitro-, 3:5-Dibromo-4-hydroxy-, and p-Dimethylamino-benzantialdoximes.—A solution of *o*-methoxybenzantialdoxime in boiling benzene was saturated with dry hydrogen chloride. The precipitated hydrochloride melted at 114° and decomposed at 130°, and, on decomposition with sodium carbonate solution or by the standard method, gave an oxime, melting at 92–94° and not depressing the melting point of the original oxime. Part of the hydrochloride was warmed with chloroform, when it dissolved slowly and some hydrogen chloride was evolved; on cooling, nothing separated, so light petroleum was added cautiously until a crystalline precipitate appeared, which sintered and partly decomposed at 75°. This was probably a mixture of hydrochloride and oxime formed by partial loss of hydrogen chloride; on treatment by the standard method, it gave an oxime melting at 92–93° which did not depress the melting point of the original oxime. A portion of the hydrochloride was heated in a glycerol bath to 115–117°, when it melted without visible evolution of gas. On cooling and scratching, the liquid solidified and, after being pressed on a porous tile and washed with a little dry ether to remove oxime, sintered at 98°, melted at 110°, and decomposed at 120°. Decomposition again gave the original oxime.

o-Hydroxybenzantialdoxime was dissolved in boiling benzene, and the solution saturated with dry hydrogen chloride. A rapid precipitation of the hydrochloride occurred. This melted and decomposed at 153° and on decomposition with sodium carbonate solution regenerated the original oxime.

2:4-Dinitrobenzantialdoxime was dissolved in boiling benzene and the solution saturated with hydrogen chloride. No precipitate formed for some time, but, as the solvent evaporated, crystals separated which were found to consist of the original oxime. A solution in boiling xylene gave no precipitate on saturation with hydrogen chloride, and, after cooling, the addition of light petroleum precipitated the original oxime. The oxime was also dissolved in liquid hydrogen chloride and part of the solution was poured into excess of sodium carbonate solution and part allowed to evaporate spontaneously. In both cases the original oxime was recovered, there being no evidence, in the latter instance, of the formation of a hydrochloride.

3:5-Dibromo-4-hydroxybenzantialdoxime in boiling benzene gave a hydrochloride, melting at 189° and decomposing at 195°, which on treatment with sodium carbonate solution dissolved completely; on acidifying the solution with dilute sulphuric acid, the original oxime was recovered.

p-Dimethylaminobenzantialdoxime in boiling benzene gave a

hydrochloride, melting and decomposing at 172° , which regenerated the original oxime on decomposition by the standard method. *p*-Dimethylaminobenzantialdoxime was added to liquid hydrogen chloride, when it dissolved. Part of the solution was added to a large excess of sodium carbonate solution, when the original oxime was precipitated; the rest was allowed to evaporate spontaneously, when a pasty, transparent, varnish-like material was obtained. This was pressed on a porous tile and after a very short time had no longer the odour of hydrogen chloride; after from one to two minutes, the varnish began to grow opaque and solidify, whilst at the same time bubbles of gas began to appear in it and the odour of hydrogen chloride became very strong. On referring subsequently to our notes made in 1914 on the action of liquid hydrogen chloride on oximes, it was found that an exactly similar observation had been recorded with this compound, although the fact had escaped our memories when the recent experiments were performed. It seems that an unstable dihydrochloride of *p*-dimethylaminobenzantialdoxime can be obtained at low temperatures.

Result of keeping Hydrochlorides.—A sample of the hydrochloride of *m*-methoxybenzantialdoxime prepared in 1914 and kept in a stoppered bottle was treated with cold 2*N*-sodium hydroxide, when only part dissolved. The mixture was diluted somewhat, filtered, and the solid, which formed about half of the original material, washed and crystallised twice from hot water, when long, white needles were obtained melting at 134° . This compound, on being warmed with sodium hydroxide solution, dissolved with the evolution of ammonia, and acid precipitated *m*-methoxybenzoic acid from the alkaline solution. This behaviour, and analysis also, indicated that the compound was *m*-methoxybenzamide, which has not been previously described (Found: N = 9.5. $C_8H_9O_2N$ requires N = 9.3 per cent.).

The alkaline solution which had been separated from the solid, on addition of ammonium chloride, gave an oil which, after extraction with ether, was identified as *m*-methoxybenzantialdoxime. The aqueous layer, on acidification with dilute hydrochloric acid and extraction with ether, yielded a small quantity of *m*-methoxybenzoic acid. Experiments on the hydrochlorides obtained from benzantialdoximes and *o*-nitrobenzantialdoxime, kept for three months in stoppered bottles in the dark, gave no indication of the formation of amide, as, at the end of that time, they were still completely soluble in cold 2*N*-sodium hydroxide.

Phenylcarbaryl Chloride.—This compound was prepared by Hentschel (*loc. cit.*) by the action of hydrogen chloride on phenylcarbimide, and by Lengfeld and Stieglitz (*loc. cit.*) by the action of

phosphorus pentachloride on phenylurethane. Although it had been found that the compound decomposed on being heated to 100°, no mention could be discovered of the action of water or alkalis upon it. The compound was prepared by the method of Hentschel. When the solid chloride was added to water, it decomposed slowly and oily drops of phenylcarbimide separated which, after some ten minutes, were further decomposed by the water, yielding diphenylcarbamide. On treatment of the hydrochloride with sodium carbonate solution, the decomposition to phenylcarbimide was immediate.

Summary.

(1) It has been demonstrated that benzaldoxime, *p*-methoxy-, 3:4-methylenedioxy-, and *m*-nitro-benzaldoximes give two hydrochlorides, one of which, on decomposition, generates the *anti*-oxime, and the other the *syn*-oxime. High temperature favours the formation of the latter hydrochloride.

(2) The so-called benzsynaldoxime hydrochloride of Luxmoore has been shown to be a hydrate.

(3) 3:4-Dimethoxybenzantialdoxime has been converted into its *syn*-isomeride by preparing the hydrochloride in boiling benzene. On the other hand, *o*-hydroxy-, *o*-methoxy-, *m*-methoxy-, and 3:5-dibromo-4-hydroxy-benzantialdoximes were not so converted under similar conditions.

(4) The hydrochloride of *m*-methoxybenzaldoxime on keeping for some years is partly converted into *m*-methoxybenzamide.

(5) The technique involved in working with these compounds has been indicated.

(6) Some modifications of the views previously put forward by us on the mechanism of isomeric change in the oximes have been described.

CCl.—*Influence of Hydrogen Chloride on the Enolising Action of Grignard's Reagent.*

By VINAYAK KESHAV BHAGWAT.

THE probable enolisation of ketones during the process of halogenation was first clearly pointed out by Lapworth (T., 1904, 85, 30), who studied the reaction in various solvents and drew the conclusion that the halogen is absorbed by the unsaturated modification of the ketone.

Dawson and his co-workers put forward a similar explanation of the mechanism of halogenation of acetaldehyde and its homologues (T., 1909, 95, 1860; 1914, 105, 275, 387). They have further found that halogenation is accelerated in the presence of a strong acid such as hydrochloric or sulphuric acid. According to their view, the presence of a negative group in the molecule or of a catalyst in the reaction mixture promotes enolisation of the aldehyde and thus accelerates halogenation.

Up to the present, however, in only one instance have acetone and acetaldehyde been observed to react in the enolic form (Freer, *Amer. Chem. J.*, 1890, 12, 355; 1891, 13, 319).

Dr. Sudborough and the author found that simple aldehydes and ketones display very little tendency to enolise in the presence of Grignard's reagent (*J.I.I.Sc.*, 1919, 11, 192); a moderately high degree of enolisation was observed, however, in the case of an acid sample of isovaleraldehyde, and the suggestion was made that this result might have been due to the enolising action of the acid. In view of the work of Dawson, the explanation seems satisfactory, but it must be remembered that the acid—presumably isovaleric acid—would decompose in presence of Grignard's reagent and therefore would have no chance to exert its enolising influence. It seems likely, therefore, that the marked enolisation in the case of the acid sample was due to the trace of water (formed in the auto-oxidation of the aldehyde) not having been removed by the calcium chloride.

In order to settle this point, the present investigation was undertaken. The results corroborate the first view, for it was found that whilst acetic acid has no influence on the enolising action of Grignard's reagent, hydrogen chloride exerts a very great influence.

EXPERIMENTAL.

As slight variations of temperature affect the vapour pressure of ethyl-etheral solutions to an appreciable extent, all the experiments were performed in pure isoamyl-etheral solution as suggested by Hibbert and Sudborough (T., 1904, 85, 934). To obviate the small errors due to the absorption of moisture, carbon dioxide, and oxygen, the apparatus was filled with pure dry nitrogen in each experiment.

The amyl ether was prepared from commercial isoamyl alcohol (b. p. 128–130°) by Schröter and Sontag's method (*Ber.*, 1908, 41, 1924), and purified by keeping over calcium chloride for about two days and then boiling twice with metallic sodium for eight hours, with intermediate distillation; it was thereafter successively treated with a little magnesium methyl iodide, sodium, and phosphoric oxide and finally distilled.

The Grignard's reagent was prepared as described by Hibbert and Sudborough, and the nitrogen by the method given by Lupton (*Chem. News*, 1876, **33**, 90).

Propaldehyde, prepared by Lieben's method (*Monatsh.*, 1883, **4**, 14), was repeatedly carefully fractionated, treated with calcium chloride, and again fractionated, until a product of constant density was obtained; b. p. 44.5–45.5°/687 mm.; d_0 0.8402.

*iso*Valeraldehyde, prepared by Bouveault and Rosset's method (*Bull. Soc. chim.*, 1894, [iii], **11**, 301), was purified as above; b. p. 88.5–89.5°/684 mm., d_0 0.8212.

Merck's extra pure acetone was dehydrated with fused calcium chloride and distilled until the density was constant; b. p. 53.5°/688 mm., d_{25} 0.7849.

Pure glacial acetic acid, m. p. 16°, was used in these experiments. A dilute solution of hydrogen chloride in dry amyl ether was prepared, and standardised by titrating with standard caustic soda the aqueous extract of a weighed quantity.

Small quantities of the acid solution and of the substance were weighed in a stoppered tube and then dissolved in about 10 c.c. of dry amyl ether. The tube containing the solution was lowered vertically into a stout filter flask of about 250 c.c. capacity, provided with an air-tight rubber bung carrying a tapped tube nearly touching the bottom of the flask. Excess of magnesium methyl iodide solution (about 10–15 c.c.) having been placed in the flask, the air was displaced by nitrogen which had bubbled through concentrated sulphuric acid and passed over phosphoric oxide. The side tube of the flask was attached to a Lunge nitrometer filled with dry mercury, and the apparatus was left for one to two hours to attain room temperature. The level of the mercury in the nitrometer and the temperature having then been noted, the two solutions were mixed by slightly tilting the flask and shaken vigorously; after about two hours, the volume of the gas evolved was read with the usual precautions, and corrections for change of temperature and pressure during the period were applied. The quantity of the enolic form was calculated from the amount of methane evolved in the reaction. Occasionally a blank experiment was made to show that the dry *iso*amyl ether used as solvent did not develop any gas with the Grignard's reagent and to make sure that the ether did not absorb any moisture.

It has been recently shown by Hess and Rheinboldt (*Ber.*, 1921, **54**, [B], 2043) that magnesium methyl iodide yields ethane when treated with hydrochloric acid. Under the conditions mentioned in this paper, however, the *iso*amyl-etheral solution of hydrogen chloride did not give any gas with magnesium methyl iodide.

The results of these experiments are given in Tables I to V and shown graphically in the figure.

In all these experiments the vapour pressure of the amyl ether was neglected.

Summary and Conclusions.

The action of Grignard's reagent upon acetone, *isovaleraldehyde*, and propaldehyde in amyl-etheral solution and in presence of acetic acid and of hydrogen chloride has been investigated with the following results:

(i) Acetic acid has no effect on the enolising action of Grignard's reagent, owing to decomposition immediately consequent on its exposure to the attack of the organo-metallic iodide. Lapworth (*loc. cit.*) ascribes the inability of acetic acid and similar acids to

accelerate the halogenation of ketones (according to his theory by enolising them) to their weakly acid character.

(ii) Hydrogen chloride exerts a great influence on the enolisation of these aldehydes and acetone, the degree of enolisation being proportional to the quantity of acid present.

In conclusion, I would like to express my thanks to Dr. Sudborough for his valuable suggestions during the progress of this work, which was done mainly at Bangalore. My thanks are also due to the Research Grant Committee of the Bombay University for a grant which has defrayed part of the expenses incurred in this work.

CCII.—*Constitutional Studies in the Monocarboxylic Acids derived from Sugars. Part I. Tetramethyl Galactonolactone and the Structure of Galactose.*

By JOHN PRYDE.

THE hexonic acids, such as gluconic and galactonic acids, together with their salts and esters, have been formulated as straight chain compounds, whilst the cyclic structure of 1 : 4*-lactones (γ -lactones) has been assigned to the dehydration products into which the free acids readily pass.

These assumptions have been justified by the evidence of Hudson (*J. Amer. Chem. Soc.*, 1910, **32**, 338), who has examined the relation between the structure and the optical activity of the lactones of twenty-four monocarboxylic acids derived from various sugars containing from five to nine carbon atoms. Hudson has brought forward convincing evidence on the following points :

(1) The lactones have a higher optical rotatory power than the corresponding free acids.

(2) The stereochemical conventions laid down in the researches of Fischer being adopted, the direction of optical rotation of the lactones in a dextro- or laevo-sense is determined by the position of the oxygen bridge on the right- or left-hand side of the carbon chain.

On the basis of these generalisations, Hudson shows that very good grounds exist for formulating all the lactones of the sugar acids examined by him as 1 : 4-compounds. But whilst this may apply to the lactones of the monocarboxylic acids derived from unsubstituted sugars, it by no means follows that the 1 : 4-oxygen bridge—or any other one type of linking—is of universal occurrence in the stable sugars themselves (compare Irvine, this vol., p. 918). Whilst the hypothesis that the 1 : 4 or butylene-oxide structure is common to all the stable sugars has been very fruitful of new ideas, it is only recently that it has been submitted to rigid experimental test. Thus it has been generally assumed that glucose has a 1 : 4-oxygen bridge in its most stable configuration, and whilst direct experimental proof is lacking, there is a mass of collateral evidence which renders this assumption highly probable. In the arguments advanced in the present communication, the 1 : 4-structure for glucose and its derivatives is accepted, but it must be pointed out that much of the evidence could be interpreted equally well on the basis of a 1 : 5-linking. In the case of the other aldo-hexoses or -pentoses, there was, until very recently, little evidence, even of

* Terminology recommended by Irvine for the sugar group.

an indirect nature, pointing to the presence or otherwise of a 1:4-bridge.

Helferich and Malkomes (*Ber.*, 1922, 55, [B], 702) have shown that δ -hydroxyhexaldehyde readily reacts as a cyclic amylenoxide substance to give a stable compound parallel in many ways to methylglucoside, and the possibility of the occurrence of 1:5-rings in the normal sugars is at once suggested. More recently, Hirst and Purves (this vol., p. 1352) have submitted evidence which shows that xylose definitely possesses an amylenoxide structure, and not a butylene-oxide structure as has hitherto been assumed.

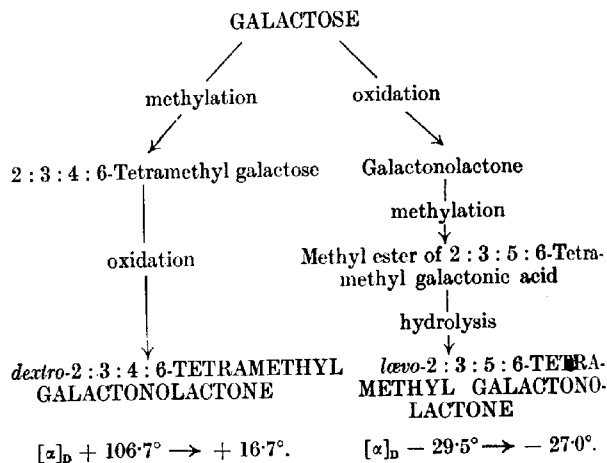

In the present investigations in the hexonic acid series, evidence has been accumulated which shows with some degree of certainty that the normal configuration of galactose is also that of an amylenoxide sugar (I), the assumption being made that Hudson's rule is as applicable to the methylated as to the non-methylated lactones—an assumption which is justifiable when it is borne in mind that in the sugars generally no profound changes in optical properties result from methylation.

d-Galactose, which is itself dextrorotatory, gives rise to a galactonolactone of lævo-rotation (Schnelle and Tollens, *Annalen*, 1892, 271, 81) to which, in accordance with Hudson's rule, formula II has been assigned. If galactose be methylated to give tetramethyl galactose, and if this substituted hexose be oxidised to tetramethyl galactonolactone, lactonisation can only occur in the position originally unsubstituted in the parent sugar, that is, in the position formerly occupied by the oxygen bridge. If this were actually the 4-position, one might expect to obtain a lævorotatory tetramethyl galactonolactone (III), since the oxygen bridge would lie on the left-hand side of the carbon chain. On the contrary, it has been found that tetramethyl galactose, prepared by direct methylation of galactose, gives on oxidation a tetramethyl galactonolactone which, like the parent hexose, is strongly dextrorotatory and therefore has its oxygen bridge on the right-hand side of the carbon

chain (IV). The oxygen linking in the parent sugar must then have occupied the same position, that is, most probably the 1 : 5.

This explanation of the dextrorotation of tetramethyl galactonolactone from tetramethyl galactose is further substantiated by the fact that the levorotatory tetramethyl galactonolactone, to which formula III is ascribed, has been prepared by methylation of galactonolactone (II), prepared by direct oxidation of galactose. It was found to be possible to methylate the lactone by means of silver oxide and methyl iodide, to give the methyl ester of tetramethyl galactonic acid, and the latter substance gave, on hydrolysis with barium hydroxide, a tetramethyl galactonolactone which, like the parent lactone, was also levorotatory. Thus, two isomeric tetramethyl galactonolactones have been obtained, one dextro-the other levo-rotatory, the direction of rotation being dependent on the particular stage of the operations at which the lactone ring is closed, as is summarised in the following scheme :

The fact that it is possible to methylate galactonolactone to give methyl tetramethylgalactonate instead of methyl pentamethylgalactonate is worthy of note. The water formed during the reaction, by methylation of the pre-existing hydroxyl groups of the lactone, produces, in the presence of silver oxide, the silver salt of the acid and this reacts with methyl iodide to give the methyl ester. The hydroxyl group on the 4-carbon atom apparently does not then methylate—possibly due to steric factors—or methylates but slowly, so that it is possible to arrest the reaction at a stage

corresponding to the ester of the tetramethyl acid. The possibility of methylating this additional hydroxyl group by a modified procedure is at present under investigation.

It is apparent from the foregoing observations that in the hexonic and allied acids lactonisation occurs, if possible, in the 1 : 4-position, but that this tendency to form 1 : 4-linkings is not so marked in the sugars themselves, although this probably is the most stable configuration in both cases. The following facts would tend to show a greater stability of the 1 : 4-linking as compared with the 1 : 5-linking, both in the parent hexoses and in the lactones of their monocarboxylic acids :

(1) *dextro*-Tetramethyl galactonolactone (1 : 5) undergoes a more rapid conversion into the open-chain acid in aqueous solution than does the corresponding *dextro*-tetramethyl gluconolactone (1 : 4),* and, moreover, the equilibrium position in the change lactone \rightleftharpoons acid lies further to the right in the case of the former lactone than in the latter, as will be seen from the fact that the initial rotations of the two lactones are of the same magnitude, whereas the final rotation of the latter lactone is much above that of the former.

(2) Schnelle and Tollens (*loc. cit.*) showed that galactonolactone (1 : 4) underwent practically no conversion into the free acid in aqueous solution, as deduced from its failure to mutarotate downwards even on warming to 70° after standing for twenty-four hours. Similarly, it is now found that *levo*-tetramethyl galactonolactone (1 : 4) alters its rotation but slightly in aqueous solution after the lapse of several days. On the other hand, the specific rotation of *dextro*-tetramethyl galactonolactone (1 : 5) declines from + 106·7° to its equilibrium value of + 16·7° in twenty-four hours at room temperature.

(3) It has already been recorded (Schnelle and Tollens, *loc. cit.*) that galactose undergoes oxidation by the agency of bromine with greater readiness than does glucose, and this fact now finds a ready explanation in the less stable 1 : 5-linking present in the former hexose as compared with the more stable 1 : 4-linking present in glucose. In the present case, parallel observations have now been made on the corresponding tetramethyl hexoses, tetramethyl galactose undergoing oxidation with bromine much more easily than does tetramethyl glucose.

* It must again be pointed out here that the stereochemical configuration of glucose is such that both 1 : 4- and 1 : 5-lactones of gluconic acid would be dextrorotatory, so that it is impossible to arrive at a definite decision as to which structure is present on polarimetric evidence alone. As already stated, other grounds exist for preferring the 1 : 4-formulation.

In the following table are collected certain observations on the optical rotatory power of gluconic and galactonic acids, their lactones, and tetramethyl lactones. These serve to illustrate further the remarks made above.

	Initial [α] _D	Final [α] _D	Time.	Ref.
Gluconic acid	- 1.7°	+11.6°	—	(1)
Gluconolactone (1 : 4)	+ 61.6°	+20.8°	47 days	(2)
Tetramethyl gluconolactone (1 : 4) ...	+100.7°	+39.5°	3 "	(3)
Galactonic acid	- 11.2°	-57.6°	23 "	(4)

* Unchanged after the substance was heated at 70° and cooled.

It is of interest to note that, whilst the Hudson rule applies with the greatest strictness to the lactones of the sugar acids in aqueous solution, it has not been found possible to apply it in a similar way to the sugars themselves, on the assumption of a common butylene-oxide structure. It seems reasonable to suggest that a revision of the current views as to the nature of the oxygen linking present in the stable sugars, more especially with a view to differentiating between 1:4- and 1:5-linkings, may make it possible to apply Hudson's rule to the sugars themselves as well as to the lactones of their acids.

EXPERIMENTAL.

Galactonic Acid and Galactonolactone.—These were prepared by oxidation of *D*-galactose with bromine as described by Schnelle and Tollens (*loc. cit.*). The twice crystallised calcium salt of the acid was treated with the equivalent of oxalic acid, and the filtered solution evaporated to dryness in a vacuum. The hot absolute alcoholic solution of the crystalline product deposited, on cooling, fine, white needles of pure galactonic acid (as determined by titration against alkali, neutralisation of the alkali proceeding at once in the cold), and the mother-liquor, concentrated to a syrup in a vacuum desiccator, slowly crystallised after complete removal of the solvent; this second fraction was galactonolactone (m. p. 92°), and comprised the bulk of the total product.

Galactonic acid has m. p. 147.5°, and in aqueous solution (*c* = 1.1015) [α]_D = -11.18°; this rose to a final value of -57.57° after twenty-three days (compare Kiliani, *Ber.*, 1885, **18**, 1551; Schnelle and Tollens, *loc. cit.*; Fischer and Ruff, *Ber.*, 1900, **33**, 2146).

The above preparation of galactonolactone showed $[\alpha]_D -69.97^\circ$ in water ($c = 0.786$) and did not appreciably alter after some days.

Methylation of Galactonolactone.—This was carried out by means of the silver oxide-methyl iodide reaction, using methyl alcohol as an extraneous solvent in the first methylation, and acetone in the second. After two methylations under these conditions, the product was completely soluble in methyl iodide, and it was then subjected to two further treatments with no extraneous solvent. After these four methylations the product was extracted with ether and distilled in a high vacuum.

The first fraction collected—a highly mobile liquid, comprising 25 per cent. of the total distillate—boiled at $100^\circ/0.75$ mm., and had $n_D^{20} 1.4402$ [Found: OMe = 57.84. Calc. for the methyl ester of pentamethyl galactonic acid, $C_6H_6O(OMe)_5$, OMe = 66.43; for the methyl ester of tetramethyl galactonic acid, $C_6H_7O_2(OMe)_5$, OMe = 58.27; for tetramethyl galactonolactone, $C_6H_6O_2(OMe)_4$, OMe = 53.0 per cent.].

In aqueous solution ($c = 1.773$), the ester has $[\alpha]_D +9.93^\circ$, its low rotation being in agreement with Hudson's generalisations already quoted.

The second fraction—60 per cent. of the total distillate—boiled at $100-110^\circ/0.6$ mm. (Found: OMe = 55.96 per cent.). This fraction, together with a third, higher-boiling fraction, was subjected to one further methylation, and the methoxyl content rose to 56.64 per cent.

Hydrolysis of Methyl Tetramethylgalactonate. *laevo-Tetramethyl Galactonolactone.*—The combined products, obtained as above described, were dissolved in water and treated with excess of approximately *N*-barium hydroxide solution for one and a half hours at $80-90^\circ$, the barium was precipitated as sulphate by addition of the exact amount of sulphuric acid, the filtered solution evaporated to dryness in a vacuum, and the residual syrup extracted with ether. The solvent was removed and the product distilled in a vacuum. It boiled at $130-135^\circ/2$ mm. as a very mobile syrup and had $n_D^{20} 1.4496$ [Found: C = 51.17; H = 7.65; OMe = 51.8. Calc. for tetramethyl galactonolactone, $C_6H_6O_2(OMe)_4$, C = 51.28; H = 7.69; OMe = 53.0 per cent.]. The substance titrated as a lactone against alkali (0.1367 gram required 5.96 c.c. of 0.1*N*-NaOH; calc., 5.84 c.c.). The specific rotation ($[\alpha]_D$) in aqueous solution ($c = 1.413$) was -29.51° after six minutes, and -26.96° after five days. At the end of the latter period, the solution on which these observations were made still titrated essentially as a lactone, showing that only slight conversion into the acid had occurred.

Oxidation of Tetramethyl Galactose.—The tetramethyl galactose was obtained by the hydrolysis of tetramethyl β -methylgalactoside, which had been prepared by direct methylation of galactose by the methyl sulphate-caustic soda process.* This preparation of the galactoside showed $[\alpha]_D + 4.4^\circ$ in water ($c = 1.3112$).

The hydrolysis was carried out in the usual way by boiling for thirty minutes with 8 per cent. hydrochloric acid, but in the subsequent working up of the product, a slightly modified procedure, recommended by Dr. Hirst, was adopted. The neutralised aqueous solution was repeatedly extracted with chloroform, the extract dried with anhydrous sodium carbonate, and the somewhat stiff, non-crystalline syrup obtained on removal of the solvent was distilled in a high vacuum. It boiled at $110^\circ/0.15$ mm., and from 10 grams of the methylated galactoside, 7.13 grams of pure, colourless, liquid tetramethyl galactose resulted. It had $n_D^{25} 1.4635$ and $[\alpha]_D$ in water ($c = 1.766$), $+ 84.9^\circ$. No mutarotation was observed and therefore the distillate consisted of the equilibrium mixture of the α - and β -forms.

The oxidation of tetramethyl galactose was effected by means of bromine, the following quantities being used: tetramethyl galactose 7 grams, bromine 9.5 grams (3 c.c.), and water 50 c.c. The sugar was dissolved in water, the bromine added gradually with frequent shaking, and the temperature kept at 30 – 35° for several hours. The mixture having been kept over-night at room temperature, and oxidation found to be complete, the main bulk of the solution was aerated to remove the excess of bromine and concentrated to half its volume by evaporation in a vacuum. The hydrobromic acid was neutralised with lead monoxide at 35 – 40° and the solution, after filtration, was treated with silver oxide until neutral to litmus. The silver in the filtered solution was precipitated with hydrogen sulphide, and the filtrate from the sulphide was evaporated, dried in a vacuum, and extracted with ether.

dextro-Tetramethyl Galactonolactone.—This was obtained from the ethereal extract above, as a pale yellow, mobile syrup from which the last traces of solvent were removed at $100^\circ/10$ mm. It was then twice distilled in a high vacuum in order to remove traces of a high-boiling fraction. The tetramethyl lactone boiled at 110 – $115^\circ/0.5$ mm. as a colourless, very mobile oil. The yield of the pure substance from 7 grams of tetramethyl galactose was 5 grams. It had $n_D^{25} 1.4571$ [Found: C = 51.27; H = 7.57; OMe = 52.16. Calc. for $C_6H_6O_2(OMe)_4$, C = 51.28; H = 7.69; OMe = 53.0 per cent.]. The product titrated as a lactone to alkali (0.1769

* I have to thank Dr. E. L. Hirst of St. Andrews for a generous supply of tetramethyl β -methylgalactoside.

gram required 7.50 c.c. of 0.1N-NaOH; theory requires 7.56 c.c.).

The rotation of the tetramethyl galactonolactone was determined in aqueous solution ($c = 1.202$); $[\alpha]_D = +106.71^\circ$ after nine minutes, and this fell to $+16.76^\circ$ after one day ($+16.90^\circ$ after six days).

The expenses of this research were defrayed by a grant from the Medical Research Council.

CCIII.—*Metallic Hydroxy-acid Complexes. Part I.* *Cuprilactates.*

By IAN WILLIAM WARK.

THE general title "Metallic Hydroxy-acid Complexes" embraces many substances. It would appear that all α -hydroxy-acids are capable of yielding such complexes, and that most of the metallic multivalent elements may enter with them into these compounds. Many of the combinations are very stable, whereas others are just the reverse. In the literature, no reference has been found to complexes formed by acids of the aliphatic series other than those in which the hydroxyl and the carboxyl group are in the α -position, nor to any formed by univalent metals.

This field of investigation overlaps, to a certain extent, the important one of the compounds formed between metallic oxides and the polyhydric alcohols. These compounds themselves may be connected in classification, through the alcoholic complexes of certain amphoteric oxides such as the trioxides of arsenic and antimony, with the complex acids formed between some acidic oxides and the alcohols, of which the best known member is, perhaps, "boroglyceric acid," which has proved so useful in the estimation of boric acid. Having traced a resemblance between the metallic complexes and those formed from acidic oxides, it is but a short step to couple both series with the more familiar group of compounds of the type of ammonium phosphomolybdate and the complex silicates.

It will be necessary to assume that both acidic and basic oxides may enter into combination with the alcoholic hydroxyl group; in other words, this group is itself amphoteric. (This view seems preferable to that in which the metallic hydroxides are regarded as playing the part of acids, though either alternative leads to the same structural formulae.) Bearing this in mind, there is no need to regard boric acid and cupric hydroxide complexes as belonging

to essentially different types; they are of precisely similar structural types so far as the alcoholic group is concerned.

The capability of any hydroxy-compound to form complexes with metallic oxides must depend on the acidity of the hydroxyl group. The more strongly this group functions as an acid, the more stable will the complexes be. Thus the aliphatic α -hydroxy-acids, whose alcoholic hydroxyl group is rendered fairly acidic by the close proximity of the carboxyl group, are capable of yielding stable compounds, whereas their isomerides among the β -hydroxy-acids, the hydroxyl group of which is much less acidic, are incapable of entering into such complexes at all. In salicylic acid, however, the phenolic hydroxyl group, although in the β -position with respect to the carboxyl group, is yet sufficiently acidic to form complexes with copper hydroxide (Pickering, T., 1912, 101 174; Wolff, *Ann. Chim. analyt.*, 1900, 5, 445). Mono-phenolic acids, in which the phenolic hydroxyl group is in the meta- or para-position with respect to the carboxyl group, and consequently is not so strongly acidic as in the isomeric ortho-series, are unable to form complexes (Weith, *Ber.*, 1876, 9, 342). Weith claimed that all phenolic acids in which the hydroxyl and the carboxylic group are not in the ortho-position are unable to form copper complexes, but Pickering has shown that both gallic and catechuic acids do yield such derivatives. Weith's generalisation is therefore too broad and one might suggest in its place the statement that only phenols and phenolic acids in which at least two of the carboxyl or phenolic hydroxyl groups are in the ortho-position yield complexes with copper hydroxide in the presence of alkalis. Possibly this statement will be incapable of withstanding the test of further experimental work, since, as pointed out above, the stability of the complex is determined as much by the acidity of the hydroxyl group as by its position.

It will be advisable, at the outset, to consider briefly the compounds formed by the alcohols themselves, for, as will be shown later, some of those derived from the hydroxy-acids are best regarded as of exactly the same type, whereas others are probably of a somewhat different nature. Boric acid yields some of the most stable and best known complexes with glycerol and other alcohols, and with some of the sugars. These are almost certainly esters, and Wohl and Neuberg (*Ber.*, 1899, 32, 3491) have isolated a crystalline substance, $\text{KO}\cdot\text{B}(\text{C}_3\text{H}_7\text{O}_3)_2$, which may well be regarded as the potassium salt of a complex "boroglyceric acid,"* $\text{HO}\cdot\text{B}(\text{O}\cdot\text{C}_3\text{H}_7\text{O}_2)_2$, in which glycerol has replaced two only of the

* A better name for this acid would be glyceroboric acid, for its present name implies some connexion between it and glyceric acid,

three acidic hydrogen atoms of boric acid. This acid proves to be much stronger than boric acid itself and, with phenolphthalein as indicator may be satisfactorily titrated against potash. Such an increase in acidity usually accompanies complex formation. In fact, one can say almost with certainty that it always runs hand in hand with the building up of complex acids. Rimbach and Neizert (*Z. anorg. Chem.*, 1907, 52, 397), finding that the conductivities of mixtures of isohydric solutions of molybdic acid and certain hydroxy-acids were three times as great as would have been the case if no compounds were formed, drew the conclusion that complex acids had been produced which were very much stronger than either of their constituent acids. An application of this principle affords some explanation of the formation of the compound $\text{NaCuC}_3\text{H}_5\text{O}_3$ by dissolution of cupric hydroxide in glycerol made alkaline with caustic soda (Bullnheimer, *Ber.*, 1898, 31, 1453). This salt would be regarded, then, as the sodium derivative of the acid $\text{HO}\cdot\text{CH}_2\cdot\text{CH}\begin{smallmatrix} \text{CH}_2 \\ \text{O}\cdot\text{Cu} \end{smallmatrix} > \text{O}$. Its solution is strongly alkaline and, like those of all heavy-metal derivatives of the polyhydric alcohols, decomposes when heated.

Among the metallic complexes, those of copper and antimony have received most attention. But no generally accepted scheme of classification has kept pace with the vast accumulation of experimental data. The simple alcoholic derivatives are notoriously unstable and difficult to crystallise, and those of the hydroxy-acids, although more stable and somewhat less difficult to handle, present such a large number of structural possibilities that up to the present no satisfactory general theory has been forthcoming. There is still doubt as to the structure of a compound so well known as tartar emetic, despite the many attempts which have from time to time been made to establish its constitution. Clarke and Stallo (*Ber.*, 1880, 13, 1788) regard it as having a structure $\text{KO}\cdot\text{Sb}\cdot\text{C}_4\text{H}_4\text{O}_6$, strictly analogous to that mentioned earlier in this communication for potassium glycerol-borate. Clarke and Evans (*Ber.*, 1883, 16, 2386) proposed the formula

Henderson, Orr, and Whitehead (*T.*, 1899, 75, 542) suggested the structure $\text{KO}_2\text{C}\cdot\text{CH}(\text{OH})\cdot\text{CH}(\text{O}\cdot\text{SbO})\cdot\text{CO}_2\text{H}$. Yet none of these formulæ accounts for the dehydration at 200° (Schiff, *Comp. rend.* 1862, 55, 511) whereby a substance is produced for which the only satisfactory formula is

Since it is only the alcohols and the hydroxy-acids which are capable of forming such complexes, it is reasonable to assume that the hydroxyl group plays an *active* part in their formation. It is, however, very difficult, on the available evidence, to decide between the alternative formulæ.

Pickering (T., 1909, 95, 1409, and in subsequent papers) published a large amount of pioneering work relating to the copper complexes and put forward the theory that copper plays the part of a quadrivalent element.

Ley and other workers, in their classical researches on "inner metallic complex" formation, have been led to regard the copper complexes formed by the α -amino-acids as possessing the structure (I), in which the secondary valence of copper has been called into play in the formation of the five-membered ring with which they associate the stability, the low copper-ion concentration and conductivity, and the abnormally high colour of these cupric amino-complexes. Werner ("New Ideas on Inorganic Chemistry," 2nd edition, Hedley's translation, p. 223) has suggested that copper malate may have a similar structure (II).

The author has found, however, that in solution at any rate, cupric malate undergoes very little, if any, complex formation, for the cupric concentration is not abnormally low (see following paper). Werner's theory will be considered more fully (*loc. cit.*), but mention should be made here of the support given to his views by the work of Grün and Bockisch (*Ber.*, 1908, 41, 3465) and of Tollens and Smith (*Ber.*, 1900, 33, 1277), who claim that one molecule of certain polyhydric alcohols and sugars, for example, ethylene, glycol, glycerol, and fructose, is capable of replacing two molecules of the water of crystallisation in certain inorganic salts. This is taken as evidence that the hydroxyl groups of the alcohols may form complexes in which the grouping

occurs. But it should be noted that compounds of this type display a greater stability than those which the alcohols form with heavy-metal oxides in the presence of alkalis, so that it is scarcely permissible to assume great resemblances between two such different series of compounds.

It will thus be seen that there are several rival theories, none of which has been applied to more than a few of the many similar compounds known to exist. It is proposed in this and succeeding communications to show how a simple application of the principles of primary valences leads to a satisfactory explanation of the properties of, and to a correlation between, all the compounds of this class.

The metallic hydroxy-acid complexes are characterised by a low value of the concentration of the metallic ion in solution. A large series of acids exists in which a heavy metal occurs in the anion, the alkali-metal salts of which are neutral, do not oxidise glucose, and, in certain cases, are surprisingly stable. To the salts of acids of this type belong such compounds as tartar emetic and the neutral cupritartrates described by Masson and Steele (T., 1899, 75, 725).

The author's work in this field began with an investigation which was undertaken with the object of elucidating the structure of the neutral cupritartrates and of the constituents of Fehling's solution (Packer and Wark, T., 1921, 119, 1348). The latter contains salts of a second class of complex acid, in which the main characteristics are a strong alkalinity (high hydroxyl-ion concentration) of the alkali metal salts, which can themselves oxidise glucose, and being somewhat unstable, have a tendency to deposit the metallic hydroxide from solution, and also show a very much lower concentration of the metallic ion than do the corresponding neutral complexes (Kahlenburg, *Z. physikal. Chem.*, 1895, 17, 577). During the progress of the work on the cupritartrates, it became obvious that, if satisfactory explanation and correlation of these compounds were to be achieved, it would be necessary to turn to some simpler acid than tartaric (a dibasic dihydroxy) acid, and initially to make a thorough study of some case more restricted in structural possibilities. It is expected that a general explanation of the constitution of the compounds will ultimately be reached and of the conditions underlying the stability of some, the instability of others, and how these depend on the number and the relative positions of the hydroxyl and carboxyl groups and on the nature of the metallic element. Up to the present, however, it has been deemed advisable to restrict the work to one metal—copper, and to study the complexes rather from the point of view of the hydroxy-acids first.

Accordingly, the author turned first to the monobasic monohydroxy acids. The copper complexes formed by glycollic acid are rather unstable (Pickering, T., 1911, 99, 1347) and are unsuited to the work. Lactic acid was therefore selected, since it is the

next member of the simple series. The complexes derived from it, too, are rather unstable; some of them are described below.

Malic acid (a dibasic monohydroxy-acid) and glyceric acid (a monobasic dihydroxy-acid) were then selected. Derivations of these two acids are at present under investigation; an account of them will be communicated later.

Cuprilactates. Their Formation, Properties, and Constitution.

Jordis (*Z. angew. Chem.*, 1902, **15**, 906; 1904, **17**, 41, 330), Moritz and Schneider (*Z. physikal. Chem.*, 1902, **41**, 129; *Z. angew. Chem.*, 1904, **17**, 1143), Henderson and Prentice (*T.*, 1895, **67**, 1030), and Henderson, Orr, and Whitehead (*loc. cit.*) have described boron, arsenic, antimony, and molybdenum complexes formed by dissolving the oxides of these elements in solutions of alkali metal lactates. One complex, which has been isolated in crystalline form by the last-mentioned workers, has a molybdenum content which agrees fairly well with that required by the formula $(\text{KC}_3\text{H}_4\text{O}_3)_2\text{MoO}_2$. Evidence has been obtained, largely as the result of the optical measurements of Henderson and D. and J. Prentice (*T.*, 1902, **81**, 658; 1903, **83**, 259), that the following compounds exist, $\text{M}^{\text{III}}\text{O}_2\text{C}_3\text{H}_4\text{O}_3\text{K}$, $\text{M}^{\text{VI}}\text{O}_2(\text{C}_3\text{H}_4\text{O}_3\text{K})_2$, where M^{III} represents B, Sb, or As and M^{VI} represents Mo or W. Moritz and Schneider claim to have isolated a compound with the formula $\text{SbO}\cdot\text{Na}_2(\text{C}_3\text{H}_5\text{O}_3)_3$, and Dreher (*D.R.-P.* 149577) another of the composition $\text{TiO}_2\cdot 4\text{C}_3\text{H}_5\text{O}_3\text{Na}$.

Corresponding copper complexes were first mentioned in 1845 by Pelouze (*Annalen*, 1845, **53**, 112) and subsequently by Strecker (*ibid.*, 1847, **61**, 216), and by Dossios (*ibid.*, 1868, **146**, 174). The last claims that *d*-lactic acid is incapable of yielding them.

Henderson and J. Prentice adopted another method of preparation of the tungsten complex, namely, by the interaction of sodium tungstate and lactic acid, and in this way obtained confirmation of their conclusions from the examination of the optical activity of a solution of tungsten trioxide in one of potassium lactate.

Pickering (*T.*, 1912, **101**, 174) introduced a further method for the formation of these lactic acid complexes when he investigated the reaction between alkalis and copper lactate, but, owing to a partial precipitation of the copper hydroxide before the solution became alkaline, he was unable to arrive at any conclusion as to the composition of the copper complexes, although he showed that about two molecules of caustic soda per atom of copper could be added without thereby rendering the solution alkaline to phenolphthalein, whilst after the addition of one only, a precipitate was formed.

Working along the same lines as Pickering, the author has found that, if the precipitation of copper hydroxide be prevented by suitable means, one molecule of copper lactate will react with two of caustic soda to form a salt—neutral to litmus and phenolphthalein—of a complex copper-containing acid. The addition of further caustic soda renders the solution strongly alkaline to these indicators. The copper-ion concentration (which is of the order 10^{-2} in a copper lactate solution containing 1/20 gram-atom of copper per litre) falls from 10^{-5} in the neutral solution, containing the maximum quantity of alkali for neutrality, to 10^{-11} when the solution is made alkaline by the addition of a further small amount of alkali.

There is little doubt that, in solution, a compound,

or $\text{Cu}(\text{C}_3\text{H}_4\text{O}_3\text{Na})_2$, exists, and that the copper of this complex is present mainly in the anion. Since this compound is neutral, the sodium atoms must occupy positions in the carboxyl groups of the lactic acid nuclei, for if they replaced alcoholic hydrogen atoms, the resulting compound would certainly be alkaline. The compound probably has the structure $\text{Cu}(\text{O}-\text{CHMe}-\text{CO}_2\text{Na})_2$, in which copper is represented as replacing the hydrogen atoms of two alcoholic hydroxyl groups. This explanation of the constitution is in agreement with that of Henderson and his collaborators for their molybdenum complex, $\text{O}_2\text{Mo}(\text{O}-\text{CHMe}-\text{CO}_2\text{K})_2$.

It is of interest to note that the compounds formed by salicylic acid—the analogous aromatic monobasic mono-hydroxy-acid—are of the same type. Weith (*loc. cit.*) and Pickering (*loc. cit.*) have shown that it is probable that the primary reaction occurs between one molecule of copper salicylate and two of caustic soda.

It will be seen that on this view of their constitution the lactic acid complexes are regarded as being very closely related to those derived from the alcohols. In all compounds in which copper functions as a connecting link between two alcoholic hydroxyl groups, it is to be expected that hydrolysis will readily occur, for the hydroxyl group must be weakly acidic. Likewise, the corresponding boron complexes would be readily attacked by water, for the alcoholic hydroxyl group cannot be strongly basic. For this reason, most of the compounds formed between the alcohols themselves and either basic or acidic oxides would be hydrolysed more or less readily, thus accounting for their known instability.

Certain compounds, such as the salts of the tartar emetic type, the neutral cupritartrates, and the cuprimalates, which will be described in a later communication, exhibit a much greater stability, but in these it is highly probable that another type of linking

occurs, the heavy metal functioning as a connecting link between hydroxyl and carboxyl groups. At any rate, it is possible to affirm that wherever the possibility of this type of linking occurs, the complexes exhibit an unusual stability. Generally, this linking is not possible among the derivatives of the monobasic mono-hydroxy-acids, and certainly they are none too stable.

EXPERIMENTAL.

The Reaction between Sodium Hydroxide and Copper Lactate.—

The copper lactate was prepared from freshly precipitated copper hydroxide and lactic acid [Found : Cu = 22·8; C = 25·2; H = 5·0. $\text{Cu}(\text{C}_3\text{H}_5\text{O}_3)_2 \cdot 2\text{H}_2\text{O}$ requires Cu = 22·9; C = 25·9; H = 4·9 per cent.]. Compare Engelhardt and Maddrell (*Annalen*, 1847, 63, 84).

On the addition of caustic soda to a solution of this salt, there is, at first, no precipitation of copper hydroxide and the solution remains neutral; the colour, however, deepens considerably. When the ratio of caustic soda (mols.) to copper (atoms) is about one—the exact ratio depending on the concentration of the solutions—cupric hydroxide begins to separate. As the amount of alkali is increased, more copper is precipitated, but much still remains in solution when the ratio $2\text{NaOH} : \text{Cu}$ is reached. At about this point the solution becomes alkaline to litmus and phenolphthalein, and if it be heated the whole of the copper will be precipitated as copper oxide. If still more alkali be added, the liquid will become strongly alkaline and there will be an intensification of its colour; it can then oxidise glucose, thus resembling Fehling's solution and other alkaline cupric solutions.

Evidently, as in the case of the cupritartrates (*loc. cit.*), a salt of some complex acid, which will be called *cuprilactic acid*, is formed by the reaction between caustic soda and cupric lactate. Moreover, this acid must be a moderately strong one, since its sodium salt is neutral. But owing to the instability of the sodium salt, which readily breaks down into sodium lactate and cupric hydroxide, it is impossible to derive its composition from these simple experiments as was done in the case of the cupritartrates.

Although sodium cuprilactate partly decomposes into sodium lactate and copper hydroxide, a certain amount of the latter dissolves in a solution of the former. The reaction which results in the precipitation is therefore a reversible one, and the events occurring when caustic soda is added to a solution of copper lactate are represented by the equation

As is to be expected, the addition of sodium lactate, whilst it cannot affect the complex, drives the second reaction to the left, or, what is the same thing, prevents the precipitation of copper hydroxide. It is thus possible to prove that the ratio for neutrality is two molecules of alkali per molecule of copper lactate, irrespective of whether the complex has been stabilised by the addition of excess sodium lactate or not.

Attempts to Isolate certain Cuprilactates.—All attempts to isolate sodium cuprilactate in a reasonably pure condition proved futile. In solution, it is stable only in the presence of a large excess of sodium lactate. Addition of alcohol to an aqueous solution stabilised by the lactate is without apparent effect, but acetone causes separation into two layers, the lower one being rich in the cuprilactate. From it much of the simple lactate may be removed by repeated washings with dilute acetone, and finally, if most of the water be removed by a few applications of anhydrous acetone, the whole mass, which has now become very viscous, will suddenly crystallise. But the sodium cuprilactate so formed always contains a large proportion of colourless sodium lactate crystals, and decomposition prevents purification by recrystallisation.

Similar attempts to isolate the ammonium, potassium, and barium cuprilactates proved unsuccessful; the latter two decompose even more readily than the sodium salt.

Unfortunately, too, none of the heavy-metal salts of cuprilactic acid is sufficiently insoluble in water to be precipitated by double decomposition between a solution of sodium cuprilactate, stabilised by means of sodium lactate, and a soluble salt of the metal in question.

It therefore appears that, owing to their instability, these neutral cuprilactates would be isolable only with great difficulty. Nevertheless, some information concerning their properties in solution seems worth recording. They are incapable of oxidising glucose, and in this property they show a resemblance to all other *neutral* copper-hydroxy-acid complexes. Hydrogen sulphide precipitates cupric sulphide from their solutions, and consequently there must be some slight concentration of copper-ions present. In order to obtain some idea of the degree of complexity of the compounds, it seemed desirable to measure this concentration.

Copper-ion Concentration.—Use was made of the Nernst formula,

$$E = EP + \frac{RT}{nF} \cdot \log_e C;$$

for copper at 18°,

$$E = 0.606 + 0.029 \log_{10} C,$$

where E volts signifies the potential difference between a copper electrode and a solution containing copper-ions at a concentration C .

The single copper electrode was connected, through a closed ungreased tap and a saturated potassium chloride solution, with a normal calomel electrode. All traces of oxygen were removed before the introduction of the copper electrode by bubbling oxygen-free nitrogen through the solution. The difference of potential of the combined cell was measured by the usual "compensation method." As the measured difference was always small, the combined cell was connected first in series with, and then against, the standard Weston cell, and the mean of the two observed differences of potential adopted.

Some difficulty was experienced in preparing copper electrodes which would give consistent values. When, finally, the following method was adopted, no trouble was found in obtaining electrodes which gave values agreeing to within one millivolt. The differences between electrodes which have been coated electrolytically with copper are usually ascribed to strains set up in the metal during electrodeposition. It seemed that the best way of removing these strains would be reversal of the current. Initially, half a dozen rods of pure copper wire were connected in parallel as the cathode, in a solution of cupric sulphate acidified by sulphuric acid and containing a little alcohol, the anode being a pure copper rod, and a current of 1 milliamp./sq. cm. of cathode was passed for some hours. Three of the rods were then used as cathode and three as anode, and the current was reversed at frequent intervals for an hour or two. Occasionally one electrode would not become uniform with the others, even after this treatment; if the discrepancy was greater than a millivolt, the electrode was discarded.

The single electrode potential differences were probably correct to within two or three millivolts. This error is unimportant in the determination of ionic concentrations by the Nernst method, since as a rule it is only the order of the concentration that is required. Nevertheless, a very small error in the determination of the potential difference leads to a much greater one in the final result. The following table shows the relation between an error of x millivolts in the measurement and the percentage error in the corresponding calculated ionic concentration.

x	1	2	3	4	5	10	-1	-2	-3	-4	-5	-10
Percentage error in C.	8	17	27	37	49	120	-8	-15	-21	-27	-33	-55

The following table shows the effect of the addition of caustic soda on the cupric-ion concentration of a solution of copper lactate. All solutions were $M/20$ with respect to copper, and the temperature was 18° .

Molecules of NaOH per mol. of $\text{Cu}(\text{C}_2\text{H}_3\text{O}_2)_2$.	Single electrode potential difference.	Copper-ion concentration.
0	0.545 volt	7.9×10^{-3}
0.10	0.546 "	8.5×10^{-3}
0.50	0.541 "	5.6×10^{-3}
(a) 0.67	0.516 "	8.3×10^{-4}
1.00	0.489 "	1.0×10^{-4}
2.00	0.441 "	2.4×10^{-4}
(b) 2.70	0.306 "	5.0×10^{-11}
3.50	0.283 "	8×10^{-12}

(a) A precipitate of copper hydroxide began to form at this stage.

(b) These solutions were prevented from precipitating any copper by the addition of sufficient sodium lactate; the results are not therefore strictly comparable with the others. It will be seen, however, that the addition of the lactate was without any marked effect.

It will be noticed that until all the copper lactate has been acted upon by the alkali, there is no very marked diminution in the copper-ion content, and that whereas the lactate gives a value of the order of 10^{-2} , that for the complex is of the order 10^{-5} . Nevertheless, this small value is sufficient to give with the hydroxyl-ions present a value of $[\text{Cu}^{++}] \times [\text{OH}']^2$ greater than the solubility product of cupric hydroxide, and therefore the latter is thrown out of solution unless retained by some artifice.

In alkaline solutions, the concentration of the cupric-ion is very small, and at the same time there is a great intensification of the colour of the solution, which can now oxidise glucose. Very little copper will remain in solution unless there is a large excess of free sodium lactate present.

Summary.

1. The compounds formed between the higher alcohols, the sugars, and hydroxy-acids and certain acidic oxides on the one hand, and certain basic oxides on the other, are of the same structural type, and the alcoholic hydroxyl group may function either as a base or as an acid in their formation.

2. The metallic complexes are the more stable, the more strongly the alcoholic hydroxyl group functions as an acid: this leads to an explanation why it is that only the α -hydroxy-acids in the aliphatic series and the ortho-phenolic acids in the aromatic series form such complexes.

3. The reaction between caustic soda and copper lactate has been investigated and evidence adduced to support the view that a compound of the composition $[\text{Cu}(\text{O}_3\text{H}_4\text{C}_3)_2]\text{Na}_2$ is formed.

4. The degree of complexity, as estimated by the cupric concentration, has been measured.

In conclusion, the author has much pleasure in expressing his

thanks to Professor F. G. Donnan for his kind advice and assistance, and to the Commissioners of the Exhibition of 1851, for a scholarship which has enabled him to carry out this work.

CCIV.—*Metallic Hydroxy-acid Complexes. Part II.* *Cuprimalates. Their Formation, Properties, and* *Composition.*

By IAN WILLIAM WARK.

ALTHOUGH comparatively little work has been carried out on the complex compounds of malic acid and cupric hydroxide, there is a fairly extensive literature dealing with those formed by other hydroxides—both basic and acidic. A short account of the more important papers is now given.

Glucinum complexes: Rosenheim and Itzig (*Ber.*, 1899, **32**, 3433). Two series are described, monoglucinum-malates, $M_2O \cdot 2G10 \cdot 2C_4H_4O_4$, and diglucinum-malates, $M_2O \cdot 4G10 \cdot (C_4H_3O_3)_2O$.

Arsenic and antimony complexes: Henderson and Prentice (*T.*, 1895, **67**, 1030) and Henderson and Barr (*T.*, 1896, **69**, 1451). Unstable derivatives of antimoniomalic acid,

are described.

Boron complexes: Adam (*Compt. rend.*, 1894, **118**, 1274); Grossmann and Wieneke (*Z. physikal. Chem.*, 1906, **54**, 385). From measurements of optical rotation the latter authors suggest that a complex $NH_4C_4H_5O_5 \cdot HBO_2$ exists.

Thorium complexes: Rosenheim, Samter, and Davidsohn (*Z. anorg. Chem.*, 1903, **35**, 424). Sodium, ammonium, and potassium thoriomalates are described. Type, $ThO(C_4H_4O_5K)_2$.

Uranium complexes: Itzig (*Ber.*, 1901, **34**, 3822) isolated the sodium salt of a complex uranomalic acid,

Molybdenum and tungsten complexes: Rosenheim and Berthier (*Z. anorg. Chem.*, 1903, **34**, 442) and Rimbach and Neizert (*ibid* 1907, **52**, 397) studied the conductivity of solutions of these complexes. Gernez (*Compt. rend.*, 1889, **109**, 151, 769; 1890, **110**, 521, 1365; **111**, 792), Itzig (*Ber.*, 1901, **34**, 2391), Grossmann and Krämer (*Ber.*, 1903, **36**, 1607; *Z. anorg. Chem.*, 1904, **41**, 50), and Grossmann and Pötter (*Ber.*, 1904, **37**, 85; *Z. physikal. Chem.*, 1901, **56**, 577) worked on their optical activity. Henderson, Orr, and

Whitehead (T., 1899, 75, 542) isolated crystalline compounds belonging to the two series $\text{MoO}_2 \cdot \text{C}_4\text{H}_5\text{O}_5\text{M}$ and $\text{MoO}_2(\text{C}_4\text{H}_4\text{O}_5\text{M})_2$.

Cupric complexes : Grossmann and Loeb (Z. Ver. deut. Zuckerind., 1908, 994) studied the effect of varying amounts of cupric sulphate and caustic soda on the rotatory power of malic acid, and came to the conclusion that a complex sodium copper malate was produced. For this compound, they suggested the composition

Pickering (T., 1912, 101, 174), studying the action of caustic soda on a solution of normal cupric malate, found that one molecule of alkali per atom of copper could be added without thereby precipitating any cupric hydroxide or rendering the solution alkaline, and that the addition of further alkali produced alkalinity. From a very concentrated neutral solution of cupric malate in caustic potash, he obtained a fine, dark blue, crystalline solid which, after drying at 100° , contained 26.12 per cent. of copper and 16.76 per cent. of potassium (Calc. for $\text{C}_8\text{H}_8\text{O}_{11}\text{Cu}_2\text{K}_2$, Cu = 26.19; K = 16.11 per cent.).

Following the methods adopted in the analogous work on the cupritartrates and the cuprilactates, the author wished to investigate the reaction between caustic soda and the normal and acid malates of copper. Difficulties were encountered in the preparation of the latter salts, and it was not until a somewhat detailed study of the ternary system malic acid-cupric hydroxide-water had been made that it became possible to prepare them at will.

A rather curious transformation occurs when the crystalline trihydrate of normal cupric malate is heated at 100° . It loses all three molecules of water of crystallisation, its colour meanwhile deepening to a bright lavender blue. Now the trihydrate has a colour very similar to that of ordinary copper sulphate, which, as is well known, loses its blue colour when dehydrated, and therefore it seemed probable that some deep-seated change must occur during the dehydration of the malate. This conclusion receives support from the fact that, in marked contrast with the normal cupric salts of organic acids, the product of dehydration is extremely soluble in water. A satisfactory explanation of this phenomenon is that, during dehydration, cupric malate undergoes an intramolecular rearrangement, "cuprimalic acid" being formed according to the equation $\text{CuC}_4\text{H}_4\text{O}_5 \rightarrow \text{H} \cdot \text{CuC}_4\text{H}_3\text{O}_5$.

In solution, measurements of copper-ion concentration and of the apparent molecular weight show that an equilibrium is quickly established between these two isomerides, the normal malate largely preponderating. Nevertheless, there is always present a sufficient concentration of hydrogen- and of cuprimalate-ions to give to the

solution some very characteristic properties not possessed by the copper salts of the simpler fatty acids. For instance, the solution is strongly acid to litmus and will remain so until one molecule of caustic soda per atom of copper has been added. This action is simply one of neutralisation: $\text{NaOH} + \text{H} \cdot \text{CuC}_4\text{H}_3\text{O}_6 \rightarrow \text{H}_2\text{O} + \text{NaCuC}_4\text{H}_3\text{O}_6$. As the added alkali reacts with the small quantity of the acid which is present initially, some of the normal cupric malate changes into the acid in an endeavour to maintain the equilibrium between them. When sufficient alkali has been added, no cupric malate will remain and the solution will contain sodium cuprimalate only.

A solution of acid cupric malate, $\text{Cu}(\text{C}_4\text{H}_3\text{O}_6)_2$, behaves towards alkalis like a mixture of malic acid and normal cupric malate. On neutralisation, a mixture of the sodium salts of malic and cuprimalic acids is formed.

Several of the cuprimalates have been isolated in a fairly pure, crystalline form. The alkali-metal salts are very soluble in water and their solutions exhibit no tendency to deposit copper hydroxide. Thus they are much more stable than the corresponding cuprilactates and of about the same degree of stability as the cupritartrates. Barium, silver, mercurous, and lead cuprimalates are much less soluble than the alkali-metal salts and are easily prepared by double decomposition. One of the most interesting compounds in this series is cupric cuprimalate, $\text{Cu}(\text{CuC}_4\text{H}_3\text{O}_6)_2$ or $\text{Cu}_3(\text{C}_4\text{H}_3\text{O}_6)_2$, first described by Liebig (*Annalen*, 1838, 26, 137), which has been regarded as a basic cupric malate up to the present time.

The degree of stability of the cuprimalates may be judged from the value of the copper-ion concentration in *N*/20-solutions of the sodium and ammonium salts. This is of the order of 10^{-4} , about 1/100 of its value in a solution of cupric malate containing the same quantity of copper per litre. Molecular-weight determinations which have been made in solutions of various cuprimalates indicate that association occurs fairly generally. In more dilute solutions, the associated molecules break down to a certain extent.

EXPERIMENTAL.

A. The Ternary System Malic Acid-Cupric Hydroxide-Water.

Several compounds belonging to this system have been mentioned in the literature (Liebig, *loc. cit.*; Pickering, *loc. cit.*; T., 1913, 103, 1355; Hagan, *Annalen*, 1841, 38, 257; Traube, *Z. Kryst. Min.*, 1898, 31, 162; Luck, *Annalen*, 1845, 54, 117).

In the present work, only three of these salts—Liebig's salt, Hagan's acid malate dihydrate, and Pickering's crystalline normal malate—have been obtained from solution, but it is not claimed that

the work on the system is at all complete. Another compound, of the composition $2\text{Cu}(\text{OH})_2 \cdot \text{C}_4\text{H}_6\text{O}_6$, is described in a subsequent section (D), but its field is not shown in the diagrams. In describing the relationships between these compounds, it will be expedient to consider briefly the form of the isotherms of the ternary system at 15° and at 50° . No solubilities have been measured, so the diagrams are purely qualitative. Nevertheless, they do show why it is that, at the ordinary temperature, neither the normal nor the acid cupric malate can be purified by recrystallisation, a fact which was, at first, rather perplexing.

Fig. 1 shows the form of the isotherm at 15°. *a*, *b*, and *c* represent the three solid phases $\text{Cu}_3(\text{C}_4\text{H}_5\text{O}_5)_2 \cdot 7\text{H}_2\text{O}$, $\text{Cu}_4\text{H}_4\text{O}_5 \cdot 3\text{H}_2\text{O}$, and $\text{Cu}(\text{C}_4\text{H}_5\text{O}_5)_2 \cdot 2\text{H}_2\text{O}$, respectively. The solubilities of Liebig's salt

FIG. 1.

Fig. 2.

and of the normal malate have been grossly exaggerated in the figures.

Like many other hydroxy-compounds, these salts crystallise very slowly, even from highly supersaturated solutions. Sometimes a week will elapse before the normal salt begins to crystallise, and "seeding" does not hasten matters. A further complication arises from the fact that a fungus growth sometimes forms on the surface of a solution exposed to the air.

A solution of the acid malate may be represented by some point, *d*, on the line joining *c* and *A*. Evaporation will bring its composition back along the same line to a point *e* where crystallisation will result in the formation of the normal salt. Thus the acid salt cannot be recrystallised from its own solution. Neither can the normal salt, as a glance at Fig. 1 will show.

Fig. 2 shows the general features of the 50° isotherm. As the temperature rises, the solubility of the normal salt increases very

rapidly, and at the temperature of this isotherm it occupies no stable region. Thus, at this temperature, the acid malate will begin to crystallise from its own solution, and, once started, this process will continue at a lower temperature where it is not so soluble, although, of course, the crystals are then metastable.

The analytical figures are now given upon which the evidence for the existence of those compounds is based and some of the properties of the salts are discussed.

Liebig's salt forms small, green crystals which are only very slightly soluble in water. It is readily soluble in acids and in ammonia, to which it imparts an extremely intense colour. Attempts to induce crystallisation in this solution proved futile. The analysis of a sample dried to constant weight at 100° confirmed the composition which Liebig adopted [Found: Cu = 34.96; C = 17.55; H = 3.04. Calc. for $\text{Cu}(\text{CuC}_4\text{H}_3\text{O}_5)_2, 5\text{H}_2\text{O}$, Cu = 35.14; C = 17.69; H = 2.97 per cent.].

Acid cupric malate crystallises in well-formed, pale blue plates which are much more soluble than Liebig's salt. They retain their water of crystallisation at 105° . Analysis pointed to the composition $\text{Cu}(\text{C}_4\text{H}_3\text{O}_5)_2, 2\text{H}_2\text{O}$ (Found: Cu = 17.35; C = 26.04; H = 4.27. Calc., Cu = 17.39; C = 26.25; H = 3.87 per cent.).

Normal cupric malate crystallises in beautiful clusters of long, deep blue needles. It is difficult to estimate the solubility of this salt, but it must be fairly low. It dissolves so slowly at the ordinary temperature that before the solution becomes saturated Liebig's salt will separate out. At higher temperatures, it dissolves with great rapidity and its solubility is high. Analysis showed it to be the trihydrate; figures for three different samples are quoted [Found: Cu = 25.49 (I), 25.47 (II), 25.47 (III); C = 19.58 (I), 19.46 (II); H = 4.15 (I), 4.12 (II); H_2O = 21.21 (II), 21.65 (III). $\text{CuC}_4\text{H}_4\text{O}_5, 3\text{H}_2\text{O}$ requires Cu = 25.47; C = 19.22; H = 4.04; H_2O = 21.65 per cent.]. Water was estimated by heating the substance to constant weight at 110° ; at 120° , it begins slowly to decompose. The same dehydration occurs slowly over phosphoric oxide in a vacuum desiccator (Found: H_2O = 19.2 per cent.).

A remarkable change occurs during the dehydration. The colour deepens and the product of dehydration is extremely soluble in water. At first it was thought that the apparent differences in solubility between this compound and the hydrate might be due to the extreme slowness with which the latter dissolves. But it was found that the anhydrous lavender-blue substance was very soluble in a solution from which the hydrate was crystallising. This seems to indicate that some profound change accompanies dehydration, and from the colour and high solubility

of the anhydrous compound it is very probable that it is one of the typical complexes which contain copper in the negative radicle. A large series of complex salts of an acid of the same composition as this substance has now been isolated, and therefore, in view of its seemingly complex nature, it is only reasonable to regard it as the acid itself. Thus, in the sequel, it will be called *cuprimalic acid*, $\text{H}\cdot\text{CuC}_4\text{H}_3\text{O}_5$.

B. The Reaction between Alkalis and Normal Cupric Malate.

Either hydrated cupric malate or the isomeric cuprimalic acid may be used. The action of alkali on either, whether in solution or in the solid state, leads to the same products. The reaction is essentially one of neutralisation, any normal cupric malate present first changing into the acid and then undergoing neutralisation according to the equations $\text{CuC}_4\text{H}_4\text{O}_5 = \text{H}\cdot\text{CuC}_4\text{H}_3\text{O}_5$ and $\text{H}\cdot\text{CuC}_4\text{H}_3\text{O}_5 + \text{NaOH} \rightarrow \text{NaCuC}_4\text{H}_3\text{O}_5 + \text{H}_2\text{O}$. The solution remains acid right up to the point of neutralisation and its colour deepens considerably during the addition of the alkali. Further addition of alkali renders the solution alkaline to litmus or phenolphthalein and there is an immediate precipitation of copper hydroxide. A large excess of dilute alkali throws most of the copper out of solution, but sufficient always remains to give to it a violet-blue colour. Very concentrated solutions of caustic soda may retain quite a lot of copper in solution, and, on standing, some crystals are deposited; these have not yet been analysed.

It may be demonstrated by Masson's electrolytic method (*Phil. Trans.*, 1899, 192, [A], 331) that the copper of the neutralised solution is mainly present in the negative ion. Some indication is given, too, of a blue kation, which moves away from the anode compartment. This is presumably the copper-ion, and experiments which are described in a later section show that there is present a definite, although low, concentration of copper-ions. There is a precipitation of copper hydroxide around the cathode, due, no doubt, to the interaction between the neutral salt and the caustic soda which is liberated there.

C. The Reaction between Alkalis and Acid Cupric Malate.

Three molecules of caustic soda per atom of copper are necessary to neutralise a solution of acid cupric malate, and about one extra molecule may be subsequently added before the precipitation of copper hydroxide commences. At first sight, this appears to be an entirely different reaction from that of alkali on the normal malate. But it has been shown that the same sodium and barium salts may

be thrown out of either solution and it has been established that the reaction may be represented by the equation

The acid malate, therefore, behaves as an equimolecular mixture of the normal malate and malic acid, the former requiring one and the latter two molecules of caustic soda for neutralisation. The free sodium malate produced during the reaction evidently opposes the precipitation of copper hydroxide formed by the reaction

and so it is possible to add some alkali after the point of neutralisation is reached without thereby precipitating any copper hydroxide. The alkaline solution thus produced is of the intense violet-blue colour characteristic of all alkaline cupric solutions and, like Fehling's solution, is able to oxidise glucose. (The neutral compounds never oxidise glucose and are of a paler colour.)

D. Salts of Cuprimalic Acid.

The production of sodium cuprimalate by the interaction between solutions of copper malate and caustic soda has already been described. Potassium and ammonium malates may be similarly prepared. The majority of the other cuprimalates are fairly soluble in water, and so it is not usually possible to prepare them by double decomposition. A few of the heavy metals do form comparatively insoluble salts in this way: barium, silver, lead, copper, and mercury (Hg'). Some of the others, for example, manganese, tin, and ferric iron, although their salts do not yield a precipitate with sodium cuprimalate, decolorise the solution, presumably by replacing, or partly replacing, the copper in the complex. An account of some of these cuprimalates follows.

Sodium Cuprimalate.—On the addition of absolute alcohol to a solution of sodium cuprimalate prepared as above, a separation into two liquid phases occurs. From the lower of these, which contains most of the complex, the water may be removed by repeatedly washing it with absolute alcohol until finally it crystallises. It is not necessary to start with pure crystalline cupric malate. Instead, cupric carbonate or hydroxide may be dissolved in the right amount of malic acid solution, and the mixture neutralised by caustic soda. Often, however, the tricupric malate of Liebig will crystallise out before the alkali can be added, and the preparation is then lost.

Better crystals may be obtained by adding alcohol or acetone to the point of an incipient cloudiness and keeping the solution for a week: at the end of this time, nearly all of the copper will have been deposited in the form of fine, deep blue crystals. Before analysis, the crystals were purified by recrystallisation and air-dried. The

PART II. CUPRIMALATES. THEIR FORMATION, PROPERTIES, ETC. 1833

figures point to a composition $\text{NaCuC}_4\text{H}_3\text{O}_5, 4\text{H}_2\text{O}$ (Found: Cu = 21.75, 21.68; Na = 7.63, 7.65; C = 16.59; H = 3.83. Calc., Cu = 21.94; Na = 7.94; C = 16.57; H = 3.82 per cent.). Sodium was estimated as carbonate after ignition in an electric furnace at 650° . Copper was estimated either electrolytically after ignition, or its percentage was deduced from the weight of the residue from ignition (which consists of a mixture of sodium carbonate and cupric oxide) and the found sodium content. Carbon and hydrogen were estimated by combustion, the former in the presence of lead and potassium chromates, which, when fused, prevent the retention of carbon dioxide by sodium. The salt loses all four molecules of water at 120° (Found: H_2O = 23.7. Calc., H_2O = 24.85 per cent.), and begins to decompose at 130° .

Another method may be adopted for the production of the alkali metal cuprimalates. As much copper hydroxide as possible is dissolved in a solution of the desired alkali metal acid malate, when the following reaction takes place—

Ammonium Cuprimalate.—It has been mentioned that the attempt to prepare sodium cuprimalate is sometimes thwarted by the precipitation of Liebig's salt during the preparation of a solution of the normal cupric malate. If the ammonium salt be desired, this precipitate is not fatal to the preparation, for it may be dissolved in an excess of ammonia. On removal of the excess of ammonia by heating on a water-bath, a pure solution of ammonium cuprimalate remains. Pure crystals separate out from such a solution to which sufficient acetone has been added to produce a slight cloudiness. Before analysis, the bright blue crystals were purified by recrystallisation, and, as they were deliquescent, were rapidly dried by acetone and ether (Found: Cu = 23.16, 23.10; N = 4.90, 4.81; C = 17.21; H = 5.72. $\text{NH}_4\text{CuC}_4\text{H}_3\text{O}_5, 4\text{H}_2\text{O}$ requires Cu = 22.33; N = 4.92; C = 16.86; H = 5.30 per cent.). Nitrogen was estimated as ammonia liberated by boiling the compound with alkali. All four molecules of water were lost at 110° (Found: H_2O = 24.96. Calc., H_2O = 25.31 per cent.).

Ammonium cuprimalate also forms in large, spherular aggregates of bright, needle-shaped crystals from a very concentrated aqueous solution. Usually it is contaminated with a little of Liebig's salt when allowed to form in this way.

Potassium Cuprimalate.—This salt cannot be induced to crystallise by adding alcohol or acetone to its aqueous solution. Like the potassium salt of many other complex cupri-acids, it passes into an emulsion instead. As a general rule, however, the potassium

salts are less soluble than the corresponding sodium salts and they may often be crystallised from a concentrated aqueous solution. Potassium cuprimalate readily crystallises, but, like the ammonium salt, it is usually contaminated with crystals of Liebig's salt. After drying at 100° , one sample, not so badly contaminated as most others, contained 28.0 per cent. of copper and 14.8 per cent. of potassium ($\text{KCuC}_4\text{H}_3\text{O}_5$ requires $\text{Cu} = 27.2$; $\text{K} = 16.7$ per cent.).

Barium Cuprimalate.—This be may prepared as a pale blue, granular precipitate by double decomposition between solutions of barium chloride and sodium cuprimalate. Although sparingly soluble in cold, it is much more soluble in hot water and may be purified by recrystallisation. For analysis, a sample was recrystallised twice and air-dried. (The exact estimation of the water of crystallisation was unimportant, since the object of the work was to examine the constitution of the compounds rather than their individual characteristics. Accordingly, it was unnecessary to take any elaborate precautions in drying the compounds.) Analysis indicated a composition $\text{Ba}(\text{CuC}_4\text{H}_3\text{O}_5)_2 \cdot 7\text{H}_2\text{O}$, but it is possible that the number of water molecules may be one more or less than 7 (Found: $\text{Ba} = 20.35, 20.90$; $\text{Cu} = 19.32$; $\text{C} = 14.67$; $\text{H} = 3.33$; $\text{H}_2\text{O} = 17.6$. Calc., $\text{Ba} = 21.06$; $\text{Cu} = 19.48$; $\text{C} = 14.71$; $\text{H} = 3.10$; $\text{H}_2\text{O} = 19.3$ per cent.). Barium was estimated as sulphate, first on the pure salt, and again after ignition. Copper was estimated electrolytically after ignition. In the estimation of carbon, admixture with lead and potassium chromates prevented the retention of carbon as barium carbonate. Water was estimated by heating the salt to constant weight at 120° ; at 130° , decomposition proceeds slowly.

Silver Cuprimalate.—This salt may be prepared by double decomposition between solutions of sodium or ammonium cuprimalate and silver nitrate. It forms pale blue granules which are soluble in excess of the cuprimalate and darken when exposed to light. For this reason the salt was prepared in artificial light; it then proved to be perfectly stable when kept for some months in a darkened place.

In the analysis, silver was estimated as chloride after the compound had been ignited, and copper electrolytically after removal of the silver. It is not possible to estimate satisfactorily the amount of water of crystallisation, for the compound is decomposed by heat before all the water is expelled. The figures showed it to be a dihydrate (Found: $\text{Ag} = 33.0$; $\text{Cu} = 17.9$; $\text{C} = 14.2$; $\text{H} = 1.9$. $\text{AgCuC}_4\text{H}_3\text{O}_5 \cdot 2\text{H}_2\text{O}$ requires $\text{Ag} = 31.9$; $\text{Cu} = 18.8$; $\text{C} = 14.2$; $\text{H} = 2.1$ per cent.).

Lead Cuprimalate.—This compound, which may be formed by double decomposition between solutions of sodium cuprimalate and lead acetate, resembles the silver salt in appearance and, like it, is soluble in excess of sodium cuprimalate. It is not sufficiently soluble in water to enable it to be purified by recrystallisation, and for analysis the precipitate was merely washed with hot water and then air-dried. The lead content is considerably higher and the copper content is much lower than the amounts that would correspond with the formation of a simple cuprimalate. It is suggested that the lead has partly replaced the copper of the complex ion (Found: Pb = 41·8; Cu = 11·7; C = 12·2; H = 1·7 per cent. for which the ratio Pb : Cu : C : H = 1·00 : 0·92 : 5·05 : 8·4. If a simple cuprimalate had been formed, the ratio would have been 1 : 2 : 8 : x).

It is of interest to note that Masson and Steele, in their work on the cuprotartrates (T., 1899, 75, 725), found a similar high lead content: they ascribed it to adsorption effects.

Cupric Cuprimalate.—As was pointed out earlier, Liebig's tricupric malate is the copper salt of cuprimalic acid. Its low solubility dominates the chemistry of the cuprimalates, giving to them an instability which somewhat overshadows their great stability in another respect, namely, that, like the α -cupritartrates, their solutions have no tendency to deposit copper hydroxide. It is easily seen why this salt so readily forms in solutions of normal cupric malate or any of the soluble cuprimalates. As has been already emphasised, a solution of normal cupric malate changes partly into the isomeric cuprimalic acid, so that both cupric (Cu^{++}) and cuprimalic ($\text{CuC}_4\text{H}_3\text{O}_5$)' ions will be present. Both of these ions are also present in a solution of sodium or ammonium cuprimalate. In either case, if the concentration be sufficiently high, the solubility product of cupric cuprimalate, a very insoluble salt, may be exceeded and then precipitation results.

The law of mass action also affords an explanation of why it is that this compound is soluble in malic acid. The following equations will serve to make the point clear.

If to a saturated solution of Liebig's salt, which will contain a certain concentration of both cupric and cuprimalic-ions (1), malic

acid be added (2), there will be formed a quantity both of cupric malate and of cuprimalic acid (equations 3 and 4). One of these reactions will reduce the concentration of the cupric-ion and the other that of the cuprimalic-ion, and accordingly more of the solid will dissolve in an endeavour to maintain its solubility product constant.

Accepting this view of the nature of Liebig's salt, one would expect it to form by double decomposition between solutions of cupric sulphate and sodium cuprimalate according to the equation $\text{CuSO}_4 + 2\text{NaCuC}_4\text{H}_3\text{O}_5 \rightarrow \text{Na}_2\text{SO}_4 + \text{Cu}(\text{CuC}_4\text{H}_3\text{O}_5)_2$. When solutions were mixed in the proportions required by this equation, there was no immediate precipitate, but on boiling, or on keeping the solution for some time, bluish-green crystals were deposited. These resembled Liebig's salt in appearance and, like it, were soluble in excess of cuprimalate. But analysis of a sample dried at 100° showed it to be a basic salt containing more copper than Liebig's salt. A second sample was obtained using ammonium instead of sodium cuprimalate; the analyses of the two samples are marked I and II, respectively [Found: Cu = 40.75 (I), 40.69 (II); C = 15.60 (I), 15.24 (II); H = 2.8 (I), 2.4 (II).

requires Cu = 40.85; C = 15.43; H = 2.6 per cent.].

Cuprimalic Acid.—It has been contended that cuprimalic acid is formed in the solid state by the dehydration of a hydrate of normal cupric malate. An attempt was made to prepare it in solution by the action of sulphuric acid on a suspension of barium cuprimalate, care being taken that there was no excess of the mineral acid. A deep blue solution was obtained which was acid to litmus. The solution could be neutralised by alkalis and then gave a precipitate of the original cuprimalate with a solution of barium chloride. The solution was in every way identical with one of the lavender-blue acid itself or with one of normal cupric malate. All three deposit crystals of Liebig's salt on standing; this enriches the solution in malic acid, and after a time, the normal malate will separate out too.

E. Molecular Weights.

The cryoscopic method was used. The freezing points of the aqueous solutions were probably correct to within 0.005° . This figure corresponds with an error of about 15 units in the more dilute solutions used. In the table, a = gram-atom of copper per litre, Δ = depression of freezing point, and m = apparent molecular weight.

Ammonium cuprimalate. $M = 212.6$.			Sodium cuprimalate. $M = 217.6$.			Cuprimalic acid. $M = 195.6$.		
α .	Δ .	m .	α .	Δ .	m .	α .	Δ .	m .
0.0500	0.120°	167	0.05	0.108°	188	0.05	0.069°	264
0.0875	0.170	203	0.10	0.218	187	0.10	0.119	306
0.262	0.498	206	0.20	0.390	208	0.20	0.185	394
0.392	0.770	202	0.50	0.932	218	0.50	0.382	477
						(0.10)	(0.111)	(328)

The values obtained for the two salts point to a partial association among the cuprimalate-ions. Were no such association to occur, ionisation of these salts would certainly give rise to much lower values of the apparent molecular weights. Association is much more advanced in concentrated than in dilute solutions; $N/20$ -solutions show a considerably lower value than $N/2$ -solutions.

The figures enclosed in brackets were obtained using a solution of normal cupric malate instead of the acid. Their nearness to the corresponding values for cuprimalic acid indicates that these compounds yield identical solutions, a conclusion which is thoroughly confirmed by the measurements of the concentrations of the copper-ion which are described in the next section. In concentrated solutions especially, there is a high degree of association. Tower (*J. Amer. Chem. Soc.*, 1902, **24**, 1012) observed similar high molecular weights in solutions of nickel and cobalt malates, and correspondingly low conductivities.

F. Copper-ion Concentrations.

The method of making the measurements has been described in the preceding paper (p. 1815). The temperature used throughout was 18°.

Normal Cupric Malate.—Table I shows the values obtained for solutions containing various concentrations of cupric malate. α represents the degree of dissociation of cupric malate into copper-ions.

TABLE I.

Grm.-atom Cu per litre.	Single electrode potential diff. (volt).	Copper-ion conc. $\times 10^3$.	α per cent.
0.05	0.552	1.4	28
0.10	0.552	1.4	14
0.20	0.555	1.7	8.5
0.25	0.551	1.3	5.2

It was impossible to obtain figures for higher concentrations than those recorded, because Liebig's salt was too readily deposited, or for lower concentrations, because the conductivity became so low that accurate measurements could not be made.

Ionisation increases so much with dilution that 1/4*M*- and 1/20*M*. solutions contain practically the same copper-ion concentration. The figures support the conclusion that in concentrated solutions associated molecules are numerous and that these loose combinations break down in more dilute solutions.

Sodium and Ammonium Cuprimalates.—Table II shows the effect of dilution on the copper-ion concentration of sodium cuprimalate.

TABLE II.

Sodium cuprimalate.

Gm.-atom Cu per litre	0.05	0.10	0.20	0.50
Single electrode pot. diff.	0.486	0.483	0.476	0.473
Copper-ion conc. $\times 10^5$	7.3	5.7	3.3	2.6

It will be seen that whilst the concentration has increased tenfold the number of copper-ions has actually decreased threefold. These figures support the view, previously expressed, that association is more advanced in concentrated than in dilute solutions.

The single electrode potential difference in a solution of the ammonium salt containing 0.05 gram-atom of copper per litre is 0.491 volt, corresponding to a copper-ion concentration of 1.08×10^{-4} .

Cuprimalic Acid.—The copper-ion concentration of a solution of sodium or ammonium cuprimalate containing 0.05 gram-atom of copper per litre is of the order 10^{-4} . That for a solution of normal cupric malate containing the same amount of copper per litre is 1.5×10^{-2} , and an identical value was obtained for a solution of cuprimalic acid of equal concentration. Hence, it is concluded that these two isomerides yield identical solutions, and, further, that in the equilibrium mixture the malate must predominate.

Influence of Alkali on the Copper-ion Concentration of Copper Malate.—Table III shows the effect produced on the copper-ion concentration by the addition of sodium hydroxide to a solution of normal cupric malate. All solutions contained 0.05 gram of copper per litre, unless otherwise indicated.

TABLE III.

Ratio NaOH : CuC ₄ H ₄ O ₆	Single electrode pot. diff. (volt).	Copper- ion conc.	Ratio NaOH : CuC ₄ H ₄ O ₆	Single electrode pot. diff. (volt).	Copper- ion conc.
0	0.554	1.6×10^{-3}	(a) 1.00	0.490	9.8×10^{-4}
0.25	0.537	6.8×10^{-3}	(b) 1.03	0.456	6.6×10^{-4}
0.50	0.526	1.7×10^{-3}	(c) 1.25	0.386	2.5×10^{-4}
0.75	0.519	1.0×10^{-3}	(d) 2.00	0.365	4.8×10^{-4}
0.92	0.503	1.3×10^{-4}			

(a) This solution was prepared from pure sodium cuprimalate. (b) Slightly alkaline. (c) Alkaline. Contained 0.75 gram-atom of copper per litre. (d) Alkaline. Practically all the copper had been precipitated as hydroxide, but sufficient remained in solution to give a slight precipitate with hydrogen sulphide.

As caustic soda is added to the solution of cupric malate, the concentration of the copper-ion falls from 10^{-2} to 10^{-4} during neutralisation. As soon as the solution becomes alkaline there is a further marked fall in the cupric content. Further, since no great quantity of copper remained in the solution marked (d), it will be seen that the reaction

$$\text{H}_2\text{O} + \text{NaCuC}_4\text{H}_3\text{O}_5 + \text{NaOH} \rightarrow \text{Cu(OH)}_2 + \text{Na}_2\text{C}_4\text{H}_4\text{O}_5$$

occurs almost quantitatively.

Influence of Potassium Chloride on the Copper-ion Concentration of Normal Cupric Malate.—It is of interest to compare the above results with those obtained on addition of potassium chloride to a solution of normal cupric malate (Table IV).

TABLE IV.

Ratio KCl : $\text{CuC}_4\text{H}_4\text{O}_5$.	Single electrode pot. diff. (volt).	Copper- ion conc.	Ratio KCl : $\text{CuC}_4\text{H}_4\text{O}_5$.	Single electrode pot. diff. (volt).	Copper- ion conc.
0	0.552	1.4×10^{-2}	2.00	0.499	2.0×10^{-4}
0.50	0.531	2.6×10^{-3}	4.00	0.483	5.8×10^{-5}
1.00	0.515	7.3×10^{-4}			

At first, potassium chloride is almost as effective as caustic soda in reducing the copper-ion concentration. In greater amounts, it has not nearly so much influence. It is probable that some complex formation is responsible for this reduction in the concentration of copper-ions. The figures show clearly why it was so essential to prevent diffusion into the electrode vessel while the potential difference measurements were in progress.

Other Measurements.—For comparative purposes it is interesting to tabulate some of these results along with those obtained for a few other compounds. Sodium α -cupritartrate was described in an earlier paper (Packer and Wark, T., 1921, 119, 1348). All solutions contained 1/20 gram-atom of copper per litre and all measurements were made at 18°.

TABLE V.

Compound.	Single electrode pot. diff. (volt).	Copper-ion conc.
Sodium cuprimalate ($\text{NaCuC}_4\text{H}_3\text{O}_5$)	0.486	7.3×10^{-5}
Ammonium cuprimalate ($\text{NH}_4\text{CuC}_4\text{H}_3\text{O}_5$)	0.491	1.08×10^{-4}
Cuprimalic acid ($\text{HCuC}_4\text{H}_3\text{O}_5$)	0.553	1.5×10^{-2}
Normal cupric malate ($\text{CuC}_4\text{H}_4\text{O}_5$)	0.553	1.5×10^{-2}
Sodium α -cupritartrate ($\text{Na}_2\text{CuC}_4\text{H}_4\text{O}_6$)	0.458	9.3×10^{-4}
Acid cupric malate ($\text{Cu}[\text{C}_4\text{H}_3\text{O}_5]_2$)	0.550	1.2×10^{-3}

Summary.

(1) The system copper hydroxide-malic acid-water has been partly investigated at 15° and at 50°, and the following compounds have been described. An acid cupric malate, $\text{Cu}(\text{C}_4\text{H}_5\text{O}_6)_2 \cdot 2\text{H}_2\text{O}$; a normal cupric malate, $\text{CuC}_4\text{H}_4\text{O}_5 \cdot 3\text{H}_2\text{O}$; and tricupric malate or cuprio cuprimalate, $\text{Cu}_3(\text{C}_4\text{H}_5\text{O}_6)_2 \cdot 7\text{H}_2\text{O}$.

(2) It has been shown that the dehydration of normal cupric malate is accompanied by the formation of an isomeride, cuprimalic acid, $\text{HCuC}_4\text{H}_3\text{O}_5$.

(3) The following salts of cuprimalic acid have been isolated: sodium, $\text{NaCuC}_4\text{H}_3\text{O}_5 \cdot 4\text{H}_2\text{O}$; ammonium, $\text{NH}_4\text{CuC}_4\text{H}_3\text{O}_5 \cdot 4\text{H}_2\text{O}$; barium, $\text{Ba}(\text{CuC}_4\text{H}_3\text{O}_5)_2 \cdot 7\text{H}_2\text{O}$; silver, $\text{AgCuC}_4\text{H}_3\text{O}_5 \cdot 2\text{H}_2\text{O}$; potassium; lead; cupric cuprimalate, $\text{Cu}(\text{CuC}_4\text{H}_3\text{O}_5)_2 \cdot 7\text{H}_2\text{O}$, mentioned in (1) above, and a basic cupric cuprimalate, $\text{Cu}(\text{CuC}_4\text{H}_3\text{O}_5)_2 \cdot \text{CuO} \cdot 5\text{H}_2\text{O}$.

(4) Measurements of molecular weight in aqueous solutions of sodium and ammonium cuprimalates, of cuprimalic acid, and of normal cupric malate indicate a partial association in concentrated solutions.

(5) The concentration of the copper-ion in solutions of some of these compounds has been measured. The value in solutions of sodium and ammonium cuprimalates is of the order 10^{-4} when the total copper-ion content is 0.05 gram-atom per litre. Cuprimalic acid and normal cupric malate yield identical solutions in which the value is 1.5×10^{-2} ; this solution contains an equilibrium mixture of the two, the normal malate predominating.

The constitution of the cuprimalates will be considered in a later communication.

The author has much pleasure in expressing his thanks to Professor Donnan for his kind advice and assistance, and to the Royal Commissioners of the Exhibition of 1851 for a scholarship which has enabled him to carry out the work.

CCV.—*The Absorption Spectra of the Vapours of Various Quinones.*

By JOHN EDWARD PURVIS.

THE absorption spectra of solutions of *p*-benzoquinone have been described by Baly and Stewart (T., 1906, 89, 502). They state that the absorption of this substance in an alcoholic solution is different from that observed by Hartley, Dobbie, and Lauder for the aqueous solution (*Brit. Assoc. Report*, 1903, 126). The latter observers found two bands with heads at frequencies of 3400 (λ 294) and 4050 (λ 246). In an alcoholic solution, Baly and Stewart observed a band the head of which was at 2100 (λ 475). As this band occurs in the visible regions of the spectrum (F is at λ 486 in the green, and G at λ 4307 in the blue), it was claimed to be the true origin of the colour of the substance. Baly and Stewart also found a band, in about the same regions, in a solution spectrum of toluquinone, *p*-xyloquinone, and thymoquinone, respectively.

Stewart and Baly (T., 1906, 89, 618) found three bands in an aqueous solution of *p*-benzoquinone. The head of the middle band, at about $1/\lambda$ 3407 (λ 294), occurs in an alcoholic solution, but it appears merely as an extension of the spectrum and not as a true band. This band was also found in various substituted quinones. The least refrangible of the three solution bands in *p*-benzoquinone becomes, in chlorobenzoquinone, a merely slanting line between λ 500 and λ 384; in 2 : 6-dichlorobenzoquinone, the line approaches more nearly to the general curve; and in trichlorobenzoquinone there is no measurable band. At the same time, the most refrangible band steadily increases in size as the least refrangible diminishes.

The absorption spectra of the solution and the vapour of *p*-benzoquinone have been described and compared by Hartley and Leonard (T., 1909, 95, 34). The vapour at various temperatures from 17° to 147° exhibited twenty-seven bands, although all these bands were not visible at any one temperature. The bands ranged between λ 4383 and λ 2343, and were divided into three groups corresponding to the three solution bands.

The author has made a more complete investigation of the absorption of the vapour of *p*-benzoquinone, and has compared this with the vapours of toluquinone, *p*-xyloquinone, thymoquinone, dichlorothymoquinone, and dibromothymoquinone. The vapours of α -naphthaquinone and anthraquinone were also investigated.

In previous papers published in the Journal, the author has shown that, generally, the numerous vapour bands of a substance disappear in the more complex derivatives as the number and type of the

substituting elements and radicles increase. In the present investigation, he has tried to show (1) whether such a rule holds good in *p*-benzoquinone and some of its derivatives, and (2) whether there is any difference in the appearance and arrangement of the vapour bands into which the three solution bands break up.

The experimental conditions have been described in previous communications. In the visible regions and just beyond, in the more refrangible parts, a Welsbach incandescent light was used, and a condensed cadmium spark for the ultra-violet regions. Each substance was introduced into a 200 mm. tube with quartz ends, which was then filled with dry carbon dioxide before adjustment in the sand-bath.

p-Benzoquinone.—The three solution bands of this substance are at about λ 475, λ 294, λ 246 (Baly and Stewart, *loc. cit.*). The 200 mm. tube containing the substance was heated in a sand-bath between the temperatures of 15° and 198°, and at varying pressures between 760 mm. and 940 mm. at interval temperatures of 10°. The rays were allowed to pass through the vapour for ten, fifteen, or thirty seconds, so as to bring out the bands of varying intensities. The weaker bands, of course, appeared at the higher temperatures and at the longer exposures. Between about λ 490 and λ 370 there were about forty bands counted. These were divided into five stronger groups, and between each pair of these there were two sets of weaker bands. Each of the five stronger groups was divided into four—the two outside ones being weaker than the two middle ones, and the more refrangible of the latter was slightly weaker than its neighbour. These stronger groups were not all of equal strength—the three inner groups were stronger than the two outer ones—and the constituents of the latter were not so easily made out as those of the stronger ones. Each of the groups of weaker bands, lying between the stronger groups, appeared to be made up of at least two narrow bands—the stronger groups showed three constituents. Here, also, the outside groups were weaker than the inside ones. A much greater dispersion will be necessary to separate these bands more exactly. Meanwhile, Fig. 1 gives some account of these phenomena. It is doubly enlarged from an original photograph. The photographs show, therefore, that the solution band at λ 475 splits up into at least forty vapour bands of different intensities and arrangement. Between λ 305 and λ 257 there are sixteen bands. They are alternately strong and weak, and some of the stronger ones show doubtful signs of further division. A much wider dispersion is required to make this separation more assured. Fig. 2 is an enlarged reproduction of an original photograph, and shows some of the bands

FIG. 1.

p-Benzquinone. Vapour bands between λ 5000 and λ 3700.

FIG. 2.

p-Benzquinone. Vapour bands between λ 305 and λ 257.

FIG. 3.

p-Benzquinone. Vapour bands between λ 255 and λ 230.

FIG. 1. The reproduction does not show the division of the stronger groups into four, but they are easily seen in the original photograph. The weaker groups in the less refrangible region also come out better at the higher temperatures.

FIG. 2. Eight of the vapour bands are easily seen in these enlarged reproductions. At lower temperatures and pressures, the more refrangible bands are seen and at higher temperatures the less refrangible ones.

FIG. 3. Six of the ten bands are fairly well seen. The others come out at the higher temperatures and pressures on the less refrangible side.

fairly well. The solution band at λ 294 divides, therefore, into a number of vapour bands, and these occur on the less refrangible side of a wider absorption which appears as the amount of vapour in the tube is increased at the higher temperatures. These bands are different in appearance and arrangement from those occurring between λ 490 and λ 370.

Between λ 255 and λ 230 there are ten vapour bands, and these are on the less refrangible side of a wider absorption. They are wider and more diffuse than the preceding groups of bands. They are alternately strong and weak, although the difference is not very marked. They do not show any signs of further division. Fig. 3 shows some of these bands enlarged from an original photograph. They are different in appearance and arrangement from the vapour bands between λ 490 and λ 370. They are more comparable with those between λ 300 and λ 285; but the latter are a little stronger and sharper. The total number of observed bands, therefore, in the vapour of *p*-benzoquinone is sixty-eight, lying between λ 490 and λ 232, and these are divided into three groups corresponding to the three solution bands. Hartley (*loc. cit.*) has endeavoured to correlate fifteen vapour bands between λ 2527 and λ 2343 with bands, or pairs of bands, in the vapour of benzene in the same regions. Such a comparison is not strictly correct. The bands of *p*-benzoquinone have not the narrowness and comparative sharpness of the benzene vapour bands. They are more like the seven solution bands of benzene in these regions.

Toluquinone.—The vapour was investigated at gradually increasing temperatures between 8° and 200° , and 760 mm. and 940 mm. pressure, at interval temperatures of 5° and 10° , and with varying times of exposure of the photographic plate. Between λ 490 and λ 380 there appeared ten groups of bands alternately weak and strong, and weaker than the bands of *p*-benzoquinone in these regions. The less and the more refrangible bands were very weak. Each group showed doubtful signs of division into two constituents, but a higher dispersion will be required to substantiate this more clearly. These bands correspond to the solution band, the head of which is at λ 454. Between λ 345 and λ 310 there are six groups of bands, which are not unlike the bands of *p*-benzoquinone in appearance in this region, but they are much weaker and not quite in the same position. The less refrangible bands occur on the less refrangible side of a wider absorption which appears at the higher temperatures and pressures. These narrow bands correspond to the weak solution band described by Baly and Stewart as an extension of the general line of absorption between about λ 335 and λ 277.

Between λ 256 and λ 235 there are four very weak, wide, and diffuse bands similar to those in *p*-benzoquinone, but much weaker and not quite in the same position. They correspond to the weak solution band the head of which is at λ 270 and λ 243.

p-Xyloquinone.—The vapour was subjected to gradually increasing temperatures between 40° and 250° , and 760 mm. and 970 mm. pressure, in the 200 mm. tube, at intervals of from 5° and 10° .

At temperatures between 180° and 250° , there were ten bands in the regions between λ 470 and λ 370 on the less refrangible side of a larger band. These were very weak and diffuse and alternately weaker and stronger. They have some resemblance with the bands of 2:5-toluquinone, but they are more diffuse and weaker. They correspond to the weak solution band the head of which is at λ 434 (Baly and Stewart, *loc. cit.*).

At 100° and 820 mm., the cadmium rays were continuous but weak between λ 325 and λ 275 and then transmitted to λ 254.

At 120° and 835 mm., only the stronger cadmium lines between λ 325 and λ 265 were visible and then the rays were transmitted to λ 258.

At 140° and 850 mm., the cadmium rays were absorbed from λ 335.

At 180° and 870 mm., the cadmium rays were absorbed from λ 340.

There was no trace of any of the narrow bands found in these regions in benzoquinone and toluquinone. This large band corresponds to the weak solution band indicated by the line of general absorption being extended between about λ 335 and λ 285 (Baly and Stewart, *loc. cit.*).

At 40° and 760 mm., the cadmium rays were continuous to λ 2120.

At 50° and 770 mm., these rays were weak between λ 250 and λ 233 and then transmitted to λ 210.

At 55° and 775 mm., the rays were absorbed between λ 252 and λ 232 and then transmitted to λ 214.

At 60° and 780 mm., the rays were absorbed between λ 253 and λ 227 and then the stronger cadmium lines transmitted to λ 214.

At 70° and 790 mm., the rays were absorbed between λ 254 and λ 218 and then the stronger cadmium lines transmitted to λ 213.

At 80° and 800 mm., the rays were absorbed from λ 256.

Again there was no trace of any of the weak diffuse bands found in quinone and in toluquinone in these regions. This vapour band corresponds to the solution band the head of which is at λ 246 (Baly and Stewart, *loc. cit.*).

Thymoquinone.—The vapour was investigated between 35° and

200°, and 760 mm. and 925 mm. pressure, at gradually increasing temperatures and pressures, as in the preceding experiments. At temperatures between 150° and 200° there are eight bands between λ 470 and λ 390 occurring on the less refrangible side of a larger band which appears at the higher temperatures. They are divided into groups and are not unlike the bands of *p*-xyloquinone described above, but they are much more diffuse and weaker. They correspond to the solution band, the head of which is at λ 454.

At 90° and 790 mm., the rays were weak between λ 315 and λ 280 and then transmitted to about λ 256.

At 100° and 800 mm., the rays were absorbed between about λ 320 and λ 280 and then transmitted to about λ 260.

At 190° and 880 mm., the rays were absorbed between λ 330 and λ 275 and then transmitted to λ 270.

There was no trace of any narrow diffuse bands, and this large band corresponds to the weak solution band indicated by an extension of the line of general absorption between λ 335 and λ 289 (Baly and Stewart, *loc. cit.*).

At 35° and 760 mm., the rays were weak between λ 247 and λ 232 and then transmitted to λ 213.

At 40° and 765 mm., these rays were almost completely absorbed between λ 250° and λ 228, and then transmitted to λ 215.

At 50° and 775 mm., the rays were absorbed between λ 253 and λ 220, and then transmitted to λ 214.

At 60° and 785 mm., the rays were absorbed from λ 255.

At 70° and 795 mm., the rays were absorbed from λ 256.

Again there was no trace of any resolution of this large band into a series of narrower bands, and in this respect it compares with xyloquinone. The band corresponds to the solution band the head of which is at λ 250 (Baly and Stewart, *loc. cit.*).

Dichlorothymoquinone.—The vapour of the substance was investigated between the temperatures of 60° and 240°, and 760 mm. and 940 mm. In the visible regions there were no bands at the highest temperature in the more refrangible parts of the visible spectrum. The rays were transmitted to about λ 500, that is, as far as the plates were sensitive. There was no trace of any of the bands found in thymoquinone in these regions. No solution band in this region has been described by Stewart and Baly (*loc. cit.*).

At 200° and 900 mm., there is a weakening of the transmitted rays between about λ 355 and λ 305, and then the rays are transmitted to λ 280.

At 220° and 910 mm., the rays are nearly all absorbed between λ 365 and λ 300, and then feebly transmitted to λ 288. This band corresponds to the weak solution band at λ 344.

At 80° and 770 mm., the rays are weak between about λ 270 and λ 250, and then transmitted to λ 214.

At 120° and 790 mm., the rays are absorbed between λ 273 and λ 245, and then transmitted to λ 214.

At 160° and 805 mm., the rays are absorbed between λ 275 and λ 234, and then transmitted to λ 215.

At 180° and 820 mm., the rays are absorbed between λ 285 and λ 230, and then feebly transmitted to λ 215.

At 200° and 935 mm., the rays are absorbed from λ 290.

There was no appearance of any narrow bands, and this large band was more diffuse on the more refrangible edge. It corresponds to the large solution band, the head of which is at λ 273.

Dibromothymoquinone.—As in the preceding experiments, the vapour of the substance was investigated between 70° and 260°, and 760 mm. and 940 mm. No narrow bands were observed in the more refrangible region of the visible spectrum. The rays were transmitted to about λ 500, that is, as far as the photographic plates were sensitive. There was no trace of any of the eight bands found in thymoquinone between λ 470 and λ 390. No solution band in this substance was found by Stewart and Baly (*loc. cit.*).

At 200° and 880 mm., the rays were weak between about λ 365 and λ 320, and then a little stronger to λ 305.

At 220° and 890 mm., the rays were weak between about λ 368 and λ 315, and then a little stronger to λ 305.

At 260° and 920 mm., the rays were weak between λ 370 and λ 310, and then a little stronger to λ 305.

There was no appearance of any narrow bands, and this weak band corresponds to the very weak solution band between about λ 400 and λ 320 (Stewart and Baly, *loc. cit.*).

At 80° and 770 mm., the rays were weak between about λ 280 and λ 255, and then transmitted to λ 215.

At 90° and 780 mm., the rays were weakly transmitted between λ 282 and λ 245, and then stronger to λ 215.

At 120° and 800 mm., the rays were absorbed between λ 286 and λ 252, and then transmitted to λ 215.

At 140° and 820 mm., the rays were absorbed between λ 293 and λ 245, and then transmitted to λ 225.

At 160° and 840 mm., the rays were absorbed from λ 305, but the group of cadmium lines at about λ 230 was just visible.

This large band was more diffuse on the more refrangible edge and did not appear to split up into any narrow bands. It corresponds to the large solution band the head of which is at about λ 285 (Stewart and Baly, *loc. cit.*).

α -Naphthaquinone.—Baly and Stewart (*loc. cit.*) describe two solution bands, the head of one at about λ 327, and a second weak band between about λ 256 and λ 232. The vapour of the substance was examined in the 200 mm. tube at temperatures between 100° and 240° .

At 160° and 805 mm., the rays were weak between about λ 335 and λ 295, and then transmitted to λ 250.

At 180° and 825 mm., the rays were absorbed between λ 337 and λ 290, and then transmitted to λ 253.

At 200° and 840 mm., the rays were absorbed between λ 342 and λ 270, and then transmitted to about λ 253.

At 220° and 860 mm., the rays were absorbed from about λ 348, but the strong cadmium line λ 257 was visible.

This large band was more diffuse on the more refrangible side—it showed no signs of division. It corresponds to the strong solution band at λ 327.

At 140° and 790 mm., the rays were absorbed between about λ 248 and λ 225, and then transmitted to λ 2120, but the strong cadmium lines at about λ 230 were visible.

At 160° and 805 mm., the rays were absorbed from λ 250.

There was no appearance of any finer bands, and the band corresponds to the solution band between λ 256 and λ 232 (Baly and Stewart, *loc. cit.*).

To investigate the visible regions of the vapour of the substance, it was heated in a 100 mm. tube at temperatures varying between 140° and 220° , but no bands were observed like those of benzoquinone described above in the blue and violet regions of the spectrum.

Anthraquinone.—Baly and Stewart (*loc. cit.*) describe two solution bands, the head of one at about λ 322 and a second λ 250. Meyer and Fischer (*Ber.*, 1913, 46, 85), in a sulphuric acid solution of the substance, found three bands, namely, one at λ 2425, a second at λ 3224, and a third weak band at λ 3765. The vapours were examined between the temperatures of 180° and 275° .

At 220° and 900 mm., the rays are weak between about λ 320 and λ 295, and then transmitted to λ 260.

At 240° and 910 mm., the rays are almost completely absorbed between λ 320 and λ 290, and then transmitted to λ 266.

At 260° and 920 mm., the rays are absorbed between λ 325 and λ 290, and then transmitted to λ 270.

At 275° and 925 mm., the rays are absorbed between λ 326 and λ 280, and then transmitted to λ 273.

This large band corresponds to the solution band at λ 322, and shows no resolution into finer bands.

At 200° and 880 mm., the bands are weak between λ 245 and λ 230, and then transmitted to λ 212.

At 220° and 900 mm., the rays are absorbed between λ 246 and λ 227, and then feebly transmitted to λ 212.

At 240° and 910 mm., the rays are absorbed between λ 247 and λ 221, and then feebly transmitted to λ 214.

At 260° and 920 mm., the rays are absorbed from λ 260, but the cadmium lines at λ 2196 and λ 2146 are visible.

At 270° and 925 mm., the rays are transmitted to λ 265.

There was no appearance of any narrower bands, and this large band corresponds to the solution band at λ 250.

The results of these observations are :

(1) Each of the three solution bands of *p*-benzoquinone splits up into a series of narrower vapour bands, and these occur on the less refrangible side of a wider absorption.

(2) In *o*-toluquinone these vapour bands are fewer in number, but each solution band shows a few such bands when the substance is vaporised.

(3) In xyloquinone and in thymoquinone there are a few narrow vapour bands corresponding to the least refrangible of the three solution bands, but there are no such narrow bands in the two more refrangible bands.

(4) In the dichloro- and dibromo-thymoquinones, the two bands are not resolved into narrower vapour bands, and there are no vapour bands on the more refrangible sides of the visible spectrum. This corresponds to the absence of solution bands in these regions.

(5) In α -naphthaquinone and in anthraquinone there is no resolution of the solution bands into narrower vapour bands.

(6) The increasing complexity of the *p*-benzoquinone compounds means the gradual disappearance of the narrower vapour bands, and of the least refrangible of the three solution bands, and at the same time the most refrangible band becomes stronger.

These results confirm the author's previous observations of benzene and many of its compounds, in that, generally, as the molecule increases in complexity, the vapour bands become more like the solution bands. They also indicate that each band has its origin in a separate and distinct type of oscillation. For example, the groups of narrow vapour bands in the visible regions of *p*-benzoquinone are quite different in appearance and arrangement from those in the ultra-violet regions. The introduction of various elements or groups of elements produces striking changes which mean that the oscillating centres are influenced by such introductions. In this connexion it may be permitted to refer to some earlier work. It has been shown by Purvis and McClelland (T.,

1913, 103, 1088) that, of the two solution bands of benzaldehyde at λ 285 and λ 245, the former splits up into a number of narrow vapour bands, whereas the band at λ 245 undergoes no such resolution; and the author (T., 1914, 105, 2482) has shown that there was no resolution into narrower bands of the more refrangible of the two solution bands in *p*-chlorobenzaldehyde, whereas there were a few narrow bands in the ortho- and the meta-compounds.

It has been assumed that the colour of the quinones is partly, if not wholly, caused by the specific absorption of the rays in the more refrangible regions of the visible spectrum. But this does not explain the colour of such substances as dichloro- and dibromothymoquinones where there is no such specific absorption. The author has shown (T., 1911, 99, 107, 1953) that, in some complex coloured substances, the colour is produced by an extension of the general absorption well into the visible regions. Although it is not necessary to assume that the colour of the substances described above is produced by selective absorption in such regions, it is obvious that such absorption has an important influence in the production of the various shades of the yellow colour.

I desire to convey my thanks to the Government Grant Committee of the Royal Society for assistance in the purchase, some years ago, of the apparatus used in these and other experiments.

CCVI.—*The Oxidation of Sabinene with Hydrogen Peroxide.*

By GEORGE GERALD HENDERSON and ALEXANDER ROBERTSON.

IN continuation of the study of the action of hydrogen peroxide on the terpenes, some results of which have already been communicated to the Society (T., 1911, 99, 1539; 1912, 101, 2288; 1913, 103, 1543), we have now examined the behaviour of sabinene towards that oxidising agent. Semmler (*Ber.*, 1900, 33, 1459) has shown that sabinene yields sabinene glycol, $C_{10}H_{16}(OH)_2$, and sabinenic acid, $C_9H_{14}(OH) \cdot CO_2H$, when oxidised by potassium permanganate, but we have found that the products of the action of hydrogen peroxide on the hydrocarbon are quite different from these. Sabinene in solution in glacial acetic acid is slowly oxidised by 30 per cent. aqueous hydrogen peroxide, and yields two isomeric compounds of the formula $C_{10}H_{16}O(OH)_2$, which appear to be

3 B*

glycol anhydrides, together with a very unstable acid, which could not be isolated undecomposed, and a little *p*-cymene.

The crude oxidation product contains the glycol anhydrides $C_{10}H_{16}O(OH)_2$ partly in the free state and partly in the form of esters of acetic acid and of the unstable acid just mentioned. After removal of the cymene by means of a current of steam, the esters were hydrolysed with alcoholic potassium hydroxide, and the liberated glycol anhydrides extracted with ether and separated from each other by fractional crystallisation from that solvent, in which their solubilities are somewhat different. The less soluble compound crystallises in delicate, colourless needles which melt at 172° , the more soluble in glistening leaflets which melt at 174° . The amount of the former compound obtained was about five times that of the latter. In alcoholic solutions, the glycol anhydride of m. p. 172° is optically inactive, whilst the other is dextrorotatory. Both compounds are soluble in water, alcohol, or ether, and to some extent in benzene or light petroleum. Both are saturated, and as they do not react with semicarbazide acetate it may be concluded that they do not contain a carbonyl radicle. In solution in glacial acetic acid, they are scarcely attacked by chromic anhydride in the cold, but on warming oxidation takes place at once, with the result that part of the glycol is completely decomposed, whilst part remains unaltered. When they are heated with dilute (1 per cent.) sulphuric acid, dehydration takes place, but only very slowly; no aldehyde could be detected in the product, which consisted of a mixture of hydrocarbons, which were not further investigated, and some of the unchanged glycol anhydride.

On treatment with the necessary quantities of *p*-nitrobenzoyl chloride, each glycol anhydride yields a *mono-p-nitrobenzoate* and a *di-p-nitrobenzoate*, respectively; these are crystalline substances of definite melting point. It was found impossible to obtain a tri-*p*-nitrobenzoate from either compound, even after prolonged treatment with excess of *p*-nitrobenzoyl chloride, and therefore it was concluded that the glycol anhydrides contain only two hydroxyl radicles, although, of course, it was realised that a tertiary hydroxyl radicle might also be present, which would not be readily esterified.

The glycol anhydride of m. p. 172° on cautious oxidation with potassium permanganate yielded as sole product the inactive form of $\alpha\alpha'$ -dihydroxy- α -methyl- α' -isopropyladipic acid, m. p. $188-189^\circ$, which was fully identified by conversion into its characteristic dilactone, m. p. $72-73^\circ$. This acid has already been obtained indirectly from sabinene by hydration and oxidation, and its constitution has been established by its synthesis from dimethyl-acetylacetone (Wallach, *Annalen*, 1908; 362, 261).

This result suggested that the supposed glycol anhydride might possibly be a trihydroxymenthane, $C_{10}H_{17}(OH)_3$. On the other hand, the only trihydroxymenthanes which could yield this acid on oxidation are the 1 : 2 : 4- and the 1 : 3 : 4-trihydroxy-isomerides, and as the melting points of these are 129° and 121° , respectively, it is clear that the glycol anhydride of m. p. 172° is a different compound.

Taking all the facts into consideration, it would appear that the constitution of the compound $C_{10}H_{18}O_3$ of m. p. 172° is best represented by formula III. It is not difficult to follow the production of such a compound from sabinene (I), possibly through the intermediate formation of 1 : 2 : 3 : 4-tetrahydroxymenthane (II), or its conversion into $\alpha\alpha'$ -dihydroxy- α -methyl- α' -isopropyladipic acid (IV) by oxidation and simultaneous hydration.

The isomeric glycol anhydride, m. p. 174° , when oxidised with potassium permanganate under similar conditions, was converted into the active form of $\alpha\alpha'$ -dihydroxy- α -methyl- α' -isopropyladipic acid, m. p. $205-206^\circ$, which was further characterised by conversion into its dilactone, which melts at $63-64^\circ$. This acid has also been prepared by Wallach (*loc. cit.*). Hence it is evident that the glycol anhydrides which melt at 172° and 174° , respectively, are stereo-isomerides, the former being an inactive and the latter a dextro-rotatory modification.

Nelson (*J. Amer. Chem. Soc.*, 1911, **33**, 1404; 1912, **35**, 84) has described two isomeric glycol anhydrides melting at $62.5-64^\circ$ and $103-105^\circ$, respectively, which he prepared from ascaridol, and to which he ascribes the formula (III) suggested for our compounds. The products of oxidation of Nelson's glycol anhydrides are, however, quite different from those obtained by us, although in other respects there are certain resemblances between the respective substances.

On hydrolysis with alcoholic potassium hydroxide of the mixture of esters of these glycol anhydrides, which was produced by the action of hydrogen peroxide on sabinene, the solution quickly darkened until almost black in colour, and when, after removal of

the liberated glycol anhydrides, the alkaline solution was acidified and extracted with ether, nothing but a black, tarry mass was usually left after distilling off the ether. In one case a few crystals of an acid were obtained, but within a few hours these underwent spontaneous decomposition into the same black mass. Various modifications of the method of hydrolysing the esters led to the same result. Consequently, the acid, which doubtless was another oxidation product of sabinene, could not be isolated for examination.

EXPERIMENTAL.

Oxidation of Sabinene and Separation of the Products.—The sabinene used in our experiments was obtained by fractional distillation, in an atmosphere of carbon dioxide, of the fraction of oil of savin boiling at 155–190°, which consists of a mixture of hydrocarbons. Since sabinene undergoes change when kept, a freshly distilled specimen (b. p. 163–165°, D_{20}^{20} 0.8479, n_D^{20} 1.4680) was taken for oxidation. Eighty-four grams of 30 per cent. hydrogen peroxide (2 mols.) were added to a solution of 50 grams of sabinene (1 mol.) in 200 grams of glacial acetic acid, and the mixture was heated at 50–55° until the reaction appeared to be complete. This required about one hundred hours. The acetic acid was then neutralised with sodium carbonate, sufficient water being added to keep the sodium acetate in solution. The faintly yellow, oily layer which separated was dissolved in ether, the ethereal solution drawn off, and the aqueous solution repeatedly shaken with fresh quantities of ether until all soluble organic substances had been extracted. The mixed ethereal extracts were dried over anhydrous sodium sulphate and distilled, when a viscous liquid was obtained. From this liquid a crystalline solid separated gradually on cooling, and when the deposition of this appeared to have reached an end, the crop of crystals was collected and freed as far as possible from the oily liquid with the aid of the pump. The filtrate was heated in a current of steam in order to remove a small proportion of a volatile liquid with which it was mixed, and the non-volatile part which remained in the distilling flask was again taken up in ether. Another crop of crystals was obtained from the concentrated solution, but the bulk remained in the form of a viscous liquid. After removal of the crystals the liquid part was hydrolysed by agitation with dilute alcoholic potassium hydroxide at the ordinary temperature. After a short time, the solution became very dark in colour, and was then heated on the water-bath, under reflux, for ten minutes in order to complete the reaction. The solution was then saturated with carbon dioxide, the alcohol distilled off, and the residual liquid extracted repeatedly with ether. The

mixed ethereal extracts were dried with anhydrous sodium sulphate and then concentrated to small bulk. On leaving the rest of the ether to evaporate slowly, several crops of crystals were obtained, and after all that was crystallisable had been collected a black, tarry mass remained. The crystalline material which had been separated from the original oxidation product was mixed with that obtained by hydrolysis of the esters and purified by crystallisation from ether. It proved to be a mixture of two isomeric glycol anhydrides, which differ somewhat in solubility and can be best separated by fractional crystallisation from ether. The less soluble of these compounds melts at 172° , the other, which was present in relatively small quantity, at 174° . A mixture of the two in equal proportions melts at $160\text{--}162^{\circ}$.

The *glycol anhydride*, m. p. 172° , crystallises from ether in delicate, colourless needles, and sublimes unchanged when heated above its melting point. Towards bromine and potassium permanganate it behaves as a saturated compound, and it does not react with semicarbazide acetate. Analysis pointed to the formula $C_{10}H_{18}O_3$ (Found: C = 64.2; H = 10.0. $C_{10}H_{18}O_3$ requires C = 64.5; H = 9.7 per cent. $C_{10}H_{20}O_3$ requires C = 63.8; H = 10.6 per cent.).

The *mono-p-nitrobenzoate* was prepared by the action of *p*-nitrobenzoyl chloride (1 mol.) on the glycol anhydride dissolved in pyridine. This compound crystallises from alcohol in colourless needles which melt at 176° [Found: N = 4.2. $(NO_2 \cdot C_6H_4 \cdot CO_2)C_{10}H_{17}O_2$ requires N = 4.2 per cent.].

Similar treatment of the glycol anhydride with two molecular proportions of the reagent yielded a *di-p-nitrobenzoate*, which separates from alcohol in delicate, pale yellow needles, m. p. $192\text{--}193^{\circ}$ [Found: N = 6.0. $(NO_2 \cdot C_6H_4 \cdot CO_2)_2C_{10}H_{16}O$ requires N = 5.8 per cent.]. This ester is less soluble in alcohol than the mono-nitrobenzoate.

The *glycol anhydride*, m. p. 174° , crystallises from ether in glistening leaflets, and does not sublime when heated above its melting point. It is rather more soluble in organic solvents than the isomeride of m. p. 172° , and in alcoholic solution is dextrorotatory, $[\alpha]_D + 34.3^{\circ}$. It also is saturated towards bromine or potassium permanganate, and in other aspects it closely resembles its isomeride. Its composition is the same (Found: C = 64.3; H = 9.8 per cent.).

On treatment with the requisite quantities of *p*-nitrobenzoyl chloride, this glycol anhydride also yields a *mono-* and a *di-p-nitrobenzoate*. The former crystallises from alcohol in short, colourless prisms, m. p. $181\text{--}182^{\circ}$ (Found: N = 4.2 per cent.). The *dinitrobenzoate* crystallises in almost colourless, lustrous plates,

which melt at 162–163°, and are more easily soluble in alcohol than the mononitrobenzoate (Found : N = 5.5 per cent.).

Oxidation of the Glycol Anhydrides.—Oxidation of the glycol anhydride, m. p. 172°, with chromic anhydride in glacial acetic acid solution gave disappointing results. In the cold, there was little or no action, whilst, on heating, some of the compound was completely destroyed and some of it left unchanged. Cautious oxidation with a dilute neutral solution of potassium permanganate produced traces of an acid, but the greater part of the compound remained unattacked. The best results were obtained by the following method of treatment : To a solution of 1 gram of the glycol anhydride in 50 c.c. of water, cooled with ice-water, 100 grams of ice were added, followed by a solution of 2.6 grams of potassium permanganate in 100 c.c. of water and then by 3 grams of sodium carbonate. The mixture was shaken, and as the oxidation proceeded more ice was added as required to keep the temperature below 5°. When the reaction was completed the solution was filtered, exactly neutralised with dilute sulphuric acid, and evaporated to dryness on the water-bath. The crystalline mass thus obtained was washed with alcohol in order to remove any neutral substance and then treated with dilute hydrochloric acid. The liberated acid was extracted with ether, the ethereal solution washed with water and dried with anhydrous sodium sulphate, and the bulk of the ether distilled off. On cooling the concentrated solution, an acid crystallised in colourless needles, m. p. 188–189°. Analysis showed the formula of the acid to be $C_{10}H_{18}O_6$ (Found : C = 51.8; H = 7.7. Calc., C = 51.3; H = 7.7 per cent.). When heated above its melting point, or with dilute sulphuric acid, the acid is converted into a dilactone, $C_{10}H_{14}O_4$, which melts at 72–73°. Thus the identity of this acid with inactive $\alpha\alpha'$ -dihydroxy- α -methyl- α' -isopropyladipic acid was proved. A small quantity of formic acid was also detected in the aqueous solution. The only neutral substance found was a little of the glycol anhydride which had escaped oxidation.

The isomeric glycol anhydride, m. p. 174°, when oxidised with potassium permanganate under the same conditions, gave a crystalline acid, $C_{10}H_{18}O_6$, which melted at 205–206°, with slight decomposition, and when heated with dilute sulphuric acid was converted into a dilactone, m. p. 62–63°. It was thus identified as the active form of $\alpha\alpha'$ -dihydroxy- α -methyl- α' -isopropyladipic acid.

Separation of the Other Products of the Oxidation of Sabinene.—

As already stated, when the crude oxidation product was heated in a current of steam a small quantity of a liquid distilled over.

This liquid was extracted from the distillate with ether, and after removal of the solvent was found to consist of hydrocarbons. On fractional distillation, the bulk came over at 174–176°. This hydrocarbon behaves as a saturated compound towards bromine, and is only very slowly attacked by potassium permanganate. The determination of the physical constants (b. p. 174–176°, D_{20}^{20} 0.8621, n_D^{20} 1.1919) suggested the identity of the substance with *p*-cymene, and this was confirmed by the production of *p*-toluic acid on treatment with nitric acid, and by sulphonation, the characteristic barium salt of cymenesulphonic acid being obtained from the product.

The black alkaline solution obtained in the process of hydrolysis of the esters present in the crude oxidation product of sabinene was acidified with hydrochloric acid and extracted with ether, but except on one occasion the substance left on evaporation of the ether was a black, tarry mass from which nothing crystallisable could be extracted. In one experiment, when the ethereal solution was reduced to small bulk and left to cool, a small quantity of a crystalline acid was separated. The crystals were collected, dried, and placed in a stoppered specimen tube, but after a few hours were found to have decomposed spontaneously with production of the black, tarry material usually obtained. Owing to its instability we were unable to examine this acid, but evidently a fair proportion of the sabinene used must have been converted into the acid by oxidation with hydrogen peroxide.

Action of Phosphorus Pentachloride and Hydrogen Bromide on the Glycol Anhydride.—A solution of the glycol anhydride, m. p. 172° in chloroform, was treated with phosphorus pentachloride (2 mols.). After the reaction was over, the solution was washed with water and dried over anhydrous calcium chloride, and the solvent removed by evaporation under diminished pressure. A solid substance, mixed with an oily liquid, was left, but these compounds proved to be unstable, decomposing quickly with evolution of hydrogen chloride. Treatment of a solution of the glycol anhydride in glacial acetic acid with hydrogen bromide yielded on addition of water an oily compound, which also was very unstable.

We desire to express our indebtedness to the Carnegie Trust for a scholarship which enabled one of us (A. R.) to take part in this work, and for a grant which defrayed part of the expense.

UNIVERSITY OF GLASGOW.

[Received, May 23rd, 1923.]

CCVII.—*Temperature Coefficients of Reactions in Tropical Sunlight.*

By NILRATAN DHAR.

THE following general results have already been established :

1. A positive catalyst diminishes, and a negative catalyst increases, the temperature coefficient of a reaction, the decrease or increase being greater the higher the concentration of the catalyst.

2. When light acts as an accelerator, the temperature coefficient of a reaction carried on in light is smaller than that of the reaction in the dark.

3. Reactions which are very sensitive to the influence of temperature are also sensitive to the influence of light.

4. The simpler the order of a reaction, the greater is its temperature coefficient. In other words, uni- and bi-molecular reactions have higher temperature coefficients than multimolecular ones.

Oxalic Acid and Chromic Acid.—In a previous investigation (Dhar, T., 1917, 111, 713), the kinetics and the temperature coefficient of the reaction between chromic acid and oxalic acid in the dark were determined. The reaction was found to be quadrimolecular, and the temperature coefficient had the value 1.85 for a 10° rise.

In the present investigation, the temperature coefficient has been determined in tropical sunlight. The experimental procedure was the same as before. The reaction mixtures were exposed in Jena glass beakers to direct sunlight. The following results were obtained :

At 35° .At 45° .

$$k_{45}/k_{35} = 1.64.$$

This reaction is slightly accelerated in presence of light and the diminution of the velocity coefficient is very small (1.85 and 1.64 for the reaction in the dark and in the light, respectively).

Oxalic Acid, Chromic Acid, Manganous Sulphate, and Sulphuric Acid.—In another investigation (Dhar, *loc. cit.*), it has been proved that, in presence of the positive catalysts manganous sulphate and

sulphuric acid, the reaction between chromic acid and oxalic acid becomes unimolecular with respect to oxalic acid and zero molecular with respect to chromic acid. The temperature coefficient for a 10° rise between 0° and 20° is 2.98, and Arrhenius's $A = 8765$. The same reaction has now been investigated in tropical sunlight and the following results have been obtained :

At 10° .				At 20° .			
t .	$a - x$.	$k_0 = x/t$.	x/at .	t .	$a - x$.	$k = x/t$.	x/at .

Mean 1.611			0.0616	Mean 2.434			0.0898

$$k_{20}/k_{10} = 1.51 \text{ and } A = 3420.$$

The velocity of the reaction is about four times as great in sunlight as it is in the dark under otherwise identical conditions. Hence light, acting as a marked accelerator, produces a concomitant lowering of the temperature coefficient. On comparing the results of this and also of the previous reaction in the light and in the dark, it will be seen that sensitiveness to temperature and sensitiveness to light go hand in hand.

Oxalic Acid, Potassium Permanganate, Manganous Sulphate, and Sulphuric Acid.—The temperature coefficient of the reaction between potassium permanganate and oxalic acid in presence of manganous sulphate and sulphuric acid (Harcourt and Esson's reaction) has been determined in the dark (Purkayostha and Dhar, *Z. anorg. Chem.*, 1922, **121**, 1561); k_{t+10}/k_t between 0° and 20° for the reaction in the dark is 3.21, and $A = 9397$.

In sunlight under otherwise identical conditions, the following results have been obtained :

At 10° .			At 20° .		
t .	$a - x$.	k_1 (unimolecular).	t .	$a - x$.	k_1 .
0	27.8	—	0	27.8	—
1	17.2	0.480	$\frac{1}{2}$	18.4	0.825
2	9.0	0.564	1	11.5	0.882
3	5.6	0.534	2	4.8	0.878
4	4.25	0.469	3	2.5	0.803
Mean 0.509			Mean 0.847		

$$k_{20}/k_{10} = 1.66 \text{ and } A = 4231.$$

In light, the velocity is practically doubled. Here also light acts as a positive catalyst and lowers the temperature coefficient.

Potassium Oxalate and Iodine.—The temperature coefficient of the reaction between potassium oxalate and iodine has the value 7.2 in the dark and 3.4 in diffused daylight (Dhar, *loc. cit.*). The same reaction has been investigated in tropical sunlight and gave the following results:

$N/2.95\text{-K}_2\text{C}_2\text{O}_4$, $N/113.6\text{-I}$, and $N/29.35\text{-KI}$.

At 36°.				At 26°.			
<i>t.</i>	<i>a - x.</i>	<i>x/t.</i>	<i>k_i</i>	<i>t.</i>	<i>a - x.</i>	<i>x/t.</i>	<i>k_i</i>
0	33.9	—	—	0	33.9	—	—
10	22.2	0.034	0.222	14	26.8	0.0148	0.093
23	12.2	0.028	0.203	27	21.5	0.0139	0.089
32	6.2	0.026	0.209	47	16.8	0.0110	0.074

			Mean 0.215	87	7.0	0.0091	0.073
							Mean 0.080

$$k_{36^\circ}/k_{26^\circ} = 2.68 \text{ and } A = 9105.$$

It will be seen that the reaction is semimolecular in light ($k_i = 2\{\sqrt{a - x} - \sqrt{a}\}/t$), and unimolecular in the dark, with respect to iodine. In light, the velocity of the reaction is markedly increased and there is a corresponding diminution of the temperature coefficient.

Sodium Formate and Mercuric Chloride.—The reaction between sodium formate and mercuric chloride has the value 4.02 for its temperature coefficient in the dark, and $A=12960$ (Dhar, *loc. cit.*). The reaction, investigated in sunlight, gave the following results:

$0.898N\text{-HCO}_2\text{Na}$ and $M/15\text{-HgCl}_2$ (2.11 grams of $\text{CH}_3\text{-CO}_2\text{Na}$ added to 150 c.c. of the reaction mixture).

At 40°.			At 30°.		
<i>t.</i>	<i>a - x.</i>	<i>k_i × 10³.</i>	<i>t.</i>	<i>a - x.</i>	<i>k_i × 10³.</i>

Mean 0.0342			Mean 0.0118		

$$k_{40}/k_{30} = 2.91 \text{ and } A = 10121.$$

The velocity of the reaction in light is about three times that in the dark, and there is a marked fall in the temperature coefficient.

It is evident that in all the cases examined, the temperature coefficients of the reactions in presence of light are smaller than those in the dark, and therefore light acts as a positive catalyst. It will also be seen that the reactions which have high temperature coefficients in the dark are most influenced by light, the velocity being greatly increased and the temperature coefficient markedly diminished. The results obtained are in harmony with those recorded in previous papers. It has been suggested (Purkayostha and Dhar, *loc. cit.*) that some reactions catalysed by light are semimolecular; at any rate, the velocity coefficients calculated according to the semimolecular equation, $k = 2(\sqrt{a} - \sqrt{a-x})/t$, show good constancy. The above equation can be applied to the photochemical oxidation of sodium sulphite by oxygen (Mathews and Week, *J. Amer. Chem. Soc.*, 1917, **39**, 635) and also to the researches of Lewis (T., 1912, **101**, 2371) and of Spencer (T., 1914, **105**, 2565) on the photochemical decomposition of sodium hypochlorite. Moreover, Banerjee and Dhar have shown that the course of those reactions in which iodine is one of the reactants in light, is approximately expressed by the semimolecular equation. It has already been shown in this paper that the oxidation of potassium oxalate by iodine in sunlight is semimolecular with respect to iodine, whilst in the dark the reaction is unimolecular with regard to iodine. It is very likely that in light atoms of iodine take part in the reaction.

Some comment should be made on accepted views concerning the temperature coefficients of photochemical reactions. Hitherto the opinion has been very generally held that in light the temperature coefficient of most photochemical reactions should be about unity (compare Nernst, "Theoretical Chemistry"; Berthelot, *Compt. rend.*, 1915, **160**, 519). It has been shown in this and in

previous papers that the temperature coefficient of a reaction occurring in light may have any value, but it will be smaller than that of the reaction in the dark if light accelerates the change. The diminution of the temperature coefficient depends on the acceleration of the reaction in light. The oxidation of potassium oxalate by iodine is a case in point. The temperature coefficient of the reaction in the dark has the high value 7.2 for a 10° rise; in the diffused light of the laboratory, the reaction is accelerated and the temperature coefficient is 3.4; in tropical sunlight, the reaction is enormously accelerated and the value of the temperature coefficient falls to 2.68. Hence the greater the acceleration of a reaction by light the greater is the fall in the temperature coefficient. It is clear, therefore, that a typical photochemical reaction such as the oxidation of potassium oxalate by iodine, which is enormously accelerated by light, may have a temperature coefficient much greater than unity.

From my researches on the temperature coefficients of thermal and photochemical reactions, I am of the opinion that there is no fundamental difference between thermal and photochemical reactions. In a photochemical reaction, the radiating body is not in thermal equilibrium with the reacting substance, as it is in a thermal reaction, and the distribution of energy amongst the different frequencies does not follow Planck's distribution law. I have shown (*Proc. K. Akad. Wetensch. Amsterdam*, 1920, 23, 308) that the reaction between potassium oxalate and iodine is accelerated by exposing the system to different parts of the arc spectrum produced with carbon electrodes; the indigo portion near the violet end produces the greatest effect, but the reaction is also stimulated by blue, green, or violet light. In other words, the reaction is sensitive to several radiations. In many cases, I have found that radiations of several different wave-lengths are effective in one and the same reaction. Recently I have been able to synthesise, in glass vessels exposed to tropical sunlight, several organic and inorganic compounds which have been obtained by Baly and his co-workers (T., 1921, 119, 1025), using quartz vessels exposed to ultra-violet light from a mercury lamp. I am therefore of opinion that ordinary chemical reactions may be sensitive to several radiations, the effects of which should be additive.

The Perrin-Lewis radiation hypothesis assumes that a chemical change is due to a specific frequency of radiation characteristic of the substance involved. It is understood that a radiation must be absorbed to be active. Langmuir (*J. Amer. Chem. Soc.*, 1920, 42, 2190) states that in some cases the predicted absorption bands do not exist, whilst Taylor and Lewis (T., 1922, 121, 665) have observed

in certain solutions the absorption bands the existence of which was predicted from measurements of the temperature coefficients. If we accept the Perrin-Lewis radiation hypothesis, we ought to find, for example, in a mixture of potassium oxalate and iodine, absorption bands corresponding to different spectral regions, since the reaction is, as already indicated, accelerated by several radiations. Experiments on the measurement of such absorption bands are in progress. Lewis (*Nature*, 1921, **108**, 241; *Trans. Faraday Soc.*, 1922, **17**, 583) emphasises the need for the separate treatment of photochemical and thermal reactions. Perrin (*Ann. Physique*, 1919, **11**, 1; *Trans. Faraday Soc.*, 1922, **17**, 546) makes no distinction between them, and I also do not find any fundamental difference between the two. The objection raised by Lindemann (*Phil. Mag.*, 1920, [vi], **40**, 671) that the velocity of sugar inversion is not affected by an enormous increase in radiation which is presumed to be active, is partly met by the fact that the inversion of sugar both in absence and in presence of acids is greatly accelerated by sunlight (Dhar, *Z. anorg. Chem.*, 1921, **119**, 177). Perrin (*loc. cit.*) and Lewis (*l.c.*, 1922, **121**, 613) now assume that most reactions occur in steps and that different frequencies are active in different steps. If two successive reactions separately accord with the Arrhenius equation, and if they be determined by radiations ν_1 and ν_2 , then the radiation ν_2 can only act after the first stage on a material already transformed by a radiation ν_1 . It is well known that some chemical reactions take place in stages; thus we have recently proved that in the reduction of iodic acid by sulphurous acid or arsenious acid, hypoiodous acid is certainly an intermediate product. Unfortunately, the introduction of the view that a series of frequencies is active in a chemical change makes the radiation hypothesis as originally enunciated lose much of its simplicity.

CCVIII.—*Electron Valency Theories and Stereochemistry.*

By SAMUEL SUGDEN.

DURING the last seven years, the atom models of the physicist have been made the basis of a number of theories of valency in which the older views on molecular structure are correlated with the interchange, rearrangement, or sharing of electrons. More recently, these theories have been applied to a wide range of chemical

phenomena and new systems of symbols have been put forward which involve the addition of + and - signs to the usual formula with or without the deletion of existing bonds (Lapworth, T., 1922, **124**, 416; Kermack and Robinson, *ibid.*, p. 427; Lowry, this vol., p. 822).

Theories of this kind are, presumably, meant to signify much more than a formal representation of chemical reactions and attempt to correlate these with some physical mechanism which is postulated as existing in the structure of atoms and molecules. Most of the later workers have discarded, implicitly or explicitly, the cubical atom of Lewis (*J. Amer. Chem. Soc.*, 1916, **38**, 775) and Langmuir (*ibid.*, 1919, **41**, 868) and concern themselves chiefly with the number of electrons in the molecule and their allocation amongst the atoms concerned. Two types of valency bindings are recognised on the lines suggested by J. J. Thomson (*Phil. Mag.*, 1914, [vi], **27**, 757) and subsequently developed by Lewis (*loc. cit.*) and by Kossel (*Ann. Physik*, 1916, [iv], **49**, 229; *Naturwiss.*, 1919, **7**, 339, 360). These authors agree in their conception of "polar" valency in which one atom gives up an electron to another, the electrostatic attraction between the ions so formed constituting the "polar" or "electro-valency" bond. At this point, however, the two theories part company and Kossel ascribes "non-polar" valencies to electrons moving in orbits similar to those postulated by Bohr in the hydrogen molecule, whilst Lewis prefers a statical conception of atom structure and ascribes "covalency" to the "sharing" of a pair of electrons between the atoms concerned.

It is the object of the present paper to indicate that even the later developments of the Lewis-Langmuir theory are open to criticism from the point of view of stereochemistry. The more important of these criticisms will be referred to briefly under two headings.

(1) *Free Rotation.*

The original cubical atom of Lewis (*loc. cit.*) was soon seen to be incapable of representing triple bonds, and Langmuir attempted to get over the difficulty by adopting Lewis's suggestion that the eight electrons of the octet are distorted from the corners of the cube and approach one another in pairs to form roughly a tetrahedron. While this enables one to picture a triple bond by two such tetrahedra with their faces in contact, it only obscures and does not eliminate another important objection to formulæ of this type, namely, that any arrangement of a pair of electrons forming a covalency must, in carbon compounds, allow of the free rotation of the carbon atoms about the line joining their centres. Now the theories of Lewis and Langmuir are essentially statical theories; the pair of electrons

forming the covalency are supposed to be held in a fixed position in space by "constraints" due to electrostatic interaction between the electrons themselves and between the electrons and the nuclei of the atoms. The problem therefore resolves itself into that of devising a space arrangement of two octets with two electrons in common which shall permit of free rotation of the electron shells about the covalency bond. Only two configurations appear to be possible. The first is one in which the electrons approach one another in pairs so that the distance between the members of a pair is small compared with the diameter of the octet. This arrangement is the one adopted by Langmuir. The second arrangement is one which does not seem to have been considered up to the present; it is obtained by placing the two electrons of the covalency symmetrically on the line joining the two nuclei. In this way it is possible to interpret, very simply, the van't Hoff theory of the carbon atom in terms of electrons. The four electrons of the carbon atom are placed at the corners of a tetrahedron and single bonds formed by bringing two such tetrahedra together until the two electrons are separated by the limiting distance to which they can approach one another. It will be seen that double and triple bonds can readily be formulated in the same manner as in the usual stereochemical theory.

Both these views are, however, open to grave objections on physical grounds, for two electrons separated from one another by such small distances would exert a large mutual force of repulsion. It is for this reason, doubtless, that Langmuir draws his distorted cube models with the shared electrons at a distance equal to $1/3$ to $1/4$ the side of the original cube. Yet as long as this distance is appreciable free rotation does not appear to be possible. It is true, of course, that Langmuir and his school assume that electrons at small distances do not obey the laws of attraction and repulsion which hold at larger distances. There is, however, definite experimental evidence which controverts this view. Rutherford's investigations on the collision of α -particles with atoms (T., 1922, 121, 402) have shown that the inverse square law does indeed break down at very short distances, but that this law holds until two nuclei approach one another to within a distance of about 10^{-12} cm. Hence throughout the greater part of the volume of the atom and certainly in the exterior zone occupied by the valency electrons we should expect to find that electrons do repel one another in accordance with this law. The theoretical difficulties which are summed up in the quantum theory are concerned, not so much with electrostatic attractions and repulsions, as with the relation between a moving electron and radiation.

The difficulty of providing for free rotation is much more easily overcome if one adopts a dynamical atom model. The one essential condition is seen to be that the orbit or orbits in which the two electrons of the covalency move must lie symmetrically about the line joining the two nuclei. A clear dynamical model of covalency would be of great value for the development of electronic theories of valency.

(2) *Geometrical Isomerism.*

Double bonds were originally written by Lewis and Langmuir as the sharing of four electrons, that is, the bond consists of two covalencies. Lewis, however, perceived that the distinction between polar and non-polar compounds is not necessarily sharp and that a covalency may be transformed into an electrovalency by the separation of the two cubical atoms, leaving the two electrons originally shared in one or other of the atomic shells. Eastman (*J. Amer. Chem. Soc.*, 1922, **44**, 438) has suggested that only two electrons are shared in a double bond, while one carbon atom makes up its octet by utilising the two inner electrons of the helium nucleus to form an extended octet of larger size. He does not appear to realise that this arrangement means that the atoms carry electrical charges. Lowry (this vol., p. 882) states this explicitly and describes a double bond (I) as consisting of an electrovalency and a covalency (II). This theory of the double bond in which one pair of electrons

only is shared does not seem adequate to account for the existence of geometrical isomerides. Since in a single bond one must have free rotation about a covalency, whatever view one adopts as to its physical nature, the mere superposition of an electrovalency on a covalency is not enough to account for the lack of free rotation in the double bond unless one makes some further special hypothesis concerning the spatial distribution of electrons around the atoms. This distribution of electrons must be such that the resultant electrostatic force between the two charged atoms is not coincident with the direction of the covalency bond. It is not easy to devise such an arrangement of electrons which could be regarded as a structure that would be physically stable, yet this further hypothesis would seem to be essential if the theory of mixed double bonds is to be retained.

This difficulty has been appreciated by Eastman (*loc. cit.*), who gives the following explanation. "Due to the differing sizes of the connected octets the electrons in double bonds are probably spread apart further than usual in the normal bond. The abnormal

stresses which result between the electrons of the bond and those of each of the adjoining structures (perhaps even involving the inner electrons of the normal octet) might easily be such as to oppose free rotation of the atomic shells with respect to each other." This vague reference to the mutual influence of electrons acting on each other according to arbitrary laws of force can scarcely be accepted as a satisfactory explanation of the existence of geometrical isomerides.

A satisfactory theory of valency must on the one hand be compatible with the atom models of the physicist as regards the number of electrons and their mutual action upon each other according to known physical laws, while on the other it should be capable of expressing the chemical and stereochemical generalisations which are connoted by the formulæ in common use. The statical valency theories which have been put forward up to the present time do not appear to satisfy either of these conditions. Yet much more is surely to be looked for in a theory based on our increasing knowledge of atom structure than a mere retranslation of the older valency theories in terms of electrons. A clearer physical conception of the nature of valency forces should enable us to account for the existence of the hydrides of boron* and the borohydrates, to quote only one of the many instances in which the older theories are defective. Finally, it is becoming increasingly evident that to be of real value a physical theory of valency must give us some quantitative discussion of the strength of the linkings between atoms and the way in which this varies from compound to compound. A beginning in this direction has been made by Kossel (*loc. cit.*), who has given a suggestive treatment of the strength of linkages in certain polar compounds.

* The hydrides of boron have been discussed by Eastman (*loc. cit.*), who, by utilising the two inner electrons of the helium nucleus to form an extended octet, has developed a formula for B_2H_4 containing a "mixed" double bond. Robinson (*Trans. Faraday Soc.*, 1923, 18, 299) has given the same formula to this substance which has been adopted by Lowry (*loc. cit.*, p. 301) and written $H_3B^+ \equiv BH_2^-$, from which he predicts that this hydride should be an analogue of ethylene and should behave as an unsaturated compound. Yet it has been found by Stock (*Ber.*, 1914, 47, 3115) that borethane reacts with chlorine to give a substitution product of the formula B_2H_4Cl and not an additive compound as is the case with ethylene.

CCIX.—*Note on the Theory of Free Rotation.*

By THOMAS MARTIN LOWRY.

1. IN reading my paper on "The Polarity of Double Bonds" I laid considerable stress on the fact that the formulæ there set out represented the reactions of the various compounds rather than the resting-states of the molecules. The metaphor used was that these formulæ represented "the dog standing up and barking" and that he might assume a very different attitude "when curled up and at rest." In some cases, the resting-states of the molecules may be identical with the reactive states; thus in methylethylaniline oxide, the limitation of the number of covalencies of the nitrogen atom to four would prevent the double bond between nitrogen and oxygen from reverting to a double covalency, and the nitrogen would retain its positive charge permanently, just as in ammonium chloride. On the other hand, the recent work of Stewart and Edlund (*J. Amer. Chem. Soc.*, 1923, 45, 1014), in which it is shown that the union of ethylene with bromine is a surface action, suggests that the resting-state of ethylene is an inert molecule which must be activated, for example, by contact catalysis, before it can unite even with a halogen. When these latter conditions prevail, the ordinary considerations of stereochemistry will apply until the reactive state is actually developed.

2. It is, however, of considerable interest to consider how far stereoisomerism is possible in activated molecules. Experimentally, it would appear that the stability of these reactive states is much less than that of the resting-states, since, as Frankland has shown (Presidential Address, 1912, T., 101, 686), many compounds which are stable in themselves undergo inversion when subjected to chemical change. On the other hand, the fact that some agents, for example, potassium permanganate, usually give the correct stereoisomerides, suggests that the inversion of the active phase may not be spontaneous, but may depend on the action of the reagent. On the theoretical side, the question appears to resolve itself into one of finding out whether three groups attached to a positively-charged carbon-atom are necessarily coplanar with it. Since the three oxygens of the anion are coplanar with carbon or nitrogen in crystals of calcium carbonate and sodium nitrate, but not in crystals of lead nitrate, it is clear that no universal rule can be laid down, but that each case must be investigated experimentally.

3. It is important to note that the original simple theory of "free

* A reply to S. Sugden (preceding paper).

rotation," according to which free rotation is always possible in the case of molecules held together by a single bond, but impossible in the case of a double bond, has now definitely broken down. The stereochemical models of van't Hoff predict definitely that symmetrical derivatives of diphenyl can show neither stereoisomerism nor optical activity. A happy chance led to the detection of a case of stereoisomerism in this series; and this has been brilliantly followed up by Kenner, who has given an impregnable demonstration based on optical activity. The "butterfly-wing" formula was invented to explain this anomaly, but this in turn has been discarded, since optical activity has been detected in the *cis*- as well as in the *trans*-form of the dinitrodiphenic acids. The proof that both stereoisomerism and optical activity are possible in classes of compounds where they were regarded as impossible by van't Hoff has removed a veto on a line of research which has already proved to be most fertile, and it is likely that scores of similar cases may now be discovered. On the other hand, if the views of Thorpe as to the structure of the isomeric derivatives of the glutaconic series be accepted, it would appear that *cis*- and *trans*-isomerism in unsaturated compounds may under some conditions be completely in abeyance, since the predicted stereoisomerides cannot in fact be prepared. This may mean only that they are interconvertible with such ease that they cannot be separated as stable isomerides; but it is also possible that the stereoisomerides are tautomeric in the sense that the compounds represented by the conventional *cis*- and *trans*-formulae are not isomeric but identical. In any case, it is necessary to recognise that the old and simple views on free rotation have broken down, and that the subject is now "open to discussion" on the broadest possible lines, including those suggested by the electronic theory of valency.

THE UNIVERSITY, CAMBRIDGE.

[Received, July 10th, 1923.]

CCX.—*New Halogen Derivatives of Camphor.* *Part III. $\alpha'\beta$ - and $\alpha'\pi$ -Dibromocamphor.*

By HENRY BURGESS and THOMAS MARTIN LOWRY.

1. *Preparation of Two New Dibromocamphors.*

ALTHOUGH $\alpha\beta$ - and $\alpha\pi$ -dibromocamphor have been known since 1880 and 1895, respectively, the stereoisomeric $\alpha'\beta$ - and $\alpha'\pi$ -dibromocamphors have not yet been described. By means of solubility measurements in neutral and alkaline alcoholic solutions, the

percentages of these compounds in equilibrium with the α -isomerides and their rotatory powers in alcoholic solution were, however, predicted as long ago as 1906 (T., 89, 1033), as follows :

Substance.	Percentage in equilibrium mixture.	Rotatory power in alcohol.	
		$[\alpha]_D$ (calc.).	$[\alpha]_D$ (found).
$\alpha\beta$ -Dibromocamphor	10 to 11	-58° to -61°	-63°
$\alpha'\pi$ - " "	11	$+105^\circ$	$+82^\circ$

These two compounds have now been isolated by the method used in the two preceding papers of this series, which is based on the observation of Kipping (P., 1905, 21, 124) that the equilibrium between the α - and α' -compounds, which is static in neutral or acid solution, becomes dynamic in alkaline solution. The mixtures of isomerides obtained in this way were then separated by slow crystallisation from acetone. The last column of the preceding table shows the approximate agreement of the observed rotatory powers with those predicted in 1906.

2. *Equilibrium Between Isomeric Dibromocamphors.*

After having prepared the $\alpha'\beta$ - and $\alpha'\pi$ -dibromocamphors from their $\alpha\beta$ - and $\alpha\pi$ -isomerides, and separated them in a pure condition, it was of interest to study more exactly the equilibrium between them. This study presented certain unexpected difficulties.

(a) In the case of the $\alpha\pi \rightleftharpoons \alpha'\pi$ equilibrium, the rotatory powers of the two isomerides differ by only about 16° , as compared with a difference of 184° in the case of the $\alpha\beta \rightleftharpoons \alpha'\beta$ equilibrium. The mutarotation of a 5 per cent. solution in a 2-dm. tube would therefore have been limited to a total range of only 1.6° , that is, approximately 1.4° for one isomeride and 0.2° for the other. These small changes could not be measured sufficiently accurately to establish with any degree of certainty the course of the reversible isomeric change. Measurements of the rotations of the two isomerides before and after the addition of alkali showed, however, that the proportions of the isomerides in equilibrium with one another were $\alpha\pi : \alpha'\pi = 89 : 11$, in close agreement with the ratio predicted in 1906.

(b) In the case of the $\alpha\beta \rightleftharpoons \alpha'\beta$ equilibrium, where the conditions appeared at first sight to be much more favourable, the study of isomeric change was rendered even more difficult by a side-reaction between the halogen compound and the alkaline catalyst, which had the double effect of destroying the catalyst and of introducing a third optically-active component into the solution. This by-product, which had already interfered very seriously with the preparation of $\alpha'\beta$ -camphor from its $\alpha\beta$ -isomeride, is apparently :

derivative of campholenic acid. Its further study, which is actively in progress and will form the subject of a separate communication, may throw fresh light on the debatable question of the structure of the β -derivatives of camphor; but in the present investigation it appears only as a disturbing factor which made itself felt in three different directions, as follows :

(i) When attempting to follow the course of isomeric change by experiments on mutarotation, it was found that, when small amounts of alkali ($N/500$) were used as catalyst, the mutarotation became progressively slower, and then stopped completely before equilibrium was reached, owing to the total disappearance of the catalyst. On the other hand, when larger quantities of alkali ($N/100$) were used, equilibrium was reached so quickly that it was quite impossible to plot the mutarotation curves, since at the end of only four minutes the rotation of the $\alpha\beta$ -compound had already reached the final equilibrium-value.

(ii) The rapid formation of the by-product also rendered it very difficult to secure an exact determination even of the *proportions* of the two isomerides in the final equilibrium. Thus, although the rotations of the two isomerides at once became identical after the addition of $N/100$ -alkali, it was clear that the formation of the by-product (the rotatory power of which is very similar to that of the $\alpha'\beta$ -compound) would increase the apparent proportion of the latter. Whilst, therefore, the uncorrected rotatory powers led to an equilibrium-ratio $\alpha\beta : \alpha'\beta = 85 : 15$, this ratio was altered to $\alpha\beta : \alpha'\beta = 90 : 10$ when a correction was made on the assumption that the whole of the alkali had been used up in forming the by-product. Since the rotatory power of the solutions was substantially the same at one hour and at two hours, it is probable that this action was already complete, and that the corrected value of the equilibrium-ratio is substantially right.

(iii) The formation of the by-product also interfered with the study of the equilibrium, and with the prediction of the rotatory power of the less stable isomeride, by the method used in 1906, namely, measuring the solubility of the more stable isomeride before and after the addition of alkali. This method had given, with $N/1000$ -alkali, the proportion of $\alpha\beta$ -dibromocamphor in the equilibrium-mixture as 89 to 90 per cent. in close agreement with the corrected value shown under (ii) above. Since, however, it was possible that a false equilibrium had been reached, these measurements were repeated with $N/900$ -, $N/450$ -, and $N/40$ -alkali. It was found that with these higher concentrations of alkali the calculated proportion of the $\alpha\beta$ -compound fell from 90 to 88, 87, and finally (at the highest concentration of alkali) to 70 per cent.,

whilst the predicted rotatory power of the $\alpha'\beta$ -compound fell from $[\alpha]_D = -61^\circ$ or -58° , to $[\alpha]_{4451} = -55^\circ$, -43° , and finally -0.3° . These observations show that the quantity of alkali used in the earlier determinations had (by accident rather than by deliberate choice) been added in sufficient quantity to carry the isomeric change through to complete equilibrium, whilst producing a minimum amount only of the by-product which is now recognised for the first time as a possible source of error in these measurements.

3. Comparison of the Properties of Five Isomeric Dibromocamphors.

Replacement of hydrogen by bromine can be effected in the camphor molecule by direct bromination in the α - and α' -positions, and by intermediate sulphonation in the β - and π -positions. Since there are four positions in which bromine can be introduced, six dibromocamphors are theoretically possible. Five of these have now been prepared, the only missing member of the series being $\beta\pi$ -dibromocamphor, which it should be possible to prepare by sulphonating β -bromocamphor with chlorosulphonic acid and converting the bromo-sulphonic acid into the corresponding bromo-camphor. For the purpose of comparison the melting points, densities, and rotatory powers in benzene of the five dibromocamphors now known are set out together in the following table :

TABLE I.

Melting Points and Rotatory Powers of Dibromocamphors.

Substance.	Melting point.	Density.*	$[\alpha]_D$.	$[\alpha]_{4451}$.
$\alpha\alpha'$ -Dibromocamphor	61°	$d_4^{21.4}$ 1.854	+39.57°	50.19°
$\alpha\beta$ "	114	$d_4^{21.7}$ 1.825	+82.0	+100.64
$\alpha'\beta$ "	136	$d_4^{21.7}$ 1.809	-70.8	- 83.11
$\alpha\pi$ "	156	$d_4^{21.2}$ 1.835	+87.3	+110.83
$\alpha'\pi$ "	182	$d_4^{21.2}$ 1.830	+98.1	+126.63

* These were determined by Mr. W. A. Wooster of Peterhouse College by the method of flotation.

It will be observed that the melting points of the new $\alpha'\beta$ - and $\alpha'\pi$ -dibromocamphors are considerably higher than those of the $\alpha\beta$ - and $\alpha\pi$ -isomerides, although it was shown in the preceding paper of this series that the melting point of α' -bromocamphor is only two degrees above that of α -bromocamphor. Again, the two new dibromocamphors are both less soluble than the α -compound, although α' -bromocamphor was found to be more soluble than the α -isomeride. The moving of a bromine atom from the α to the α' position decreases the density of the $\alpha\beta$ -compound, but increases that of the $\alpha\pi$ -compound; no obvious explanation of this contrast

is available. Finally, whilst the rotatory powers of (α and α')- β -dibromocamphor, like those of (α and α')-monobromocamphor, are opposite in sign and differ from one another very widely, those of (α and α')- π -dibromocamphor are of similar sign and differ from one another only to an insignificant extent. Since the rotatory powers of these two compounds are altered in opposite directions by change of solvent in the series

it is actually possible to interchange their rotatory powers almost quantitatively, for example, by changing from alcohol to benzene or conversely. It is, however, very difficult indeed to suggest any reason why the very large influence on the rotatory power of a compound of an interchange of hydrogen and bromine in the α - and α' -positions should be practically destroyed by introducing a halogen in the π -position, when a halogen in the β -position leaves this influence almost as strong as ever.

Measurements have been made of the rotatory dispersion of the two pairs of isomerides now under consideration; but these will be described and discussed in a paper dealing specifically with the rotatory dispersion of the derivatives of camphor.

The crystallographic properties of the two new dibromocamphors are described in the present paper, so that the crystallographic constants of five isomerides are now known. Since, however, these constants do not exhibit any immediately-obvious morphotropic relationships, the detailed consideration of these data may be postponed until it is possible to supplement them by X-ray examination of the crystals, for which preparations are already being made.

EXPERIMENTAL.

4. *Materials Used.* (a) The $\alpha\beta$ -dibromocamphor was recrystallised three times to a constant melting point of 113–115°. A portion melting at 92–96°, which was probably a mixture of $\alpha\beta$ - and $\alpha'\beta$ -dibromocamphors, was not used for the preparation of $\alpha'\beta$ -dibromocamphor.

(b) The $\alpha\pi$ -dibromocamphor was made by a slight variation of the method of Kipping and Pope (T., 1895, 67, 356), the ammonium π -bromocamphor- π -sulphonate (14 grams) and phosphorus pentabromide (20 grams) being mixed under dry chloroform (100 c.c.) and left over two nights to complete the action. The solution was filtered, washed three times with cold water, dried over sodium sulphate, and the chloroform distilled off; a little ether was added, and the sulphonyl bromide was allowed to crystallise (yield = 83

per cent. of theory). The sulphonyl bromide was decomposed by heating at $160-165^{\circ}$ for thirty minutes, as described by Kipping and Pope; the tarry product was steam-distilled, and the colourless dibromocamphor, which came over very slowly, was filtered off and recrystallised. In this way, nearly half of the substance was obtained pure (m. p. $154-155^{\circ}$). The residue, which melted at $128-132^{\circ}$, even after crystallising three times from alcohol, was shown to be a mixture of $\alpha\pi$ - and $\alpha'\pi$ -dibromocamphor, since, when it was crystallised from an alkaline alcoholic solution, crystals melting at $154-155^{\circ}$ were at once obtained. The whole of the mixture was converted in this way into pure $\alpha\pi$ -dibromocamphor in order to make sure that no other impurity was present when the preparation of $\alpha'\pi$ -dibromocamphor was begun.

5. *Preparation of Isomerides.*—In order to prepare mixtures of $\alpha'\beta$ - and $\alpha\beta$ - and of $\alpha'\pi$ - and $\alpha\pi$ -dibromocamphor, 100 grams of the α -compound were dissolved in 800 c.c. of 95 per cent. alcohol, sodium ethoxide was added to a concentration of about $N/100$, and the mixture was boiled for five minutes to establish equilibrium. It was then made slightly acid with acetic acid and cooled. A large proportion of the original substance which separated out was filtered off and used again. The filtrates were evaporated to small bulk, and, on cooling, deposited a mixture of isomerides.

6. *Separation of $\alpha'\beta$ -Dibromocamphor.*—(a) When trying to separate this substance, an oil was first obtained, which had a rotation of $[\alpha]_{5461} = -78.5^{\circ}$ (in alcohol). This was approximately the rotation expected from the α' -isomeride; but on purification and analysis the oil was found to have the empirical formula $C_{12}H_{18}O_2Br$. Since it is very soluble in alcohol, the presence of the oil did not introduce any difficulty in the separation of the isomeric dibromocamphors, when once its character and method of formation were known. From the mixture of $\alpha\beta$ - and $\alpha'\beta$ -dibromocamphors (m. p. $93-95^{\circ}$, $[\alpha]_{5461} + 56^{\circ}$) which had been freed from this by-product, $\alpha'\beta$ -dibromocamphor was separated in two ways.

(i) The mixture was crystallised from methyl alcohol. The first fractions consisted principally of $\alpha\beta$ -dibromocamphor; but, when the excess of this compound had been crystallised out, the subsequent fractions had an almost constant specific rotation $[\alpha]_{5461} + 30^{\circ}$ (approx.). These later fractions were then crystallised from ethyl alcohol, when crystals having $[\alpha]_{5461} 0^{\circ}$ (approx.) were obtained. On further crystallisation, these gave pure $\alpha'\beta$ -dibromocamphor. As this was an extremely slow method, even when improved by judicious seeding, a second method, which was much quicker, was used.

(ii) The mixture was dissolved in acetone and left to crystallise by slow evaporation during a period of five weeks. By this method large crystals were obtained, and these were crushed separately and their melting points determined. By this method about 16 grams of nearly pure material were separated in two days from 70 grams of the mixture.

(b) The composition of the compound was shown clearly (i) by its preparation from $\alpha\beta$ -dibromocamphor, (ii) by its reconversion to $\alpha\beta$ -dibromocamphor in presence of alkali, and (iii) by estimation of bromine (Found : Br = 51.57. $C_{10}H_{14}OBr_2$ requires Br = 51.56 per cent.).

7. *Properties of $\alpha'\beta$ -Dibromocamphor.*—(a) $\alpha'\beta$ -Dibromocamphor has a slight odour resembling that of $\alpha\beta$ -dibromocamphor. It is very soluble in cold benzene, acetone (about 16½ grams per 100 c.c.), chloroform, ethyl acetate, ether, and the hot alcohols; it is soluble in the cold alcohols, but only slightly soluble in cold petroleum. It is slightly less soluble in organic solvents than $\alpha\beta$ -dibromocamphor. From hot benzene or ligroin it crystallises in long, thin prisms; measurable crystals were obtained by the slow evaporation of a solution in acetone.

(b) $\alpha'\beta$ -Dibromocamphor differs from the $\alpha\beta$ -isomeride in being strongly laevorotatory. A series of fractions which gave $[\alpha]_{5461} - 64^\circ$ or more was recrystallised four times from ethyl alcohol, and gave the successive melting points 135° , 135.6° , 136° , and 136° . The rotatory power of the final product in a series of solvents was found to be as in Table II, where for the purpose of comparison determinations are also given of the $\alpha\beta$ -compound.

(c) The crystallographic properties of the compound were determined in the Mineralogical Department by Mr. W. A. Wooster of Peterhouse College under the supervision of Mr. A. Hutchinson, F.R.S., as follows :

System : Orthorhombic.

Axial Ratios : $a : b : c = 1.0117 : 1 : 0.4599$.

Habit : Usually occurs in plates with the $s(201)$ planes largely developed. The crystals were small and did not give good reflexions.

Forms Present: $a = (100)$, $b = (010)$, $m = (110)$, $p = (210)$, $s = (201)$, $t = (201)$.

Angles observed.	No. of measurements.	Limits.	Mean observation.	Calculation.
$am = 100 : 110$	2	45° 14' — 45° 23'	45° 18'	45° 20'
$ap = 100 : 210$	4	26 37 — 27 5	26 50	—
$as = 100 : 201$	2	47 46 — 47 53	47 51	47 43
$bt = 010 : 021$	4	47 27 — 47 51	47 36	47 24
$sp = 201 : 210$	7	52 55 — 53 27	53 6	—
$st = 201 : 021$	5	56 43 — 57 1	56 52	57 0
$sm = 201 : 110$	2	61 34 — 61 48	61 41	61 46
$mt = 110 : 021$	2	61 16 — 61 32	61 24	61 12

Cleavage: None observed.

Optical Characters: The optical axial plane is parallel to $b(010)$, the acute bisectrix being perpendicular to $c(001)$. The angle $2V$ for sodium light = 24° approx. The double refraction is negative in sign. The refractive indices as determined by immersion in oils are $\alpha = 1.56$, $\beta = 1.64$, $\gamma = 1.64_5$.

$\alpha\beta$ Di-bromocamphor.

8. *Mutarotation.*—A solution of $\alpha\beta$ -dibromocamphor in acetone (5 grams/100 c.c.) gave $[\alpha]_{5461}$ 127.1° and 126.9°, mean 127.0°. When made up with $N/100$ -alkali, the rotation was $[\alpha]_{5461}$ 95.6° and 95.0°. Similarly $\alpha'\beta$ -dibromocamphor gave $[\alpha]_{5461}$ — 85.2° initially, and with $N/100$ -alkali $[\alpha]_{5461}$ 95.5°. The mean value for the rotatory power of the equilibrium mixture is $[\alpha]_{5461} + 95.4^\circ$.

From these numbers the proportion of $\alpha'\beta$ -dibromocamphor in the equilibrium-mixture would appear to be 14.8 per cent. If, however, a correction is made for the by-product, assuming that all the alkali is used up, this proportion is reduced to 9.8 per cent., as compared with the proportion of 10 or 11 per cent. deduced from the earlier measurements of solubility. Quantitative mutarotation curves could not be obtained, because the alkali was used up before equilibrium was reached, when $N/500$ -alkali was used, whilst the change was already complete in three or four minutes when $N/100$ -alkali was used.

9. *Measurements of Solubility and of Rotatory Power of Saturated Solutions.*—The solubility of $\alpha\beta$ -dibromocamphor was determined in 99.2 per cent. alcohol at 20°, (i) alone, (ii) in presence of $N/900$ -, $N/450$ -alkali, and $N/40$ -sodium ethoxide. Saturated solutions were prepared by stirring the crystals with alcohol for two hours and allowing them to settle for five minutes. Three samples of 10 c.c. of solution were then withdrawn in a warmed pipette, and evaporated in the weighing bottle at about 40° during six to seven

days. The bottle and contents were then dried to constant weight in a vacuum desiccator over soda-lime and sulphuric acid. Samples were also taken for measuring the rotatory powers of the saturated solutions. It was noticed that drying in the desiccator led to no change in weight with $\alpha\beta$ -dibromocamphor alone, but gave a loss of about 3 milligrams for each sample with $N/900$ -alkali, 9 milligrams with $N/450$ -alkali, and 33 milligrams with $N/40$ -alkali. In the last case the sample was still slowly decreasing in weight after fourteen days in the desiccator. These observations suggested that the loss in weight in a vacuum was probably due to the oily by-product evaporating and leaving the dibromocamphors behind. The results of these measurements are recorded in Table III, in which the earlier results are also reproduced for comparison. These are substantially confirmed, although lower values were obtained for the ratio $\alpha/(\alpha + \alpha')$, when an increased amount of alkali was used. The by-product formed by the alkali was probably all driven off during the evaporation and drying of the samples; but its solvent action would tend to increase the solubility of the $\alpha\beta$ -compound, and so diminish the solubility ratio from which the proportion of this compound in the equilibrium-mixture is deduced. This effect would also account for the diminished values of the predicted rotatory power of $\alpha'\beta$ -dibromocamphor, since the "corrected" rotations shown in the table were obtained by allowing for the rotatory power of the by-product, but not for its solvent action upon $\alpha\beta$ -dibromocamphor.

TABLE III.

Concentration and Rotatory Powers of Saturated Solutions of $\alpha\beta$ -Dibromocamphor.

		Concentrations of saturated solutions. Grams per 100 gms. of solvent.			Observed rotations of saturated solutions (2-dcm. tube).			Specific rotations of saturated solutions.

* New series.

† Old series.

10. *Separation of $\alpha'\pi$ -Dibromocamphor.*—The rotatory powers of $\alpha\pi$ - and $\alpha'\pi$ -dibromocamphor differ so little that they cannot

be used in the same way as those of $\alpha\beta$ - and $\alpha'\beta$ -dibromocamphor to follow the course of the separation. Since the use of melting points for this purpose is extremely troublesome, the separation was effected by slow crystallisation from acetone. Under these conditions the $\alpha'\pi$ -compound crystallised in characteristically-shaped prisms, many of which projected from the general mass at an angle of about 60° to the horizontal plane. These prisms were separated and their individual melting points and rotatory powers were determined. Those having $[\alpha]_{5461}$ above 115° in benzene were crystallised from alcohol until the melting point reached 170° . Four further crystallisations then gave a pure product, the melting points recorded after these four crystallisations being 180 — 181.5° , 181.5° , 182° , and 182° .

The composition of the product was established (i) by its method of preparation, (ii) by reversion to $\alpha\pi$ -dibromocamphor, (iii) by analysis (Found: Br = 51.72. $C_{10}H_{14}OBr_2$ requires Br = 51.46 per cent.).

11. *Properties of $\alpha'\beta$ -Dibromocamphor.*—(a) The compound has a slight odour resembling those of the other dibromocamphors. It is very soluble in chloroform, less soluble in ethyl acetate or ether; benzene and acetone both dissolve about 6 grams per 100 c.c. of $\alpha'\pi$ -dibromocamphor, as compared with some 15 grams of $\alpha\pi$ -dibromocamphor. Cold methyl or ethyl alcohol dissolves about 1 gram per 100 c.c. Measurable crystals were obtained by the slow evaporation of a solution in acetone.

(b) The melting point of $\alpha'\pi$ -dibromocamphor, at 182° , differs widely from that of $\alpha\pi$ -dibromocamphor, at 156° .

(c) The rotatory powers of $\alpha\pi$ - and $\alpha'\pi$ -dibromocamphor in several solvents at 20° are given in Table IV.

TABLE IV.

Rotatory Powers of $\alpha\pi$ - and $\alpha'\pi$ -Dibromocamphor in Different Solvents.

Solvent.	$\alpha'\pi$ -Dibromocamphor.		$\alpha\pi$ -Dibromocamphor.	
	Concentration. Grams/100 c.c.	Rotatory power. $[\alpha]_{5461}$.	Concentration. Grams/100 c.c.	Rotatory power. $[\alpha]_{5461}$.
Acetic acid	1	99.0°	1	135.0°
Ethyl acetate	5	108.6	5	128.9
Alcohol	0.66	109.0	0.66	128.1
Acetone	5	111.7	5	128.2
			7.5	128.3
Chloroform	10	118.6	10	125.9
"	2	119.5	2	126.4
Ethylene dibromide	5	120.0	5	140.9
Toluene	5	120.9	5	108.4
Benzene	5.63	126.6	14.75	110.8

This table shows that the effect of the solvent on the rotation of the two compounds is very similar numerically, but that the effect on one is the reverse of that on the other. The rotations in acetic acid and benzene were measured in a 6-dcm. tube, in alcohol in a 4-dcm. tube, and in the other solvents in a 2-dcm. tube. The effect of change in concentration is seen to be only small.

(d) The crystallographic properties of $\alpha'\pi$ -dibromocamphor were determined by Mr. W. A. Wooster as follows :

System : Orthorhombic.

Axial Ratios : $a : b : c = 0.9573 : 1 : 0.4142$.

Habit : Usually developed in flat plates parallel to $t(021)$. The crystals were small and not well suited for measurement, though sometimes clear and colourless.

Forms Present : $a = (100)$, $b = (010)$, $m = (110)$, $s = (201)$, $t = (021)$.

Angles observed.	No. of measurements.	Limits.	Mean observation.	Calculation.
$as = 100 : 201$	6	$49^\circ 4' - 49^\circ 12'$	$49^\circ 8'$	—
$tt = 021 : 021$	2	$78 \ 26 - 78 \ 34$	$78 \ 30$	$79^\circ 16'$
$tb = 021 : 010$	2	$50 \ 21 - 51 \ 6$	$50 \ 44$	$50 \ 22$
$st = 201 : 021$	3	$54 \ 5 - 54 \ 7$	$54 \ 6$	$54 \ 23$
$sm = 201 : 110$	3	$61 \ 40 - 62 \ 1$	$61 \ 48$	—
$mt = 110 : 021$	4	$63 \ 52 - 64 \ 12$	$64 \ 5$	$63 \ 50$

Cleavage : None observed.

12. *Mutarotation*.—A solution of $\alpha\pi$ -dibromocamphor in acetone (5 grams in 100 c.c.) gave $[\alpha]_{5461} + 128.2^\circ$ (mean of 128.0° and 128.3°). When the solution was made up with the addition of $N/250$ -alkali the rotation fell to $+126.4^\circ$. In a solution of the same strength, $\alpha'\pi$ -dibromocamphor gave $[\alpha]_{5461} + 111.7^\circ$, and when $N/250$ -alkali was present the final rotation was $+126.5^\circ$. The proportion of $\alpha'\pi$ -dibromocamphor in the equilibrium-mixture is therefore 11 per cent. as deduced in 1906 from measurements of solubility.

$\alpha'\pi$ Di-bromocamphor.

Summary.

(1) $\alpha\beta$ - and $\alpha'\pi$ -Dibromocamphor have been prepared from the $\alpha\beta$ - and $\alpha\pi$ -isomerides, by adding alkali and then stabilising the equilibrium-mixtures by adding an acid.

(2) Unlike α' -bromocamphor, these two compounds have much higher melting points than the corresponding α -compounds.

(3) The rotatory powers of $\alpha\beta$ - and $\alpha'\beta$ -dibromocamphor are opposite in sign, and differ widely from one another. Those of $\alpha\pi$ - and $\alpha'\pi$ -dibromocamphor are very similar to one another, but are affected in opposite ways by changes of solvent.

(4) During the action of alkali on $\alpha\beta$ -dibromocamphor an oily by-product is formed. This is probably a derivative of campholenic acid.

One of us (H.B.) is indebted to the Commissioners of the Exhibition of 1851 for a grant, with the help of which the work was carried out.

THE UNIVERSITY, CAMBRIDGE.

[Received, June 15th, 1923.]

CCXI.—Resolution of the $\alpha\delta$ -Dihydroxy- α -methyl- δ -isopropyladipic Acids.

By THOMAS ANDERSON HENRY and HUMPHREY PAGET.

In a previous paper (T., 1921, **119**, 1720), it was shown that the hydrocarbon fraction of chenopodium oil on oxidation with potassium permanganate in acetone yielded considerable quantities of the two $\alpha\delta$ -dihydroxy- α -methyl- δ -isopropyladipic acids, melting at 189° and 203 – 204° , and that these were derived from α -terpinene. Both acids proved to be optically inactive, as was to be expected. A third inactive form of the acid, melting at 190 – 191° , was described by Nelson (*J. Amer. Chem. Soc.*, 1911, **33**, 1411; 1913, **35**, 87) as produced by the oxidation of the erythritol (II) derived from ascaridole (I). In the course of the authors' work on chenopodium oil, considerable quantities of these acids have been obtained, and they have taken the opportunity of investigating them more completely.

Inspection of the formula of the acid indicates that only two inactive modifications (III and IV) should exist, and re-examination of Nelson's acid shows that it is identical with the acid melting at 203 – 204° , and not, as Wallach suggested (*Annalen*, 1912, **392**, 67), with that melting at 189° . The known inactive acids are thereby reduced to two.

Of these, one melts at $203\text{--}204^\circ$, is very sparingly soluble in water and other solvents, and loses two molecules of water with great difficulty, yielding Wallach's supposed dilactone, m. p. 62° . The other acid melts at 189° , is readily soluble in water, and yields Wallach's second dilactone, m. p. 74° , with great ease. These differences are characteristic of those which exist between the inactive forms of $\alpha\delta$ -substituted adipic acids, such as $\alpha\delta$ -dimethyladipic acids (*meso*-form, m. p. 142° , solubility in water 0.56 per cent.; *racemic* form, m. p. $70\text{--}72^\circ$, solubility in water 6.7 per cent.; Noyes, *J. Amer. Chem. Soc.*, 1910, **32**, 1057), and $\alpha\delta$ -dihydroxyadipic acids (*meso*-form, m. p. 174° , less soluble; *racemic* form, m. p. 146° , more soluble; Le Sueur, T., 1908, **93**, 716; 1910, **97**, 173).

It seemed reasonable to assume, therefore, that the acid melting at $203\text{--}204^\circ$ corresponded to the *meso*-form and that melting at 189° to the *racemic* form of these analogous acids, and could be regarded respectively as *anti*- (III), and *para*- (IV) forms; terms which have been revived by Dakin to distinguish the two inactive forms of hydroxyaspartic acid, which are analogous with the acids now dealt with (*J. Biol. Chem.*, 1921, **48**, 273; 1922, **50**, 403).

The facts are, however, not quite so simple. The acid of higher m. p. does not, as Wallach stated, lose two molecules of water when boiled with hydrochloric acid and form the "dilactone," m. p. 62° . This change occurs only on dry distillation under reduced pressure. Further, the supposed "dilactone" is in reality the anhydride (V) of 1 : 4-cineolic acid, and yields the latter acid on hydration. The more fusible acid, on the contrary, readily yields a dilactone, m. p. 74° , when boiled with hydrochloric acid, but only to the extent of 50 per cent. of its weight, and the residual liquor left in the flask now contains the remaining 50 per cent. in the form of the acid melting at $203\text{--}204^\circ$. Further, this dilactone on hydration yields a new acid, m. p. 198° , intermediate in solubility between the two already described, which reproduces the dilactone, m. p. 74° , in the calculated yield when boiled with hydrochloric acid. Separation of the two components of the acid m. p. 189° can also be partly effected by crystallisation of the quinine salt, the *d*-form of the acid m. p. $203\text{--}204^\circ$ separating first and the *d*-form of the acid m. p. 198° remaining in the final mother-liquors, but the optical antipodes of these cannot be isolated from the middle fractions by crystallisation.

As Wallach had already synthesised the acid melting at 189° (*Annalen*, 1908, 362, 268) from dimethylacetylacetone, his experiments were repeated, and yielded not one but all three inactive acids, the relative amounts obtained being acid of m. p. 203—204°; acid of m. p. 189°; acid of m. p. 198° = 3 : 1 : 1. There can be no doubt that the acid melting at 189° is a chemical individual, since it crystallises quite differently from the other two forms, is more soluble than either, and is separable from either by crystallisation. Further, it can be prepared by dissolving the other two forms in hot water, allowing whichever form is in excess to crystallise out, and then concentrating the liquid until crystallisation again begins, when the form, m. p. 189°, invariably separates.

A similar form of $\alpha\alpha$ -dimethylglutaric acid,

m. p. 105—107°, was described by Bone and Perkin (*T.*, 1896, 69, 268), which, though not separable into its components by fractional crystallisation from any solvent, could be separated into the ordinary *trans*- and *cis*-forms by crystallisation of the calcium hydrogen salt (compare Auwers, *Ber.*, 1895, 28, 263), or by warming with acetyl chloride, when the *cis*-form readily yielded an anhydride, whilst the *trans*-form remained unchanged.

It seems clear in view of their physical properties and the difference in their modes of losing water that the acid of m. p. 203—204° is the *anti*-form, and the acid of m. p. 198° the *para*-form, whilst the third acid, m. p. 189°, is a combination of these two. Unlike most of the similar acids in this series, no evidence has been found of interconversion between the *anti*- and *para*-forms.

The *anti* and *para*-acids have both been resolved into their optically active forms, the former by fractional crystallisation of the quinine and cinchonine salts, the second alkaloid being the more convenient agent, and the latter by the use of quinine. The principal facts regarding the two pairs of optically active forms and their salts are summarised in the table opposite.

It will be seen from this table that in the case of the *anti*-acid, *l*-quinine and *d*-cinchonine both separate the dextro-form of the acid first, whilst *d*-quinidine effects virtually no separation, the salts with the *d*- and *l*-forms of the acid being about equally soluble. In the case of the quinine salt, there appears to be no change in the sign of rotation, the salt with the *d*-acid being, as is to be expected, of lower rotation than that of the salt with the *l*-acid. With quinidine, on the contrary, such a change does occur, the salt with the *l*-acid having a higher rotation than that with the *d*-acid. In the case of cinchonine no comparison can be made, as the salt with the *l*-acid is abnormal in composition.

α,δ -DIHYDROXY- α -METHYL- δ -460PROPYLADIPIC ACIDS. 1881

Name.	M. p.	$[\alpha]_D$.	Solubility at 20°. Grams in 100 c.c.

sodium salt	—	+4·41	—
neutral quinine salt	213	—111·4	Less soluble.

* There is little difference in the solubility of the quinidine salts of the *d*- and *l*-acids.

† The cinchonine salts of the *d*- and *l*-forms are not comparable (see p. 1886).

With the *para*-acid, the opposite state of things occurs as regards the solubility of the quinine salts, the salt of the *l*-acid separating first. Further, there is a change of sign on conversion of the active acids into sodium salts, the sodium salt of the *l*-acid being dextro-rotatory, and *vice versa*, and this also seems to occur with the quinine salts, that of the *d*-acid having a higher lævorotation than that of the *l*-acid. Changes of sign on conversion into salts have been noticed before in this series of acids; for example, Le Sueur's *d*-dihydroxyadipic acid gave a lævorotatory ammonium salt (*loc. cit.*). With regard to the relative solubilities of the salts of the optically active forms of acids with alkaloids of the cinchona group, King has shown recently (T., 1922, 121, 2578), that the stereochemical factor is not the sole determining influence on the solubility of these salts; for example, the least soluble tropate of *l*-quinine and *d*-hydrocinchonine is the salt of the *d*-acid, whilst with *d*-hydroquinidine it is the salt of *dl*-tropic acid, and with *d*-quinidine the salt of the *l*-acid.

EXPERIMENTAL.

Preparation of the Acids.—(a) From α -terpinene. The preparation and separation of the two forms, m. p. 203—204° and m. p.

189°, from the α -terpinene present in chenopodium oil has been described already (*loc. cit.*). The yield from 1,000 c.c. of the hydrocarbon fraction of the oil, which probably contains about 16 per cent. by volume of α -terpinene, is about 16 grams of the crude crystalline acids, from which, on recrystallisation from boiling water, about 10 grams of the high-melting and about 5 grams of the low-melting form are eventually obtained.

(b) *By synthesis from dimethylacetylacetone.* The dimethylacetylacetone (b. p. 209–212°/751 mm.) was prepared from methylheptenone made by Verley's method from citral (*Bull. Soc. chim.*, 1897, [iii], 17, 175). The yield of the diketone, expressed on the citral used, was about 21 per cent.

After preliminary trials, the following method was found to give the best yield of the required acids. Twenty grams of the diketone, cooled to 0°, were mixed with 24 grams of potassium cyanide dissolved in 30 c.c. of water, and, after standing for some time at room temperature, 31.5 c.c. of concentrated hydrochloric acid were added very slowly, the mixture being kept well cooled and shaken, and then left for forty-eight hours at room temperature. On extraction with ether, this yielded 25 grams of viscous, yellow oil, which was at once mixed with twice its volume of concentrated hydrochloric acid, heated during 1 hour at 100°, and then steam-distilled. The dilactone came over slowly as a viscous, yellow oil, which sometimes crystallised at once in the condenser or the receiver and sometimes only after saturation of the aqueous distillate with salt. After filtering off the separated dilactone, the remainder, mixed with some neutral products, was obtained by extracting the distillate with ether. The total yield of dilactone was about 5 per cent. of the weight of diketone taken; it melted at 74°, and the melting point was not changed by recrystallisation from ether (Found: C = 60.40; H = 7.39. Calc. for $C_{10}H_{14}O_4$, C = 60.60; H = 7.07 per cent.).

The mother-liquor left in the distillation flask, which was apparently not examined by Wallach, was allowed to cool, poured from the considerable quantity of tar formed, and thoroughly extracted with ether, when it yielded about 5 grams of crude crystalline acids, which on recrystallisation from boiling water were separated into the acid of m. p. 203–204° (4 grams), and the acid of m. p. 189° (1 gram), neither of which showed any depression in melting point when mixed with the acids of similar melting point prepared from α -terpinene.

The crystalline dilactone, m. p. 74°, and the mixture of this with neutral products (see above) were separately treated with 2*N*-sodium hydroxide; the former dissolved completely, and on acidification the solution yielded an acid crystallising in rosettes of transparent

prisms which melted sharply with effervescence at 198°, and after cooling re-melted at 72–74°, being reconverted into the dilactone. The oily product did not dissolve completely in 2*N*-sodium hydroxide solution even after standing several days, or on heating on the water-bath. The liquid was therefore extracted with ether, and the clear alkaline solution on acidification yielded the same acid melting at 198°. Seven grams of the pure acid were dissolved in 250 c.c. of boiling water (forming a supersaturated solution, which only began to crystallise after some days), and crystallised in six fractions, all of which melted at 198° (Found: C = 51.06; H = 7.67. Calc. for dihydroxymethylisopropyladipic acid, C₁₀H₁₈O₆, C = 51.27; H = 7.69 per cent.). Mixed with the acid of m. p. 203–204°, the melting point is depressed to 187–189°, whilst a mixture with the acid of m. p. 189° begins to melt at 189°.

The oily neutral product extracted, with some of the dilactone, from the distillate by ether, after purification with sodium hydrogen sulphite, distilled at 105–130°/10 mm. or 205–215°/760 mm., and on treatment with semicarbazide yielded two substances melting at 189–190° and 174° respectively. These were separated by crystallisation from alcohol; the former, which is the less soluble, crystallised in pearly plates and was identified as the semicarbazone of tanacetophorone (Found: C = 59.29; H = 8.54; N = 22.59. Calc. for C₉H₁₅ON₃, C = 59.67; H = 8.29; N = 23.2 per cent.), this being formed, no doubt, from dimethylacetylacetone by the loss of a molecule of water thus:

The second semicarbazone, m. p. 174°, crystallised in colourless needles. It was obtainable only in small amount, showed no depression in melting point when mixed with tanacetophorone-semicarbazone, and is possibly the latter with some persistently adherent impurity (Found: C = 58.61; H = 8.48 per cent.).

Separation of the Acid of m. p. 189° into the Acid of m. p. 198° and the Acid of m. p. 203–204°.—One gram of the acid of m. p. 189°, obtained by the oxidation of α-terpinene, was boiled for forty-five minutes with 20 c.c. of concentrated hydrochloric acid, and the solution diluted with water and steam distilled, yielding 0.44 gram of crystalline dilactone, m. p. 72–74°. From the residual liquor in the flask, 0.53 gram of acid was isolated, which on recrystallisation melted at 204°. The dilactone on hydrolysis by alkali yielded the calculated amount of the acid of m. p. 198°. In a second experiment, from 3.5 grams of the acid of m. p. 189°, 1.6 grams of dilactone, m. p. 72–74°, were obtained.

Conversion of the Acid of m. p. 203–204° into the Supposed Dilactone, m. p. 62°.—Wallach stated that this acid was readily

converted, by boiling with moderately concentrated hydrochloric acid, into a dilactone, m. p. 62° . 1.2 Grams of the acid were boiled with 30 c.c. of 20 per cent. hydrochloric acid for one hour, and the liquid distilled almost to dryness. The dissolved acid crystallised out during the distillation, and was recovered unchanged. It was then boiled for one hour with 20 c.c. of concentrated hydrochloric acid, and again distilled almost to dryness, with the same result, and eventually 1.14 grams of the acid were recovered unchanged. Repetition of Wallach's dry distillation of the acid was, however, more successful. One gram of the pure acid was distilled under reduced pressure in a small distilling flask, through which a slow stream of carbon dioxide was passed by means of a capillary tube, the flask being heated in a bath of liquid paraffin. Decomposition began at 200° , and heating was continued until evolution of gas stopped. A viscous, yellow oil, amounting to 0.76 gram (90 per cent. of the theoretical), collected in the receiver. On standing on ice, part of the oil crystallised, and this, after recrystallisation from ether, melted at 65° (Found: C = 59.7; H = 6.5. Calc. for $C_{10}H_{14}O_4$, C = 60.60; H = 7.07 per cent.). The low figure for carbon and the high figure for hydrogen are due to the difficulty of drying such a small quantity of a somewhat volatile substance. On addition of the calculated quantity of 2*N*-sodium hydroxide solution, the product dissolved, forming a clear liquid, which on acidification deposited an oil which crystallised almost at once in fine needles; these, after recrystallisation from hot water, melted constantly at 122° . Admixture with 1:4-cineolic acid caused no depression in melting point (Found: C = 55.51; H = 7.7. Calc. for 1:4-cineolic acid, $C_{10}H_{16}O_5$, C = 55.5; H = 7.46 per cent.). The volatile, crystalline product must therefore be the anhydride (V) of this acid. Nelson has already recorded the formation of this substance by the dry distillation of his α , δ -dihydroxy- α -methyl-isopropyladipic acid, m. p. 190 — 191° (*loc. cit.*). The formation of this substance by dry distillation confirms the view that the 203 — 204° acid is the *anti*-form.

Resolution of the anti- and para-Acids.

A. *anti-Acid*, m. p. 203 — 204° .—Wallach only obtained this acid by the oxidation of optically active terpinen-4-ol, and he described it as active, but produced no evidence for this. The acid is too sparingly soluble in all ordinary solvents for satisfactory observation in a polarimeter, but a 15 per cent. aqueous solution of the sodium salt showed no optical activity.*

* Except where otherwise stated, the polarimeter tubes used had $l = 2$ dm.

To 7.3 grams of the acid, dissolved in 300 c.c. of boiling 96 per cent. alcohol, the calculated quantity of quinine base, dissolved in 100 c.c. of alcohol, was added, and the solution left standing for four days, when it had deposited 14 grams of quinine salt. The latter was then recrystallised from 96 per cent. alcohol until the specific rotation became constant at about -128° and the melting point at 227° . About 10 grams of material of this quality were accumulated by repeatedly working through the middle fractions. The acid regenerated from this, and recrystallised, gave a sodium salt having $[\alpha]_D + 3.53^\circ$, but on repeating the separation it was found that the constancy in melting point and rotation of the quinine salt was only apparent, and with other conditions other results were obtained, sometimes higher and sometimes lower. Recourse was then had to cinchonine, and after various trials it was found that crystallisation of the acid cinchonine salt, $C_{19}H_{22}ON_2 \cdot C_{10}H_{18}O_6$, from 96 per cent. alcohol gave much better results, a fraction melting constantly at 174° and having $[\alpha]_D + 116^\circ$ being readily separable. From 23 grams of the crude salt, 7.5 grams of the pure salt of the dextro-acid having $[\alpha]_D + 115.2^\circ$ were obtained ($\alpha_D = +4.6^\circ$ in alcohol; $c = 2.11$; $l = 1.894$). This salt crystallises in prismatic plates, sparingly soluble in alcohol and scarcely soluble in water. It was suspended in fine powder in hot water and the calculated quantity of 2N-soda added, the cinchonine filtered off, washed twice in a mortar with water, and the washings and filtrate concentrated to low bulk under reduced pressure, again filtered, and the clear solution acidified, when it deposited 3.0 grams of well-crystallised acid melting at 214° . This was converted into sodium salt, which had a specific rotation $[\alpha]_D + 5.1^\circ$ ($\alpha + 1.94^\circ$ in water, $c = 19.02$). A second determination gave $[\alpha]_D + 5.36^\circ$ for the same conditions.

The acid regenerated from the sodium salt and recrystallised gave in alcoholic solution $[\alpha]_D^{25} + 7.37^\circ$ ($c = 0.6$ to 1.25), but owing to the difficulty of reading such small rotations no great stress is laid on the quantitative value of this result.

The quinine salt made by neutralising the pure *d*-anti-acid with quinine and recrystallising from 96 per cent. alcohol had m. p. 231° , and $[\alpha]_D - 127.2^\circ$ in alcohol ($\alpha - 1.79^\circ$, $c = 0.7454$, $l = 1.894$). The quinidine salt of the *d*-acid, made similarly, crystallises from 30 per cent. alcohol, and has m. p. 144° and $[\alpha]_D + 154.4^\circ$ in alcohol ($\alpha + 15.84^\circ$, $c = 5.417$, $l = 1.894$).

The more soluble cinchonine salt could only be obtained as an oil for some time, but eventually a portion of this was induced to crystallise from a syrupy solution in 10 per cent. alcohol. Yield 5.5 grams = 24 per cent. The acid regenerated from this was

converted into the sodium salt, as already described, and gave in successive readings, the acid being recrystallised each time, $[\alpha]_D - 5.71^\circ$, $- 5.78^\circ$, $- 5.62^\circ$ in water ($c = 17.94$ to 18.03). The acid itself, regenerated as described in the case of the *d*-acid, melted at 214° , and in alcoholic solution gave as a mean of three determinations $[\alpha]_D - 7.20^\circ$ ($c = 0.76$ to 1.42), but for the reason given in the case of the *d*-acid great accuracy is not claimed for this result.

The pure cinchonine salt of the *l*-acid was made by adding the calculated quantity of base to the acid, dissolved in water, and distilling off the excess of solvent. On cooling, the salt crystallised in colourless, triangular plates, which began to soften at 178° and melted completely at about 190° . This salt is abnormal and appears to have approximately the composition $3C_{19}H_{23}ON_2 \cdot 2C_{10}H_{18}O_6$. It is soluble in little more than its own weight of 96 per cent. alcohol. $[\alpha]_D + 145.7^\circ$ in alcohol ($\alpha + 6.96^\circ$, $c = 2.521$, $l = 1.894$).

The quinine salt, similarly prepared, crystallises from 50 per cent. alcohol in warty masses of colourless needles, m. p. 225° , $[\alpha]_D - 135.6^\circ$ in alcohol ($\alpha_D - 2.72^\circ$, $c = 1.057$, $l = 1.894$). The quinidine salt of the *l*-acid, similarly made, crystallises from 30 per cent. alcohol in warty masses of needles closely resembling the quinine salt in appearance. It melts at 154° and has $[\alpha]_D + 162.4^\circ$ in alcohol ($\alpha + 17.37^\circ$, $c = 5.645$, $l = 1.894$). The quinidine salts of both the *d*- and the *l*-acid separate from hot solution in dilute alcohol as oils, which slowly crystallise on standing, and are to some extent soluble in water.

para-Acid, m. p. 198° .—Five grams of this acid were converted into the neutral quinine salt, and the crude salt recrystallised from 96 per cent. alcohol in the usual manner until a constant product, m. p. 212° , $[\alpha]_D - 111.9^\circ$ in alcohol ($\alpha_D - 3.18^\circ$, $c = 1.420$), was obtained. The yield was 2.5 grams. A repetition of this separation, using 8.3 grams of acid and crystallising from dilute alcohol (30 to 50 per cent.), gave 6.8 grams of pure quinine salt, m. p. 213° , $[\alpha]_D - 111.4^\circ$ in alcohol ($\alpha_D - 4.62^\circ$, $c = 2.074$), but the use of weaker alcohol, involving a higher temperature on concentration, leads to gradual darkening of the solution and makes it more difficult to recover the more soluble quinine salt.

The acid regenerated from the pure less soluble quinine salt melted at 208° , re-solidified on cooling, and then re-melted at 74° , owing to conversion into the dilactone. The sodium salt in aqueous solution gave $[\alpha]_D + 4.25^\circ$, $+ 4.41^\circ$ ($\alpha + 1.49^\circ$, 1.62° ; $c = 17.54$, 18.36). The free acid had $[\alpha]_D^{21} - 10.96^\circ$ in water ($\alpha - 0.22^\circ$, $c = 1.004$) and $- 9.55^\circ$ in 96 per cent. alcohol ($[\alpha]_D - 0.74^\circ$, $c = 4.091$, $l = 1.894$).

The more soluble quinine salt was difficult to obtain in satisfactory

condition, for the reason already stated, but after many crystallisations (1) 8.6 grams of well-crystallised salt, m. p. 207° , $[\alpha]_D - 129.4^{\circ}$ in alcohol ($\alpha - 4.99^{\circ}$, $c = 2.035$, $l = 1.894$), and (2) 6.5 grams of ultimate residue, partly crystalline, were obtained. Fraction 1 proved to be only partly resolved, since the sodium salt of the acid regenerated from it had $[\alpha]_D - 1.69^{\circ}$. Fraction 2 yielded an acid which melted at 206° and after cooling re-melted at 74° . On conversion into the sodium salt, the latter gave $[\alpha]_D - 3.95^{\circ}$, -4.11° in water ($\alpha - 0.46^{\circ}$, 0.48° ; $c = 6.3$, $l = 1.894$), and the acid regenerated from this still melted at 206° , and showed specific rotation $[\alpha]_D + 9.03 + 9.94^{\circ}$ in water ($\alpha + 0.20^{\circ}$, 0.22° , $c = 1.107$), and $[\alpha]_D + 9.12^{\circ}$ in alcohol ($\alpha + 0.72^{\circ}$, $c = 4.17$, $l = 1.894$). The quinine salt made from the pure acid and recrystallised from dilute alcohol melted at 207° and had $[\alpha]_D - 134.5^{\circ}$ in alcohol ($\alpha - 7.60^{\circ}$, $c = 2.98$, $l = 1.894$).

Acid, m. p. 189° .—This acid on conversion into the quinine salt and fractional crystallisation of the latter yielded (i) a small fraction which after purification had m. p. 228° and $[\alpha]_D - 130.5^{\circ}$, (ii) a large middle fraction which showed varying melting points on recrystallisation, and (iii) a small ultimate fraction, which could not be obtained well crystallised. The acid regenerated from fraction (i), on recrystallisation from water, proved to give a dextrorotatory sodium salt, and on fractional crystallisation from boiling water was separated into the acid of m. p. 205° and the acid of m. p. 187° in about equal proportions. The acid regenerated from fraction (ii) was largely unchanged acid of melting point 189° , whilst that recovered from fraction (iii) gave a levorotatory sodium salt, and appeared to consist in part of the dextro-form of the acid m. p. 198° . As shown already (p. 1883), results obtained in other ways proved that the acid melting at 189° is a combination of the *anti*- and *para*-acids, into which it can be separated.

The authors desire to express their thanks to Mr. F. Walton and Mr. S. E. Pusey for much help with the experimental work.

WELLCOME CHEMICAL RESEARCH LABORATORIES.

[Received, June 16th, 1923.]

CCXII.—*Studies on the Dolomite System.—Part II.*

By ALLAN ERNEST MITCHELL.

THE process of formation of dolomite, still a matter of obscurity, is of interest in connexion with recent developments in geophysical chemistry. Hitherto, we have had to look almost entirely to

the geologist for an explanation, since, with one notable exception, no work of a quantitative nature has been attempted.

Pfeff (*Neues Jahrb. Min. Geol. Beil-band*, 1907, 23, 529), in an examination of the Seine bank formation in France, concluded that in this particular case the substance was formed partly by direct precipitation from sea-water and partly by replacement of calcium in calcite during interaction with magnesium salt solutions; the presence or absence of organic material had nothing whatsoever to do with the formation, which was in general due to replacement and was quite independent of the depth.

Judd and Skeats (*Roy. Soc. Rep.*, 1904, 362), from an examination of the specimens collected by the David expedition to Funa Futi, claimed that in this particular instance the dolomite was precipitated along with calcite and arragonite from sea-water, and that in all cases the specimens are distinctly shallow-water formations.

David (*Proc. Roy. Soc.*, 1897, 62, 200), in an examination of the Funa Futi atoll, found that dolomitisation of the reef was apparent from the surface downwards and was complete at a depth of only sixty feet.

Link (*Tonindustrie Ztg.*, 1909, 33, 609) suggests that the principal source of dolomite is calcareous sediment of animal or vegetable origin that has been subjected to the action of ammonium carbonate produced by the decomposition of the organic material of the sediment, in the presence of magnesium salt solutions, and, further (*Monatsh. Deutsch. Geol. Ges.*, 1909, 230, 41), that dolomite is formed at but slightly elevated temperatures and pressures as the result of a simple equilibrium between calcium- and magnesium-ions and the solid carbonate in accordance with the law of mass action.

Spangenberg (*Zeit. Kryst. Min.*, 1914, 52, 529), working with various forms of calcium carbonate and magnesite at temperatures up to the boiling point of the solutions and under various pressures of carbon dioxide, isolated a substance which he claimed as synthetic dolomite. From a comparison of its physical properties with those of the purest natural mineral, however, it seems that the substance was not dolomite, but was more probably a mixture of calcite and magnesite, or of vaterite and magnesite.

Leitmeier (*Jahrb. Min. Beilageband*, 1916, 40, 655) was unable to crystallise dolomite by evaporation of solutions containing both calcium and magnesium bicarbonates.

Numerous other attempts to explain the formation of dolomite from various solutions under varying conditions have all failed. The general opinion seems to be that direct precipitation from

sea-water and also replacement reactions with calcite may be the responsible processes. Views regarding the conditions of temperature and pressure obtaining during the formation are somewhat indefinite, but these are usually considered as being very little above sea temperature and atmospheric pressure.

Although the experiments described on pp. 1893, 1902, furnish evidence of the formation of certain definite compounds under the conditions stated, nothing much is to be derived from them in elucidation of the problem under consideration. Sea-water is certainly alkaline, but the alkalinity is by no means as large as that required for the production of the compounds obtained; moreover, the solutions employed were so complex ionically that it would be impossible under the present conditions to discuss their equilibria in any way.

Failure to produce dolomite by these methods may easily be explained if we consider the time factor involved in the formation of the mineral. Geological evidence goes to show that the formation takes place practically at sea level. The evidence collected by the Funa Futi expedition, the object of which was primarily to test the various theories of the formation of coral reefs, shows that the Darwin and the Murray theory both furnish acceptable explanations of the various phases of the formation. Elevation or subsidence as a geological phenomenon requires geological times for its completion, and thus it is easy to see that if dolomite is deposited from sea water, the time factor is in its favour under these conditions, and that the only hope of preparing dolomite in the laboratory would be to increase the velocity of the reaction enormously.

The most obvious method of doing so is to increase the concentration of the carbon dioxide, and therefore of the alkaline-earth carbonates, in the solution by increasing the pressure of the gas above it. For the proper study of this system, therefore, it is necessary to investigate, first of all, the solubility relationships of the carbonates of calcium and magnesium, both alone and when mixed as solid phase, under varying pressures of carbon dioxide and up to the critical pressure for the formation of either solid bicarbonate; in the first instance, this involves the separate investigation of the solubilities of calcite and at least one of the carbonates of magnesium.

The Equilibrium of a Carbonate or of a Mixture of Two Carbonates in Contact with Water.

With most electrolytes the determination of the solubility product is a simple matter because the solvent is pure water. But with the system under investigation here, the simple determination

is impossible, since, first, in pure water there is an indeterminate but appreciable amount of hydrolysis, and, secondly, it has been shown by Johnston (*J. Amer. Chem. Soc.*, 1915, **37**, 2001) that with these substances there cannot be true equilibrium unless the solutions be in contact and have come to equilibrium with a definite partial pressure of carbon dioxide.

If this second condition be realised and the concentration of the solution in contact with a definite solid phase be known, the solubility product can be calculated. Consider the case of a carbonate MCO_3 in contact with its saturated solution in equilibrium with a definite partial pressure (P atms.) of carbon dioxide. We then have

- (i) $[\text{M}^{++}][\text{CO}_3^{--}] = K_M$,
- (ii) $[\text{H}^+][\text{HCO}_3^-]/[\text{H}_2\text{CO}_3] = K_1$,
- (iii) $[\text{H}^+][\text{CO}_3^{--}]/[\text{HCO}_3^-] = K_2$,

in which the solubility product is expressed by (i), whilst (ii) and (iii) have their usual significations in expressing the first and second dissociation constants respectively for carbonic acid. Then the equilibrium in the solution between carbon dioxide and the carbonic acid formed from it may be represented by

$$[\text{H}_2\text{CO}_3]/[\text{CO}_2]_g = n/1 - n,$$

where n denotes the fraction of carbon dioxide existing in the solution as carbonic acid and $[\text{CO}_2]_g$ denotes the concentration of free carbon dioxide. An actual determination of the molal solubility, c , of the gas gives

$$([\text{H}_2\text{CO}_3] + [\text{CO}_2]_l)/P = c,$$

so that we may write

$$(iv) [\text{H}_2\text{CO}_3] = ncP.$$

No definite value can be assigned to n , but it has been shown by Walker and Cormack (*J. Amer. Chem. Soc.*, 1900, **77**, 13) to be greater than 0.5 at 18° , so that it cannot be omitted from consideration. It will be seen also that on the value assigned to n the ultimate numerical value of K_M must depend.

Values of c are very easy to determine, and work has been carried out with a considerable number of solutions as well as with water alone. Bohr (*Ann. Physik*, 1899, **68**, 509) gives values for the solubilities of carbon dioxide in water and in sodium chloride solutions for a range of temperatures up to 60° , and Geffcken (*Z. physikal. Chem.*, 1904, **49**, 527) gives values for several other salt solutions and for a few common acids. These two investigations show that the value of c is almost the same in different

salt solutions, and that it is practically inversely proportional to the concentration of the solutions, or, more accurately, inversely proportional to the total ionic concentration.

All the absorption coefficients required have been obtained from a large-scale graph of Bohr's figures on the assumption that the value of c is the same for alkaline earth bicarbonate solutions as for sodium chloride solutions of the same equivalent concentrations.

From equations (ii) and (iii), we get, by division,

$$(v) [\text{HCO}_3']^2/[\text{CO}_3''][\text{H}_2\text{CO}_3] = K_1/K_2 = r,$$

and combining (iv) and (v),

$$(vi) [\text{HCO}_3']^2/[\text{CO}_3'']cP = nr.$$

Johnston (*loc. cit.*) has calculated the value of nr from McCoy and Smith's results (*Amer. Chem. J.*, 1903, **29**, 437) by means of Noyes's rule, and found that it is independent of pressure for any fixed concentration, but diminishes with increasing concentration, and that the limiting value for zero concentration of salt is 5600. By means of this value we can arrive at a more definite value of K_2 than has hitherto been obtained, for, from the work of Walker and Cormack (*loc. cit.*),

$$\text{we have } \frac{[\text{H}^+][\text{HCO}_3']}{[\text{H}_2\text{CO}_3] + [\text{CO}_3]_s} = 3.04 \times 10^{-7} \text{ at } 18^\circ,$$

$$\text{whence } K_1 = 3.04 \times 10^{-7}/n \text{ at } 18^\circ \text{ or } 3.4 \times 10^{-7}/n \text{ at } 25^\circ.$$

$$\text{Therefore } K_2 = K_1/r = \frac{3.4 \times 10^{-7}}{n} \cdot \frac{n}{5600} = 6 \times 10^{-11} \text{ at } 25^\circ.$$

This value is identical with the original result of McCoy, and with that of Shields (*Z. physikal. Chem.*, 1893, **12**, 167), which on recalculation gives $K_2 = 5.9 \times 10^{-11}$.

Substituting the value of $[\text{CO}_3']$ (equation i) in equation (vi), we get

$$(vii) nrK_M = [\text{M}''][\text{HCO}_3']^2/cP.$$

We are thus able to calculate the solubility product for a carbonate of the type of MCO_3 if we know the factors on the right-hand side of equation (vii), and these are very easily obtained from the measurements of the solubility as postulated above. When working with solutions of low carbon dioxide content, it will, of course, be necessary to correct for the small amount of neutral carbonate unavoidably present. Then, if the appropriate degrees of ionisation are known, all the necessary factors will be determinable.

This simple case may now be extended to that of a solid phase

composed of a mixture of two carbonates, MCO_3 and NCO_3 . Equation (i) of the initial case now becomes

$$(ia) [M''][N''][\text{CO}_3''] = K_{MN},$$

where K_{MN} represents the combined solubility product or $K_M \times K_N$, whilst the other equations (ii to vii) remain as before.

Substituting the value of $[\text{CO}_3']^2$ (equation ia) in equation (vi), we get.

$$(viii) n^2 r^2 K_{MN} = [M''][N''][\text{HCO}_3']^4 / c^2 P^2.$$

The expression of the results will be the same as before, with the exception that in this case we must take into account the effect of the common ion upon the degrees of ionisation of the two salts in solution. The widely established Noyes rule has been employed for this purpose and the results thus obtained have been used in the corresponding calculations of $n^2 r^2 K_{MN}$ ($= n^2 r^2 K_D$ for dolomite).

EXPERIMENTAL.

Conditions of Formation of Dolomite.

In view of the prevalent idea that dolomite can be formed by direct precipitation from sea-water, it seemed that the most natural way to investigate the problem would be to introduce the conditions of concentration, etc., which prevail in the sea, and to apply the methods in common laboratory use for the growth of crystals of sparingly soluble substances. Solutions were therefore made up from the formulæ given in the reports of the Challenger expedition, and by Schlessing (*Compt. rend.*, 1906, **142**, 320), except that in this case the proportions of magnesium chloride and calcium carbonate were slightly increased.

Five hundred c.c. of "artificial sea-water," lacking magnesium chloride and calcium carbonate, were very slowly stirred in a beaker while solutions of $N/25$ -magnesium chloride and saturated calcium bicarbonate, prepared by saturating a calcium hydroxide solution with carbon dioxide at atmospheric pressure, were allowed to enter drop by drop from burettes placed at diametrically opposite sides of the beaker until 100 c.c. of each had been added; no precipitate formed, even after several days. The solution was now rendered alkaline by means of 10 c.c. of $N/20$ -sodium carbonate; a precipitate appeared six hours after and had increased to twice its bulk after a week. The grains were of extremely irregular character and were so small as to prevent accurate determination of their optical properties, except that it was possible to see that the refractive index was slightly greater than 1.69, and the birefringence was very strong. The substance was neither hydrated

nor basic in character (Found: $\text{CaO} = 26.50, 26.45$; $\text{MgO} = 25.10, 25.10$; $\text{CO}_2 = 48.61, 48.58$ per cent.).

Other experiments were carried out in which the proportions of the reagents were varied over a wide range, and although the results were not always in good agreement amongst themselves and were not always reproducible, it was found that, in general, under conditions of slight alkalinity, that is, $p_H = 7-9$, and with concentrations of calcium and magnesium salts up to $N/10$, the product of reaction at 25° was very similar to that obtained by Link. The crystals consist of sphericular aggregates of refractive index very similar to that of dolomite. The birefringence is very high, but because of the interference, is obviously anomalous. Analyses show that the crystals do not vary much in composition and are very similar to those obtained by Link.

	Normality of magnesium salts.				Link's salt.
	$N/50$	$N/20$	$N/15$	$N/10$	
% CaCO_3	55.50	55.23	55.41	55.60	54.8
% MgCO_3	44.26	44.80	44.85	44.60	44.8
	99.76	100.03	100.26	100.20	99.6

In another set of experiments, equal volumes of a solution containing equivalent quantities of calcium and magnesium chlorides and $N/10$ with respect to total chlorine, and of a $N/10$ -solution of sodium carbonate were allowed to drop as before into a litre of water, about 500 c.c. being added in eight hours. A fortnight later, when some 300 c.c. of water had evaporated, a very fine-grained precipitate was obtained. This was almost structureless as far as could be seen from microscopic examination, although it was definitely anisotropic. The refractive index was 1.63 (Found: $\text{H}_2\text{O} = 14.81, 14.62, 14.75$; $\text{CaO} = 23.51, 23.59, 23.82$; $\text{MgO} = 16.20, 16.14, 16.23$; $\text{CO}_2 = 46.00, 46.03, 45.97$ per cent.). The composition therefore corresponds very closely to the formula $\text{CaCO}_3 \cdot \text{MgCO}_3 \cdot \text{H}_2\text{O}$, and is similar to that of some of the hydrolomites described by Doelter ("Handbuch der Mineralchemie," Bd. I, p. 364, etc.).

Solubility of Calcium and Magnesium Carbonates.

Apparatus.—In most of the previous measurements of the solubility of these carbonates, Henry's law was assumed to hold with fair accuracy for carbon dioxide, but in very few experiments were actual measurements of pressure made. In the present work it was regarded as essential that it should be possible actually to measure the pressures of carbon dioxide employed, and since these were necessarily greater than 20 atmospheres, the design of

a suitable apparatus gave some difficulty. The apparatus actually employed is shown in detail in Fig. 1. The central vessel, *V*, is a cylindrical steel bomb, rendered gas-tight by means of the lead washer at *L*. The actual details of the construction are evident from the diagram. All valves are of the usual needle type, working through stuffing-glands packed with cotton and tallow. In order to obviate errors which would arise through solutions coming in contact with the steel of the vessel, *V* is provided with a tightly fitting silver liner, the lid of the bomb is covered on the inside by a silver face-plate, and the tube *S*, which admits the gas to the solution, is also of silver. The silver vessel was about two-thirds

FIG. 1.

filled with water, and the solids were added. It was then slid into place, and all joints having been made tight and the valves *A* and *B*, being open, carbon dioxide from a cylinder entered through the coupling at *E*, passed through *A* and the filter tube *G*, bubbled through the liquid, and finally escaped at *B*. The particles employed were all small enough to remain suspended for considerable periods, and therefore efficient stirring could be secured by regulating the rate of out-flow of the gas at *B*. When equilibrium had been established, and it was required to remove the solution for analysis, *A* and *B* were closed and *C* and *D* opened, so that the liquid was forced by the pressure through the filter tube *G*, in which any suspended solid was collected, and the liquid issuing at *T* could then be collected in any vessel at will. The construction

of G is such that any filtering material can be placed between the perforated plate Y and the plug X . Various substances, including spongy silver, asbestos, and cotton-wool, were tried for this purpose, and the last proved to be the most efficient. The bomb and the valve blocks were contained in an oil-bath which was electrically heated and its temperature controlled to $\pm 0.1^\circ$. The pressures were measured by means of an accurate Bourdon gauge at E , which was tested from time to time against a standard gauge and corrections applied when necessary.

Effect of Pressure on the Solubility.—McCoy and Smith (*J. Amer. Chem. Soc.*, 1911, **33**, 468) have shown that at 25° the critical carbon dioxide pressure for the formation of solid calcium bicarbonate is in the neighbourhood of 15 atmospheres. All their pressures were, however, arrived at by use of Henry's law, which, as has been shown by Wroblewski (*Compt. rend.*, 1882, **94**, 955, 1355) and others, is not necessarily valid for the gas under consideration. It was therefore deemed necessary to repeat their work with calcium carbonate, actual estimations of the carbon dioxide present in the solutions being made for every pressure. This work served two main purposes: (1) as regards the solubility of carbon dioxide in solutions of calcium bicarbonate at different pressures, to determine the deviations from Henry's law, and (2) by working with a known system, to test the accuracy of the technique described above.

Hulett (*Z. physikal. Chem.*, 1901, **37**, 385) has shown that the limit below which the size of the grain has an effect on the measured solubility of a sparingly soluble substance is 2μ . Bäckström (*ibid.*, 1921, **97**, 197) has shown that the same limit holds for calcite and aragonite. As the calcite used in the experiments now described was precipitated analytical reagent of a very high degree of purity, which on microscopic examination was found to contain no particles of diameter less than 10μ , there was no need to take into consideration the effect of the size of the particles in the solubility. Bäckström has shown that equilibrium between calcite or aragonite and water under carbon dioxide at atmospheric pressure is attained only after at least 140 hours. The conductivity method as applied by him could not be employed here, so that it was necessary to rely on analysis of the solutions from time to time to obtain the rate of approach to equilibrium. This was determined in the case of calcite in water at 25° and 4 atms. pressure. The solutions were allowed to react for a given time and a sample was then blown out into a weighed evacuated flask, and its weight determined. The total base was estimated by direct titration with $N/20$ -hydrochloric acid. The time was then

increased until the hydrochloric acid titre became constant for a constant weight of sample. The results of this are shown in Table I.

TABLE I.

Time (hours).	Total calcium (mol./litre).	K.	Time (hours).	Total calcium (mol./litre).	K.
24	0.010	—	96	0.0180	0.0386
36	0.01295	0.0383	120	0.01802	—
60	0.0159	0.0367	150	0.0180	—
84	0.01745	0.0390			

The values of K have been determined from the equation of Noyes and Whitney for rate of solution,

$$K = \frac{2.302}{(t_2 - t_1)} \log_{10} \frac{(C - c_1)}{(C - c_2)},$$

in which C is the concentration of the saturated solution, that is, the final concentration, and c_1 and c_2 are the concentrations at times t_1 and t_2 (hours), respectively.

From these results it will be seen that the reaction should be allowed to proceed for at least 100 hours; actually, 150 hours were allowed.

Analytical Methods.—Carbon Dioxide. Winkler's standard method (*Z. anorg. Chem.*, 1897, **13**, 127) having proved unsatisfactory, and precipitation methods in general being untrustworthy (Drane, *Diss.*, London, 1922), carbon dioxide was estimated by the method described by Johnston (*J. Amer. Chem. Soc.*, 1916, **37**, 947), who states that the only satisfactory way in the case of a carbonate in solution in the presence of carbon dioxide is that of pumping the gas off while acid is being added to the solution; the volume of evolved gas is then measured, and the carbon dioxide removed by absorption in potash solution, the contraction giving the volume of the carbon dioxide. The amounts of free and of combined carbon dioxide having thus been estimated, a knowledge of the total quantity of base present and of the other factors previously mentioned enables us to calculate the composition of the components of the solution. When a constant-volume, water-jacketed burette was used for the measurement of the gas, very good results were obtained by this method.

Total Base.—This was estimated by direct titration of the carbonate solutions with $N/20$ -hydrochloric acid, with methyl-orange as indicator. $N/20$ -Hydrochloric acid was found to be affected very considerably by free carbon dioxide, so that the precaution had to be taken to titrate until the colour of the solution was the same as that of a saturated solution of carbon dioxide in water containing the same amount of methyl-orange.

In the case of the more saturated solutions, the results were checked as follows: *calcium* was precipitated as oxalate, which was washed with hot water, dissolved in dilute sulphuric acid, and titrated with *N*/20-permanganate; *magnesium* was precipitated as magnesium ammonium phosphate from the boiling solution, and the precipitate, after standing twenty-four hours, washed with 10 per cent. ammonia, dried in an air-oven at 60° for an hour, dissolved in excess of *N*/10-sulphuric acid, and titrated with *N*/10-potassium hydroxide, with methyl-orange as indicator. This modification of Handy's method gave excellent results.

Separation of Solid Phases in Mixtures.

In the experiments on mixtures of calcite and nesquehonite, it was necessary to make a separation of the solid phases when the solution had been drawn off. Spangenberg (*loc. cit.*) made use of the differential solubility of the carbonates in *N*/3-copper nitrate solution. This method was tried, but proved unsatisfactory owing to the formation of large amounts of basic copper salts. A solution of 2 per cent. acetic acid was finally employed for this separation. Calcite and nesquehonite are readily soluble in it, and disappear after only one hour's stirring, whilst ordinary natural dolomite is practically untouched in that time. It was thus found possible to estimate the dolomite in mixtures of calcite, nesquehonite, and dolomite, with an error of 1—2 per cent. The results were found to agree to within 1 per cent. in duplicate estimations, and all figures given are mean values.

Preparation of Nesquehonite.—For the preparation of the carbonate, $\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$, two general methods were employed: (1) the method of Knorre (*Z. anorg. Chem.*, 1903, **34**, 260), and (2) a modification of Gjaldbeck's method (*Kgl. Landbohøjskole Aarskrift*, 1921, 245), in which air is blown through a solution of *M*-magnesium sulphate and 2*M*-sodium bicarbonate in equal volumes for about forty-eight hours at the temperature of the laboratory (18°).

Both methods yield a crystalline trihydrate, which, after being washed several times with water, is absolutely free from sulphate. The second method was mostly employed on account of its rapidity and relative economy of reagents.

The Solubility of Calcite in Water containing various amounts of Carbon Dioxide.

In the high-pressure solubility apparatus described, measurements of the solubility of calcite in water in contact with carbon dioxide at pressures between 4 and 24 atmospheres have been

made at 25°. The results are given in Table II. The values of α (degree of ionisation) given are those calculated from the conductivity of equivalent solutions of calcium acetate. It is readily seen from the figures that, since the ratio of total carbon dioxide to calcium is in all cases greater than 2:1, there is no neutral carbonate present in the solutions. Some of the values of McCoy and Smith have been recalculated to bring them into line with the present work, and these figures are shown in Table III. If we follow McCoy and Smith, and plot the concentration of total calcium against the cube root of the concentration of un-ionised carbon dioxide in the solution, we have a convenient method of obtaining an approximately linear relationship, for if we assume

FIG. 2.

for the purpose that all the carbon dioxide in the solution exists as H_2CO_3 we have the relationship

$$K = \alpha \times [Ca(HCO_3)_2] / \sqrt[3]{[H_2CO_3]},$$

where K is the equilibrium constant. When this is done, we find that the curve is almost the same as that given by them, and that the transition pressure is not far removed from their value, since it is (as nearly as it is possible to measure) 14.2 atmospheres.

In the calculations of McCoy and Smith's figures, the values of α used are those given by them, and the figures thus obtained do not agree well with the present results. The value obtained by them for the solubility product K_{Ca} from the relationship

$$K_{Ca} = [Ca''] [CO_3''] = 4k_2 K^3 / k_1,$$

where k_1 and k_2 have their usual significance, is 0.93×10^{-8} . If the value of nr be taken as 5,600, then we have $nrK_{Ca} = 5.3 \times 10^{-5}$

which is in close agreement with the values obtained here. The concentration of the saturated solution of calcium bicarbonate at 25° is found from the curve to be 0.0267 mol./litre (shown in Fig. 2), which also agrees fairly well with the figures of McCoy and Smith.

As regards the deviations from Henry's law, it is seen from Table II that these are by no means large, and become really apparent only at pressures of carbon dioxide greater than 11 atmospheres.

The Solubility of Magnesium Carbonate Trihydrate in Water containing various amounts of Carbon Dioxide at 25°.—It was decided that as a commencement it would be interesting to work with nesquehonite instead of with magnesite (as one would normally do in the investigation of the formation of a member of an iso-morphous series).

The examination of the system was carried out in exactly the same way as that described for calcite, and the results of the measurements are given in Table IV. The values of α employed are those of equivalent solutions of magnesium chloride derived from conductivity data. In connexion with the values of c calculated from Bohr's observations and those actually measured, it is seen that the deviations from Henry's law are not so large in this case as in the former one, but the divergence comes in the same place in each series.

Engel (*Ann. Chim. phys.*, 1888, **13**, 353) has made determinations of the solubility of the substance under pressures of carbon dioxide up to 6 atmospheres, and at temperatures up to 50°. Calculation

of these constants have been made by Johnston, and when the variation of the constant with temperature is plotted, it is found that at 25° the interpolated value is 0.45, which agrees almost exactly with that determined in this work for a much wider range of pressures. This variation of constant with temperature is apparent from Table V.

The Solubility of mixtures of Calcite and Nesquehonite in Water containing various amounts of Carbon Dioxide at 25°.—Experiments have been conducted with equimolecular mixtures of these two carbonates under pressures of carbon dioxide up to 20 atmospheres.

The results are given in Table VI, where the values of α_1 and α_2 are those calculated for calcium bicarbonate and magnesium bicarbonate, respectively, by means of the Noyes rule. The values of "c observed," and "c calculated" are respectively obtained from the actual analyses of the solutions and by interpolation from the figures of Bohr for sodium chloride solutions on the assumption that, for mixtures of salts, as is actually the case for the individual constituents, the nature of the dissolved salt has no effect on the solubility of the gas.

In an experiment in which the pressure was 20 atmospheres, much difficulty was experienced in separating the liquid owing to the presence of very finely divided material which it was impossible to remove by the ordinary method of filtration. Hence all analyses at this stage were considerably vitiated. A method of filtration has been devised which, it is hoped, will prove satisfactory, but at the present time no figures are available for these solutions.

Examination of the solid phases from these solutions gave the following results:

At *six atmospheres*, after separation of the calcite and the nesquehonite, a small residue was obtained which was composed of perfectly definite crystals of such a small size as to make their microscopic identification impossible. The amount was only of the order of a few milligrams, so that chemical analysis was impossible. This experiment was carried on for a fortnight.

From an experiment at *eleven atmospheres*, lasting a fortnight, a residue was obtained which was only slightly greater in bulk than the previous one. The crystals were larger, however, and it was possible to determine some of the optical properties. The refractive index, determined by the embedding method, was found to be 1.68 ± 0.005 , while the figures for normal dolomite quoted in the literature are all of the order of 1.68. By use of a pycnometer of about 1 c.c. capacity it was possible to determine the density with an accuracy of about 2 per cent. The values obtained in this way were 2.920, 2.922, 2.918, 2.920, mean 2.920.

The value 2.920 is within the range 2.914—2.924, given by Groth ("Chemische Krystallographie," II, 207) for normal dolomites. The double refraction was of a fairly high order, but its accurate determination was not possible. The sign of the birefringence was negative. A micro-analysis by a modification of the Rosiwal method, in which the calcium and the magnesium were precipitated together as oxalates and the bulks averaged for various haphazard sections of the micro-slide, gave the molecular ratio of calcium carbonate to magnesium carbonates as approximately 9:10. This method of analysis cannot claim any high degree of accuracy.

At pressures of *sixteen and twenty atmospheres*, the results were identical, and in all about half a gram of material was isolated from experiments extending over a fortnight in each case. The crystals were of definite form and showed the rhombohedral habit associated with dolomite. The refractive index, determined by the embedding method, was 1.682, and the birefringence was negative and of the order of 0.19. The density was found by the

pycnometer method to be 2.918. Analysis showed that the composition does not depart appreciably from that corresponding to the formula $\text{CaCO}_3, \text{MgCO}_3$ (Found: $\text{CaO} = 30.36, 30.34, 30.37$; $\text{MgO} = 21.92, 21.94, 21.90$ per cent.).

The Solubility of Algerian Dolomite in Water containing various amounts of Carbon Dioxide at 25°.—Owing to the scarcity of pure dolomite, it has only been possible to do these experiments at low concentrations of carbon dioxide for various pressures up to one atmosphere. Air mixed with various amounts of carbon dioxide was passed through a cylindrical solubility vessel provided with platinum electrodes, and the conductivity of the solution determined from time to time. The gas, entering through a side tube sealed to the vessel close to its constricted base, served to stir the solution and solid, and escaped through a constant-pressure blow-

off, which could be adjusted by hand to counteract variations of barometric pressure. The streams of air and carbon dioxide were also controlled by hand-regulated blow-offs, so that the flow could be kept constant. The vessel was made of best resistance glass, which was carefully steamed and cleaned before use. Analysis of the issuing gas from time to time gave a very ready method of checking the partial pressure of the carbon dioxide in the mixtures. The construction of the vessel was such that large particles could be used; they were easily held in suspension by the gas stream, but settled very readily when a measurement of conductivity was required. The approach to equilibrium (Fig. 3) was determined from these measurements, and the results obtained were all of the same form as those of Bäckström for calcite and aragonite. The results obtained at the equilibrium state are given in Table VII.

We thus have a peculiar case in which two salts, containing equi-valent constituents, affect each other's solubility in opposite directions. This is at present inexplicable and the system requires

TABLE VII.

much more complete investigation, especially in the region of saturation with respect to calcium bicarbonate, and unsaturation with respect to magnesium carbonate. The 25° isotherm, roughly shown in Fig. 4, has a very peculiar shape, indicating that solid solutions were being formed in the region just referred to. There is no theoretical objection to the shape of the isotherm, but previous

FIG. 4.

$p_{CO_2} = 20$ atm. $t = 25^\circ$. Dolomite solubility extrapolated from 1 atm.

experience rather goes against its possibility. It seems obvious from the experiment that we are actually dealing with solutions super-saturated with respect to dolomite, but that the rate of precipitation is extremely slow (the possible shape of the isotherm given would lead to this conclusion). It may also be accidental that the concentration of the solution saturated with respect to both calcite and nesquehonite does fall on the line corresponding to the formation of dolomite. Evidently, further investigations on the following points will be necessary:

1. The solubility of dolomite at high pressures of carbon dioxide.
2. The composition of the solid phases along the solubility curves.
3. Experiments with magnesite instead of nesquehonite.
4. Experiments involving the use of mineralisers, particularly sodium chloride.

Work on these lines is in progress.

The material prepared from calcite and nesquehonite is certainly

more definitely dolomitic than any other recorded preparations, and from the observed physical properties and chemical composition there does not seem much doubt that dolomite has actually been prepared from calcite and nesquehonite, although the amounts obtained have so far been exceedingly small.

Summary.

1. An apparatus for the determination of the solubility of substances under moderately high pressures of carbon dioxide has been designed, and proved satisfactory.

2. This apparatus has been employed to measure the solubilities of calcite and nesquehonite, and mixtures of the two, at 25° and at pressures of carbon dioxide up to 20 atmospheres. The critical pressure required for the formation of solid calcium bicarbonate has been redetermined, the value found being almost the same as that given by McCoy and Smith. The solubility of nesquehonite agrees very well with the interpolated value obtained from the figures of Engel. It has been shown that dolomite can be prepared from an aqueous solution of calcite and nesquehonite in the presence of carbon dioxide up to 20 atmospheres pressure. The physical properties of this preparation are in every way comparable with those of the purest natural mineral.

3. A tentative isotherm for the system calcite-nesquehonite-water at 25° is given.

4. It has been shown that the observations of Wroblewski on the deviations of the solubility of carbon dioxide from Henry's law hold in the case of its solubility in solutions of calcium and magnesium bicarbonates. In all cases, these deviations are by no means large until the pressure is in the neighbourhood of 11 atmospheres.

The author expresses his thanks to Professor Donnan for his interest in this work and for his many valuable suggestions, and also to the Government Grant Committee of the Royal Society for a grant which enabled the high pressure solubility apparatus to be constructed.

PHYSICO-CHEMICAL LABORATORIES,
UNIVERSITY COLLEGE, LONDON.

[Received, June 6th, 1923.]

Les Gaz Rares des Gaz Naturels.

A LECTURE DELIVERED BEFORE THE CHEMICAL SOCIETY ON
JUNE 14TH, 1923.

By PROFESSOR CHARLES MOUREU, President of the Société
Chimique de France.

INTRODUCTION.

MONSIEUR LE PRÉSIDENT,
Messieurs et chers collègues,

C'est un honneur insigne, dont je le remercie avec des sentiments de profonde gratitude, que m'a fait le Conseil de la "Chemical Society" en m'invitant à venir exposer devant vous des recherches relatives à une famille d'éléments dont la mise au jour, exclusivement londonienne, marque une des étapes les plus glorieuses de la Science britannique.

Toujours aussi grande, en effet, du point de vue de la Philosophie naturelle, apparaît encore, après plus d'un quart de siècle de conquêtes scientifiques merveilleuses, la découverte de l'argon, bientôt suivie de celle de ses congénères, que firent dans l'air atmosphérique, à Londres, en 1894, Lord Rayleigh et Sir William Ramsay.

L'entrée en scène d'un élément rebelle à toute combinaison était une nouveauté absolue, qui affirmait le caractère capricieux de la matière, et qui ouvrait aux physiciens et aux chimistes un champ de recherches absolument imprévu sur le problème de l'affinité. Si l'on songe, d'autre part, que des milliers de chimistes, avant les deux illustres savants anglais, avaient analysé notre atmosphère sans qu'ils y eussent aperçu ce singulier élément, on pouvait penser que l'étude systématique et approfondie d'autres milieux naturels mettrait en lumière des faits du même ordre encore insoupçonnés. Nombreux apparaissaient ainsi, dans la Nature, les problèmes analogues ou connexes se présentant à l'activité des chercheurs.

Dès l'année qui suivit la découverte de l'argon, l'hélium, qu'on savait, depuis l'éclipse du Soleil du 18 Août 1868 (Frankland et Lockyer, Janssen), exister dans le Soleil, fut extrait par Ramsay d'un minéral uranifère, la clévéite. Peu après, sa présence était reconnue dans l'air par H. Kayser, de Bonn, ainsi que dans diverses étoiles. On sait, et nous reviendrons sur ce point, qu'il se produit dans la désintégration des substances radioactives.

C'est également de l'air que, dans le laboratoire de Ramsay, le krypton, le néon et le xénon furent retirés successivement, en 1898 (Ramsay et Travers).

Les cinq nouveaux gaz sont des corps simples, des éléments.

L'étude de leurs propriétés a montré qu'ils constituent une famille naturelle.

Entre autres caractères communs, mentionnons les suivants, particulièrement remarquables :

1. Ils se sont montrés jusqu'ici absolument inertes au point de vue chimique : on n'a encore pu combiner aucun d'eux avec un corps quelconque, et l'on n'en connaît aucun composé défini.

2. D'après le rapport $\frac{C}{c}$ des chaleurs spécifiques à pression constante aux chaleurs spécifiques à volume constant, rapport qu'on a déterminé en mesurant la vitesse du son dans ces gaz, leurs molécules sont formées d'un seul atome.

3. Ils présentent des spectres très nets de lignes.

Voici leurs principales constantes :

	Pds. du litre normal (en gr.) t = 0° H = 760.	Poids ato- miques.	Points d'ébulli- tion sous 760 mm.	Tempé- ratures critiques (en de- grés centi- grades).	Pressions criti- ques en atmosph.
Hélium	0.17834	4.00	-268.89	-267.91	2.26
Néon	0.8985	20.2	-245.93	-227.36	26.86
Argon	1.7837	39.9	-185.85	-122.45	48.00
Krypton	3.708	82.92	-151.8	-62.50	54.27
Xénon	5.851	130.2	-106.9	+16.6	58.2

D'après les plus récentes déterminations, l'air atmosphérique renferme les proportions suivantes des cinq gaz :

	Proportions dans 100 parties d'air.	
	En poids.	En volumes.
Argon	1.29	0.9323
Néon	0.0012	0.0018
Hélium	0.00007	0.0005
Krypton *	0.0003	0.0001
Xénon *	0.00004	0.00001

* Ch. Moureu et A. Lepape (recherches inédites).

D'une longue suite de recherches commencées en 1895 et qui ont été poursuivies jusqu'à nos jours, avec, en 1906, le concours de M. Robert Biquard, et, depuis 1907, la collaboration constante de M. Adolphe Lepape, il résulte que les cinq gaz sont présents dans l'atmosphère interne comme dans l'atmosphère externe de la Terre. Ils accompagnent partout l'azote libre dans la Nature, mais toujours en faible proportion. C'est pour cette raison que, en égard aux gaz courants (azote, oxygène, anhydride carbonique), etc., on les désigne généralement sous le nom de *gaz rares*.

Nous avons examiné un grand nombre de gaz naturels. La plupart provenaient de sources thermales. Un certain nombre d'autres

mélanges, de nature variée (grisous, gaz de pétrole, etc.), ont également retenu notre attention. Différents auteurs, en outre, ont exécuté des travaux, généralement assez sommaires, sur le même sujet.

Je vous parlerai successivement des diverses catégories de gaz naturels, qui ont été étudiées.*

I.—*Les Gaz Rares des Sources Thermales.*

A.—*Historique. Hélium et Substances Radioactives.*

(a) Dès la publication des premiers travaux de Rayleigh et Ramsay, l'attention des physiciens et des chimistes fut immédiatement appelée sur les diverses sources gazeuses qu'on rencontre dans la Nature, en vue de la recherche spéciale des nouveaux et si curieux éléments. Un certain nombre de gaz spontanés de sources thermales furent rapidement étudiées (Rayleigh et Ramsay, H. Kayser, Bouchard et Troost, Moureu, A. Kellas et Ramsay, Bouchard et Desgrez, Ramsay et Travers; Bamberger; Nasini, Anderlini et Salvadori; Bamberger et Landsiehl, Parmentier et Hurion, Liveing et Dewar, Moissan). Si l'on y trouvait généralement l'argon, dans maintes de ces sources on ne réussissait pas à caractériser l'hélium; la présence du néon était reconnue dans une seule source; quant au krypton et au xénon, on ne les signalait nulle part en dehors de l'air atmosphérique.

(b) En 1903, Ramsay et Soddy annoncèrent que le radium et son émanation (qui est un véritable gaz radioactif) produisent spontanément, et d'une manière continue, de l'hélium.

Avant d'aller plus loin, ouvrant ici une parenthèse, je rappellerai, très brièvement, en quoi consistent les phénomènes essentiels de radioactivité. Considérons le radium, le corps radioactif que nous connaissons le mieux.

Le radium est un élément instable, dont l'atome (poids atom.

* Notre sujet a été développé longuement (Historique, technique expérimentale, résultats expérimentaux, conclusion et considérations générales) dans les deux mémoires suivants : Ch. Moureu, *Recherches sur les gaz rares des sources thermales ; leurs enseignements concernant la radioactivité et la Physique du Globe* (Journ. de Chim. Phys. XI (1913), 63-154); Ch. Moureu et A. Lepape, *Les gaz rares des grisous*, Annales de Chimie, (9), t. IV et V (1915-1916). Voir aussi : *Les gaz rares des gaz naturels d'Alsace-Lorraine*, Ch. Moureu et A. Lepape, Comptes rendus, t. 171, p. 941 (1920).

Nous avons, au cours de ces dernières années, grandement élargi notre base expérimentale (sources thermales nouvelles, gaz de pétrole, etc.). L'ensemble de nos résultats est résumé dans le présent travail. Toutes ces recherches seront exposées en détail, accompagnées d'une abondante documentation bibliographique, dans les *Annales de l'Institut d'Hydrologie et de Climatologie*, organe de l'Institut d'Hydrologie et de Climatologie récemment fondé (Paris, Collège de France).

226) se fragmente graduellement. Outre l'hélium (poids atom. 4), élément stable et non radioactif, le radium fournit, d'abord, une première substance, un gaz radioactif, auquel Sir E. Rutherford a donné le nom d'*émanation* (*radon*). Ce gaz (poids atom. 222) se détruit spontanément, pour donner un nouveau corps, le *radium A*, lequel, à son tour, se convertit en *radium B*. Le radium B engendre le *radium C*, et Rutherford a pu suivre les transformations jusqu'au *radium F*, lequel est identique au *polonium*; celui-ci aboutit enfin à un dernier élément stable le *plomb* (poids atom. 206).* Au cours de cette dégradation progressive de ses atomes, le radium libère, sous forme de lumière, de chaleur, d'électricité et de rayons analogues aux rayons X, d'énormes quantités d'énergie. D'une manière générale, aux détails et à l'intensité près, des phénomènes analogues s'observent chez les diverses substances radioactives. Ajoutons que si le radium a des descendants, il a aussi des ascendants. L'ancêtre le plus ancien qu'on lui connaisse est l'*uranium* (poids atom. 238) d'où il dérive suivant un processus analogue au précédents.

Fermons la parenthèse et retenons le fait suivant : l'émanation du radium, qui est un gaz matériel, engendre, spontanément et d'une manière continue, de l'hélium.

Quelques temps après cette observation capitale de Ramsay et Soddy, Debierne constate que l'actinium produit également de l'hélium. Puis, successivement, la formation de l'hélium a été observée : à partir du thorium et de l'uranium par Soddy, aux dépens du polonium par Boltwood.

Ces faits, qui sont les premiers exemples bien certains de transmutation, se conçoivent aisément à la lumière des travaux qui ont été effectués sur les rayons α émis par les corps radioactifs, et qu'on doit principalement à Rutherford. Il résulte, en effet, de ces travaux, que les rayons α sont tous de même nature, et constitués par des atomes d'hélium portant des charges électriques positives (particules α) et animés de grandes vitesses (de l'ordre de 20'000 km. par seconde). D'après cela, l'hélium doit être un des produits de désintégration de tous les éléments radioactifs qui émettent des particules α .

D'un autre côté, de délicates et nombreuses recherches, qui ont été continuées sans interruption jusqu'à nos jours, et parmi lesquelles celles d'Elster et Geitel, de Boltwood, d'Eve, de Bumstead et Wheeler, de R. J. Strutt, de Blanc, de Joly, etc., sont particulièrement remarquables, indiquaient la présence universelle de traces de matières radioactives dans l'atmosphère, le sol, les minéraux et les roches.

En ce qui concerne spécialement les sources, les expériences se

* Le plomb isotopique issu du thorium a pour poids atomique 208.

poursuivaient aussi de divers côtés. Mentionnons les recherches de Sir J. J. Thomson (1902), puis de H.-S. Allen et Lord Blythswood, et de R. J. Strutt (actuellement Lord Rayleigh), en Angleterre; de Pochettino et Sella, et de R. Nasini, en Italie; de H.-A. Bumstead et L. D. Wheeler, en Amérique; de F. Himstedt, en Allemagne; et surtout, en France, un travail d'ensemble de Pierre Curie et Albert Laborde (1904), portant, avec des déterminations quantitatives d'émanation, sur une vingtaine de sources. Ces divers auteurs trouvaient généralement, en proportions d'ailleurs très variables, l'émanation du radium dans les gaz spontanés des sources et en dissolution dans les eaux, et, parfois même, le radium à l'état de sel dans les eaux, les boues et les sédiments. Toute une pléiade de physiciens et de chimistes se sont, depuis, occupés du même sujet. A l'heure actuelle, on peut évaluer à plusieurs milliers le nombre de sources qui ont été examinées à ce point de vue. Comme on pouvait le prévoir, d'après ce qui a été dit plus haut de la diffusion des substances radioactives dans l'écorce terrestre, toutes les sources ont été trouvées plus ou moins radioactives. Aussi, dans la pratique, ne considère-t-on comme telles que celles qui le sont notablement plus que les eaux courantes. On sait (nous nous bornons à le rappeler en passant) tout l'intérêt que présente la radioactivité des sources au point de vue de l'hydrologie médicale.

(c) La découverte fondamentale de Ramsay et Soddy (production de l'hélium par le radium) concordait avec la présence constante, préalablement établie, de l'hélium dans les minéraux radioactifs, et aussi dans l'atmosphère terrestre, où l'on trouvait des traces d'émanations du radium et du thorium. Si l'on généralisait, l'hélium devait être, en quelque sorte, le compagnon, dans la Nature, des corps radioactifs, à côté desquels il fallait s'attendre à le rencontrer partout. On pouvait se demander, d'ailleurs, si certaines matières radioactives, connues ou inconnues, et plus ou moins répandues au sein de la Terre, ne seraient pas susceptibles de subir des transformations du même ordre aboutissant, en dehors de l'hélium, à des corps de la même famille : néon, argon, krypton, xénon.

Ce sont ces considérations, et aussi la pensée qu'un grand travail d'ensemble pourrait apporter des documents utiles, en outre, à la Géologie, à l'Hydrologie proprement dite, à la Physique du globe et à la Médecine thermale, qui m'engagèrent, en 1903, à poursuivre plus activement que je ne l'avais fait jusqu'alors, l'étude des gaz des eaux minérales. Aussi bien celles-ci, par leur grand nombre et par la variété de leurs origines souterraines, offraient-elles un champ d'expérience aussi vaste que propice.

A un autre point de vue, ces recherches venaient d'ailleurs fort à propos. C'est en effet au même moment qu'Armand Gautier

poursuivait ses belles études chimiques sur les roches ignées, à la suite desquelles il formula sa théorie si hardie et si séduisante du volcanisme et de la genèse des eaux thermales. Une discussion allait s'ouvrir, où les données expérimentales entreraient surtout en ligne de compte.

B.—*Composition Générale des Gaz Spontanés des Sources Thermales.*
Débits.

(a) *Technique expérimentale.*—1. Le gaz spontané, bien exempt d'air, après avoir été décarbonaté et rigoureusement desséché, circule dans un appareil spécial, tout en verre soudé, et disposé en circuit fermé, qui comprend une série de tubes contenant : du calcium métallique, qui fixe ou rouge l'azote et l'oxygène ;* de l'oxyde de cuivre, qui brûlera au rouge les gaz combustibles ; de la potasse fondue et de l'anhydride phosphorique, qui absorberont les produits de la combustion (gaz carbonique et vapeur d'eau). A la fin de l'opération, le résidu se trouve constitué par l'ensemble des gaz rares, incombustibles : l'argon et ses congénères. On y caractérise directement, au spectroscope, l'argon et l'hélium.

Les trois autres gaz : néon, krypton, xénon, étant toujours moins abondants, leur spectre n'apparaît pas d'ordinaire dans le mélange, et, pour les caractériser avec certitude, le fractionnement est indispensable. Nous l'opérons, utilisant les beaux travaux de Sir James Dewar sur l'occlusion des gaz par le charbon à basse température, au moyen du charbon de noix de coco. Celui-ci, refroidi dans l'air liquide fixe les trois gaz lourds : argon, krypton et xénon (les deux derniers sont toujours en proportions négligeables devant celles de l'argon), et laisse libres les deux gaz légers : hélium et néon (la proportion de ce dernier est presque toujours négligeable devant celle de l'hélium).

Dans les gaz légers, outre l'hélium, on caractérise aisément le néon par ses principales raies spectrales. Pour caractériser le krypton et le xénon, on réchauffe lentement le charbon, et, en examinant au spectroscope la dernière portion du gaz qui se dégage, on voit, outre le spectre de l'argon, les principales raies du krypton et du xénon.

En fractionnant les gaz lourds au moyen du charbon refroidi vers -23° (chlorure de méthyle bouillant) ou vers -80° (neige carbonique + acétone), on arrive à concentrer dans un faible volume le krypton et le xénon, qu'on dose ensuite spectrophotométriquement.†

* La plupart des gaz souterrains sont exempts d'oxygène ou n'en renferment que des traces.

† Ch. Moureu et A. Lepape, C. R. 152, 691 et 934 (1911), 153, 740 (1911), 174, 908 (1922).

2. Pour reconnaître et doser l'émanation du radium, nous utilisons sa propriété caractéristique de se détruire de moitié dans l'espace de 3·85 jours, en ionisant les gaz qui en sont chargés, la conductibilité qui leur est ainsi conférée étant proportionnelle à leur richesse en émanation. L'emploi de l'électroscope de Cheneveau et Laborde nous a donné, pour ces mesures, toute satisfaction. Beaucoup de dosages dans nos gaz ont d'ailleurs été effectués par d'autres que nous (Curie et Laborde, Brochet).*

(b) *Résultats analytiques qualitatifs.*—Nous avons toujours observé la présence de l'azote, fréquemment accompagné de proportions plus ou moins notables d'anhydride carbonique, moins souvent d'oxygène et de gaz combustibles, tout au moins en quantités appréciables.

En ce qui concerne spécialement l'oxygène, nous pensons que sa présence dans les gaz très riches en azote est purement accidentelle, tandis qu'elle apparaît constante et normale dans les gaz très riches en anhydride carbonique. Ajoutons que, dans ces derniers, également, les gaz combustibles ont été rencontrés chaque fois qu'ils y ont été recherchés.

Voici les résultats quant aux gaz rares : Nous avons examiné 108 gaz thermaux. Les cinq gaz rares y ont été caractérisés sans aucune exception.

Nous en concluons qu'ils sont présents dans toutes les sources.

Rappelons que l'émanation du radium a été trouvée aussi dans toutes les sources où on l'a recherchée.

(c) *Résultats analytiques quantitatifs.*—La composition des gaz spontanés peut être entièrement différente suivant les sources, comme l'est la composition de l'eau minérale elle-même. Nous avons rassemblé, dans un tableau synoptique, les résultats de nos nombreuses déterminations. Ils expriment la composition centésimale, en volumes, des mélanges gazeux secs.

Le plus souvent absent, l'oxygène, quand il est présent, s'y rencontre généralement en faible proportion, et il en est de même des gaz combustibles. L'anhydride carbonique peut aussi manquer complètement; mais il arrive parfois, au contraire, que la proportion en est très élevée, et, dans quelques sources, comme celle de Chomel, à Vichy, le gaz de l'eau minérale peut être considéré comme de l'anhydride carbonique pratiquement pur. Il ne semble pas

* Ajoutons qu'on devrait rencontrer, dans toutes les sources, au moins deux autres émanations : celles du thorium et de l'actinium, éléments radioactifs dont on a généralement retrouvé des traces dans tous les terrains. Ces deux émanations existent, comme l'émanation du radium, dans l'atmosphère. Elles se détruisent très rapidement : celle du thorium de moitié en 54 secondes, et celle de l'actinium de moitié en 3·9 secondes. Aussi leur recherche est-elle beaucoup plus difficile que celle de l'émanation du radium.

1* 2

* Il est évident que tous les gaz spontanés que nous avons trouvés exempts d'oxygène avaient été récoltés tout à fait à l'abri de l'air. Quant à ceux où nous avons trouvé de l'oxygène, nous signalons par un point d'interrogation (?), dans notre tableau, les cas où la

récolte des gaz n'a pas été faite par nous-mêmes.

† Pour les sources où la recherche des gaz combustibles n'a pas été faite, ceux-ci sont compris dans la proportion d'azote. La colonne Azote figure donc, suivant les cas, soit le mélange azote-gaz combustibles.

que l'azote soit jamais totalement absent : souvent il prédomine, et l'on avait cru pendant longtemps qu'il constituait seul ou presque seul l'élément gazeux de certaines sources.

Les proportions des gaz rares varient dans de larges limites. On trouve, par exemple, que, pour 100 vol. de Gaz spontané brut, il y a une proportion de mélange global des gaz rares égale à : 0.019 à Vichy (Grande-Grille), 0.67 à Salins-Moutiers, 1.85 à Nérès, 2.04 à Luxeuil (Grand-Bain), 3.36 à Grisy (source d'Ys), 6.59 à Maizières (source Romaine), 10.843 à Santenay (source Lithium).

Nous n'avons pas encore dosé le néon dans nos mélanges, mais, d'après des essais sommaires, nous pouvons affirmer qu'il n'y en a jamais que des traces.

Nous avons reconnu également que les proportions de krypton et de xénon étaient toujours extrêmement faibles.

Essentiellement variables sont les proportions d'hélium. Pour 100 vol. de Gaz spontané brut, on trouve, par exemple, 0.0015 à Vichy (Chomel), 0.207 à Plombières (source Vauquelin), 0.893 à Saint-Honoré, 1.83 à Bourbon-Lancy (source Lymbé), 5.77 à Maizières, 10.14 à Santenay (source Lithium). Les gaz spontanés des sources de Santenay sont les plus riches connues en hélium. On voit à quel degré peuvent atteindre les concentrations en hélium, et ce fait est extrêmement remarquable.

Les proportions d'argon présentent également de fortes variations; depuis 0.0027 pour 100 à Vichy (Chomel) jusqu'à 1.643 pour 100 à Plombières (Vauquelin), où nous avons la plus forte teneur. Il est remarquable que les proportions d'argon, loin d'égaler certaines valeurs très élevées de l'hélium, ne dépassent jamais notablement celle qu'il présente dans l'atmosphère (0.93 pour 100).

Les teneurs en émanation du radium sont, elles aussi, essentiellement variables, allant depuis une fraction de millimicrocurie* jusqu'à plusieurs centaines de millimicrocuries par litre. Les plus fortes, dans les sources françaises qui ont été étudiées jusqu'ici, se rencontrent à Bagnères-de-Luchon, la Bourboule et Plombières. Exceptionnellement riches sont les gaz spontanés de Badgastein, qui renferment 508.8 millimicrocuries par litre.

A titre de comparaison, rappelons que la teneur moyenne de l'atmosphère en émanation du radium est voisine de un-dix-millième de millimicrocurie par litre.

* Le millimicrocurie est le milliardième de curie (10^{-4} curie). Le curie, unité internationale d'émanation du radium adoptée au Congrès de radiologie de Bruxelles (septembre 1910), est la quantité d'émanation en équilibre avec 1 gr. de radium métal (soit 0.6 millimètre cube), c'est-à-dire la quantité maxima d'émanation que l'on peut obtenir en enfermant 1 gr. de radium dans un vase clos. Pratiquement, cette limite supérieure est atteinte au bout d'un mois, la proportion d'émanation qui se détruit alors à tout moment égalant celle qui se produit durant le même temps.

(d) *Débits gazeux*.—Il convient de rapprocher les résultats qui précèdent de quelques données d'un autre ordre. Nous avons mesuré les débits en gaz spontanés de diverses sources. En combinant les valeurs trouvées avec les compositions centésimales, nous avons pu dresser le tableau ci-dessous. On voit que les débits des diverses sources, tant pour les gaz rares que pour les gaz totaux, peuvent être très différents. Les sources de Luxeuil, d'Ax et de Maizières ont des débits en gaz rares (en bloc) et hélium déjà importants. La source qui dégage le plus d'argon est celle de Saint-Joseph, à Aliseda. Les sources de Bourbon-Lancy, Santenay et Nérès sont de véritables gisements d'hélium.

TABLE II.
Débits Gazeux de quelques Sources Thermales.

En ce qui concerne l'émanation du radium, les quantités rencontrées varient également dans des limites très étendues. La source la plus remarquable est celle de Choussy, à la Bourboule, qui est susceptible de fournir 65,486 microcuries d'émanation.

D'autres sources, curieuses aux mêmes points de vue, et peut-être plus riches encore, seront sans doute signalées dans l'avenir. Mais, d'ores et déjà, il est acquis que les sources thermales déversent sans cesse des quantités relativement considérables de gaz rares, et spécialement d'hélium et d'émanations radioactives, dans l'atmosphère.

Messieurs,

Nous voici en possession de résultats nouveaux auxquels il ne manque ni la multiplicité ni la variété. Il s'agit maintenant de dégager les enseignements qui se dissimulent sous l'aridité des faits et des chiffres.

C.—Conclusions. Observations et Considérations Générales

Les multiples résultats ou remarques que nous venons de présenter aboutissent à une conclusion aussi nette que générale; sans parler des gaz courants (azote, anhydride carbonique, etc.), toutes les sources contiennent une série d'autres gaz : de l'hélium, du néon, de l'argon, du krypton, du xénon et des émanations radioactives, dont elles amènent sans cesse au jour des quantités notables, et fort différentes suivant les sources.

Ce fait et la présence des gaz rares et des émanations radioactives dans l'air atmosphérique sont ainsi en parfait accord. Si, d'autre part, on se place au point de vue quantitatif, trois remarques principales s'imposent immédiatement à l'esprit : 1° l'extrême variété de composition des mélanges gazeux des sources, contrastant avec la fixité presque absolue de composition de l'air; 2° l'absence complète ou presque complète de l'oxygène dans la plupart des sources, alors que l'air en contient une proportion notable ($\frac{1}{5}$ environ); 3° les teneurs souvent énormes des gaz des sources en hélium, tandis que dans l'air il n'en existe qu'une très faible proportion ($\frac{1}{200000}$, en volumes); 4° la richesse considérable en émanation du radium de certaines sources.

Pour ne considérer que les gaz rares et les émanations radioactives, conformément à l'objet principal de notre travail, nous savons quel lien étroit rattache l'hélium aux corps radioactifs, et cette relation, ainsi que les débits d'hélium, suggèrent diverses réflexions intéressantes concernant la Physique du globe et l'Astrophysique.

Il arrive enfin, quand on compare certaines données analytiques,

qu'on découvre, entre ces éléments chimiquement inertes que sont les gaz rares, des relations numériques simples et systématiques, qui conduisent à élargir encore, dans le même ordre d'idées et d'une manière fort imprévue, le cadre de notre sujet.

Nous allons envisager successivement ces divers points.

(a) *Hélium des sources et radioactivité.*—L'hélium est un des éléments gazeux de toutes les sources. Ce fait expérimental constitue une vérification complète de notre conception initiale. L'hélium, en effet, se produit dans la désintégration des substances radioactives, et des traces de celles-ci se rencontrent partout dans le sol et le sous-sol (minéraux, roches, eaux minérales, gaz). On devait donc trouver l'hélium dans toutes les sources.

Ce résultat capital étant acquis, divers points sont intéressants à examiner.

Remarquons, tout d'abord, qu'il n'existe aucun parallélisme, même grossier, entre la radioactivité des sources et les proportions d'hélium. Telle source, riche en hélium, sera peu radioactive, alors que telle autre, fortement radioactive, sera pauvre en hélium.

Cette absence de proportionnalité entre l'hélium des sources et leur radioactivité entraîne à elle seule, presque fatalement, la conclusion qu'il n'y a qu'une partie de l'hélium des sources qui provienne de la destruction *actuelle* des substances radioactives présentes dans les terrains traversés. On s'en rend d'ailleurs aisément compte par le raisonnement suivant.

Parmi les substances radioactives que peuvent contenir les sources, considérons la seule émanation du radium, à laquelle, au surplus, la généralité des sources semblent devoir pratiquement toute leur radioactivité. Nous savons que cette émanation se détruit de moitié environ en 3.85 jours, et nous savons, en outre, que cette destruction est accompagnée de production d'hélium. Dans son parcours, la source à tout instant, a drainé de nouvelles doses d'émanation, dont la destruction graduelle l'a enrichie sans cesse en hélium. Soit, pour fixer les idées, le cas de la source Vauquelin, de Plombières, qui est fortement radioactive. Elle débite en une journée, 98 cent. cubes d'hélium. Si l'on calcule, d'après les résultats des mesures effectuées directement sur du radium par Ramsay, par J. Dewar, par Boltwood et Rutherford, le poids de radium capable de produire en un jour l'émanation d'où provient cette dose d'hélium, on obtient le chiffre énorme de 230 kgs. Et si l'on suppose, pour se rapprocher des conditions de la Nature, cette masse de radium disséminée dans les roches de l'écorce terrestre (dont la teneur moyenne en radium est de l'ordre de quelques millièmes de milligramme par tonne), on trouve que le poids des roches dont l'eau minérale aurait dû prendre toute

l'émanation qu'elles produisent en un jour serait d'au moins 46 milliards de tonnes. Ces chiffres fabuleux sont évidemment invraisemblables. On ne saurait admettre que, dans une journée, une source thermique puisse lessiver 46 milliards de tonnes de roches. Et une très minime fraction seulement de l'hélium de la source Vauquelin a pu être engendrée par l'émanation rencontrée. Or cette source est à la fois une des plus radioactives et une des moins riches en hélium de toutes celles que nous avons étudiées. Le raisonnement qui précède s'appliquerait donc, à fortiori, aux sources faiblement radioactives et riches en hélium.

Il est ainsi hors de doute que, dans la grande généralité des cas, il n'y a qu'une infime fraction de l'hélium des sources qui provienne des substances radioactives entraînées par elles dans leur parcours. Sauf cette minime partie, l'hélium des sources, dans les terrains traversés, existait préformé (libre ou occlus), et l'eau, après l'avoir dégagé en désagrégeant les minéraux et les roches, l'a entraîné jusqu'à la surface. Si donc il y a, dans les sources, de l'hélium de formation récente, et même actuelle : de l'hélium *jeune*, la presque totalité, sans aucun doute, est très ancienne : c'est de l'hélium *fossile* ; et son âge moyen doit être moindre, à la vérité, mais du même ordre que celui des minéraux qui l'ont cédé à la source (millions de siècles ?).

En résumé, il n'existe aucune uniformité, même approximative, dans les rapports entre la radioactivité et l'hélium des sources : la relation est purement qualitative. Mais elle est générale et absolue : toutes les sources sont plus ou moins radioactives, toutes aussi contiennent de l'hélium.*

(b) *Constance de certains rapports. Théorie astrophysique explicative.*—1. Les teneurs de nos mélanges en chacun des corps gazeux (gaz ordinaires ou gaz rares) que nous avons rencontrés peuvent différer d'une source à une autre dans des limites très étendues. Toutefois, si les valeurs absolues des nombres sont essentiellement variables, on observe, par contre, quelques relations simples quand on compare les proportions de certains éléments deux à deux.

Ce sont les résultats de nos dosages de krypton qui nous révélèrent tout l'intérêt que pouvait présenter la considération des rapports mutuels des proportions des gaz rares.†

Envisageons le rapport, en volumes, du krypton à l'argon dans

* Dans le Mémoire du *Journal de Chimie-Physique* (t. XI, No. I, 1913, pp. 63—164), diverses autres considérations ont été développées, notamment sur l'hélium de l'atmosphère dans ses rapports avec l'hélium que fournirait la masse de radium capable de maintenir constante la chaleur terrestre.

† Ch. Moureu et A. Lepape, C.R., 27 Mars et 16 Octobre 1911.

les sources, et comparons-le au même rapport dans l'air, que nous prendrons pour unité.

L'étude de 19 gaz spontanés de sources nous a donné comme limite inférieure 1.1 et comme limite supérieure 1.8. Comme on le voit dans le tableau ci-dessous, trois faits principaux ressortent de la comparaison des chiffres : 1°. Les limites entre lesquelles varie le rapport krypton : argon dans ces mélanges naturels sont très étroites. 2°. Les valeurs du rapport krypton : argon y sont voisines de celles du même rapport dans l'air. 3°. Le rapport krypton : argon, dans ces mélanges, se montre toujours supérieur à la valeur qu'il présente dans l'air. Réservant ce dernier point, nous retenons ici un fait essentiel : la constance *approximative* du rapport krypton : argon dans les mélanges gazeux naturels.

On a déjà rencontré, en étudiant les corps radioactifs, plusieurs rapports constants entre les proportions de deux substances déterminées dans des milieux différents. Serait-ce que l'argon et le

krypton sont issus l'un de l'autre, comme le radium l'est de l'uranium. Rien, dans l'état actuel du sujet, n'autorise à le supposer, attendu qu'on n'a jamais constaté le moindre indice de radioactivité chez l'un ou l'autre de ces deux gaz.

En cherchant ailleurs l'explication, nous avons été conduits au raisonnement suivant :

2. Un caractère fondamental domine toutes les propriétés de l'argon et de ses congénères (gaz rares) ; ces éléments sont chimique-

ment inertes, en ce sens qu'ils n'ont jamais pu être combinés ni entre eux ni avec aucun autre corps. Une propriété physique de ces mêmes éléments, qui intervient aussi dans notre raisonnement, est la faculté qu'ils possèdent de conserver l'état gazeux entre de très larges limites de température et de pression, et, par suite, de tendre toujours à se répartir uniformément dans tout l'espace offert à leur expansion.

Reportons-nous par la pensée, dans l'histoire de la genèse du système solaire, jusqu'à la nébuleuse génératrice. Tous les corps, éléments libres ou combinaisons, sont à l'état gazeux, et la masse, grâce à d'inévitables tourbillons et brassages, doit être un mélange relativement homogène dans toutes ses parties. Le fragment constitutif de la Terre se détache, et celle-ci comprend bientôt trois régions concentriques : une masse incandescente en fusion, une écorce solide essentiellement hétérogène, et l'atmosphère gazeuse. Les phénomènes géologiques, lents et continus, ou brusques et violents, se poursuivent sans interruption. Au cours de cette incessante évolution de la planète, tous les corps doués d'affinités chimiques ont contracté des combinaisons mutuelles. Seuls les gaz rares, en vertu de leur inertie chimique, sont restés en totalité libres, et, en quelques points ou par quelques mécanismes qu'ils se soient concentrés ou dilués, ils n'ont pu qu'être des témoins indifférents et respectés de tous les bouleversements géologiques qui se sont accomplis et de toutes les métamorphoses dont la matière a été le siège.

Considérons spécialement le krypton et l'argon. Il est clair que le rapport entre les proportions de ces deux gaz devait être sensiblement le même, au début, en tous points de la nébuleuse. Si, dans la suite des temps, il est arrivé qu'il se soit altéré localement, des actions physiques ont seules pu en être la cause : occlusion, diffusion, dissolution, etc. ; et ce rapport n'a, par conséquent, dû subir, dans les divers points de la planète, que de faibles modifications. En d'autres termes, le mélange des deux gaz doit, à ce point de vue, se comporter sensiblement comme un gaz unique.

Cette théorie, comme on le voit, n'emprunte à l'Astronomie et à la Géologie que les conceptions classiques sur l'Évolution des Mondes. Ayant son point de départ dans la phase astronomique de la Terre, elle est indépendante de toute hypothèse sur la genèse des eaux thermales.

3. Plusieurs conséquences découlent immédiatement de cette manière de voir :

a. Tout d'abord la suivante : Nos cinq éléments étant chimiquement inertes, c'est-à-dire assurés de rester toujours en liberté, et gazeux, c'est-à-dire en perpétuel mouvement dans tous les sens,

il doit se retrouver au moins un peu de chacun d'eux dans tous les mélanges gazeux de la Nature. En fait, les nombreuses expériences que nous avons exécutées établissent que, de même qu'ils existent dans l'atmosphère, les cinq corps sont présents dans tous les mélanges de gaz qui se dégagent aux griffons des sources; et nous montrerons, en outre, qu'ils font aussi partie constitutive des griseux et autres gaz naturels.

En second lieu, notre raisonnement, relatif aux rapports *krypton* : *argon*, doit, sauf raisons spéciales, s'appliquer aussi aux autres gaz rares.

β. En fait, le rapport dans l'air étant, comme ci-dessus, pris pour unité, nous avons trouvé dans 17 sources : pour le rapport *xénon* : *argon* des valeurs variant de 1·2 à 2·5, et pour le rapport *xénon* : *krypton* des valeurs variant de 0·9 à 1·6. Malgré que le champ de variation soit ici relativement étendu, la valeur de chaque rapport oscille, dans des limites assez étroites, autour d'une valeur moyenne, laquelle est d'ailleurs voisine de celle qu'il possède dans l'air; et l'impression de constance se dégage nettement de l'examen d'ensemble des nombres que l'expérience a fournis.

Nous poursuivrons des recherches dans le même ordre d'idées sur le néon.

γ. Quant à l'hélium, on n'aperçoit nulle proportionnalité entre ce gaz et aucun autre gaz quelconque. Les rapports *hélium* : *argon*, par exemple, si l'on prend pour unité le rapport *hélium* : *argon* dans l'air, varient, dans les gaz spontanés de source étudiés par nous, de 7·49 à 24·814. La raison de l'absence de toute uniformité dans

ces rapports est aisée à concevoir. Nous savons que, partout dans l'écorce terrestre, de l'hélium se produit continuellement aux dépens des corps radioactifs; et les roches doivent en dégager plus ou moins suivant leur richesse radioactive, leur âge, leur structure physique, la température, la pression, etc. On ne saurait, par suite, trouver que très capricieux et irréguliers les rapports des proportions avec celles des autres gaz dans les mélanges naturels. L'exception que nous offre l'hélium ne fait donc que confirmer la règle.

* Pour ces Gaz de Sources, la proportion de Néon, vis à vis de celle de l'Hélium, n'étant pas négligeable, nous avons pris les rapports $\frac{\text{He plus Ne}}{\text{Ar}}$, comparés au même rapport dans l'air.

8. On rencontre dans toutes les sources, comme il existe dans l'atmosphère, un gaz *relativement* inerte : l'azote, qui suit partout

les gaz rares, dont il est le diluant constant. Si notre théorie est fondée, il faut s'attendre à trouver pour le moins une certaine uniformité dans les rapports entre l'argon et l'azote, par exemple, dans les mélanges gazeux naturels. Cette prévision est aussi vérifiée par l'expérience d'une manière satisfaisante : le rapport dans l'air étant toujours pris pour unité, nous le trouvons compris : dans 31 sources, entre 0.26 et 0.99 ; dans 54 sources, entre 1 et 1.35 ; dans 10 sources, entre 1.35 et 1.69 ; dans 9 sources entre 1.69 et 3.39. La moyenne générale est voisine de 1.18.*

A la vérité, les écarts sont ici plus forts que ceux rencontrés en comparant les rapports Krypton : Argon, Xénon : Argon et Xénon : Krypton ; mais l'impression de constance ne s'en dégage pas moins clairement.

Au surplus, il convient de ne pas oublier que l'inertie chimique de l'Azote est toute relative : l'Azote est seulement, de tous les gaz courants, le moins apte à contracter des combinaisons. Au point de vue de la Géologie, on peut le considérer comme un gaz *sensiblement* inerte.

Si, d'ailleurs, faisant entrer en scène un gaz facile à combiner, on considérerait le rapport *argon : anhydride carbonique*, par exemple, on constaterait que, suivant les sources, ce rapport peut prendre toutes les valeurs possibles, depuis zéro jusqu'à l'infini.

On voit que tous ces résultats sont en harmonie avec la théorie astrophysique exposée plus haut. Il nous reste à prouver, pour qu'elle ait toute sa force, que les autres variétés de gaz naturels (grisous, gaz de pétroles, etc.) possèdent une composition également concordante avec cette théorie.

II.—Les Gaz Rares des Grisous.

Nos études sur les gaz rares présents dans les gaz spontanés des sources thermales nous ayant révélé, à M. Lepape et à moi, toute l'importance que présente l'étude de la dissémination de ces éléments dans la Nature, nous nous sommes naturellement occupés, au même point de vue, d'autres mélanges gazeux souterrains. Il y

* Il est à remarquer que les plus forts écarts s'observent parmi les gaz très riches en gaz carbonique (valeurs extrêmes : 0.26 et 3.39). On constate, en outre, que les rapports sont généralement très élevés pour cette catégorie de gaz (ils sont supérieurs à 1 dans 22 cas sur 25, parmi lesquels 18 présentent des valeurs comprises entre 1.3 et 3.39).

En ce qui concerne les gaz très riches en Azote, les limites entre lesquelles varient les rapports sont beaucoup plus étroites (0.58 et 1.39). Et l'on remarque que c'est chez les plus riches en Hélium que se rencontrent les rapports les plus faibles.

Nous nous bornons, pour l'instant, à constater ces faits, que nous tenterons d'expliquer par la suite.

a là un vaste problème dont l'intérêt s'étend à tous les gaz naturels. Les grisous, en raison de leur origine spéciale, ont sollicité tout d'abord notre attention.

Nombreux sont les travaux dont les grisous ont, à divers points de vue, déjà fait l'objet. Nous mentionnerons tout spécialement, à cause de son grand intérêt et parce qu'il est dans le même ordre d'idées que celui de nos propres recherches, un important travail de Th. Schloesing fils sur la composition de ces gaz naturels. En dehors de la partie combustible, qui, d'après cet auteur, est généralement formée de méthane pur, il y a toujours rencontré de l'azote accompagné d'argon. Nous avons entrepris un examen approfondi de cette fraction non combustible, constituée en grande partie par de l'azote (azote brut) et qui, d'après nous, devait contenir, outre l'argon qu'y avait signalé Schloesing, les quatre autres gaz rares : helium, néon, krypton, xénon.

Nos prévisions ont été pleinement vérifiées par l'expérience. Et nous avons même, en ce qui concerne l'hélium, rencontré dans les grisous d'importantes proportions de ce gaz. Or nous connaissons sa parenté avec les substances radioactives, et il y avait lieu, par suite, d'étudier la radioactivité des grisous et des charbons grisouteux d'où ils étaient issus. Nous avons donc recherché : dans les premiers, l'émanation du radium, et, dans les seconds, le radium et le thorium. Si la détermination de l'émanation du radium est relativement simple, il n'en est pas de même de celle de traces de radium et surtout de thorium. Nous* donnons plus loin un aperçu des procédés que nous avons suivis.

De la sorte, après l'azote brut des grisous, nous étudierons la radioactivité des grisous et des houilles. Nous terminerons par les conclusions et diverses considérations générales.

A.—Étude de l'Azote brut des Grisous-Débâs.

Les grisous que nous avons étudiés, au nombre de dix, proviennent de soufflards ou de trous de sonde des mines de Liévin (Pas-de-Calais), Lens (Pas-de-Calais), Anzin (Nord), Frankenholz (Palatinat), Agrappe (près Mons), Spittel (Sarre-et-Moselle).

(a) *Technique expérimentale.*—L'objet de nos travaux étant la recherche, dans les grisous, de gaz peu abondants et présents dans l'air atmosphérique, la prise d'essai du gaz était toujours faite avec des précautions spéciales afin d'éviter toute contamination par l'air. Nous avons, en général, opéré sur un volume relativement grand de grisou (plusieurs litres et jusqu'à 20 litres).

Notre mode opératoire, en principe, est le même que celui que nous avons mis en œuvre pour l'étude des gaz thermaux. Ici toutefois, la partie combustible était de beaucoup la plus importante,

nous devons l'éliminer dans un appareil spécial, où nous la brûlions par l'oxyde de cuivre. L'azote brut étant obtenu, nous le traitons comme dans le cas des gaz thermaux : action du calcium au rouge fractionnement du résidu de l'absorption (gaz rares) par le charbon refroidi, examen des spectres.

(b) *Résultats analytiques.*—Nous rassemblons dans le tableau suivant les résultats numériques de nos expériences concernant les dosages d'azote et de gaz rares dans les grisous étudiés et qui conduisent à la composition centésimale, en volumes, des grisous.

TABLE VII.

Origine du grisou.	Volume de grisou traité (en litres).	Azote brut du gaz naturel sec pour 100.	Gaz rares de l'Azote brut pour 100.	He + Ne des gaz rares en bloc pour 100.
Agrappe	18.75	0.37	14.33	94.20
Anzin	16.10	1.92	3.40	67.30
Frankenholz	3.80	2.11	2.28	57.00
Lens	19.50	1.85	2.01	0.87
Liévin	12.35	2.47	2.127	25.10
Spittel	—	1.065	1.69	11.11

TABLE VIII.

Composition centésimale des grisous secs, en volumes.

Lieux d'Origine.	Anhydride carbonique.	Oxygène.	Gaz combustibles.	Azote.	en bloc.	Gaz rares.	
						Argon + traces de Kr et Xe (Gaz lourds).	Hélium + traces de Ne (Gaz légers).
Agrappe ...	traces	néant	99.60	0.317	0.053	0.003	0.050
Anzin	0.16	néant	97.92	1.854	0.065	0.021	0.044
Frankenholz	2.80	traces	95.09	2.06	0.048	0.021	0.027
Lens	néant	néant	98.15	1.81	0.037	0.0367	0.0003
Liévin	0.5	néant	97.03	2.41	0.053	0.040	0.013
Spittel	0.67	néant	98.26	1.047	0.018	0.0156	0.0023

(c) *Débîts.*—Les dégagements de grisous, en général, sont très abondants, mais leur durée est relativement courte, et, de plus, ils sont irréguliers. Aussi est-il fort difficile de connaître avec exactitude le volume de gaz rares qu'un grisou répand dans l'atmosphère.

Pour trois de nos six grisous, voici quelques chiffres, certainement exacts quant à l'ordre de grandeur.

TABLE IX.

Débits (en mètres cubes par an).

	Argon.	Hélium.

B.—Radioactivité des Grisous et des Houilles.

(a) *Emanation du radium des grisous.*—Nous n'avons pas étudié à ce point de vue le grisou de Sarre-et-Moselle. Dans aucun des cinq autres, nous n'avons pu mettre en évidence la présence de l'émanation du radium. Etant donné que la quantité minima d'émanation que notre méthode nous permettait de déceler et de mesurer est d'environ $2 \cdot 10^{-11}$ curie par litre de gaz, nous pouvons affirmer que les cinq grisous étudiés par nous en contiennent moins que $2 \cdot 10^{-11}$ curie, soit 0.02 millimicrocurie, par litre. Nos analyses nous ont montré que, pour ces cinq grisous, les proportions moyennes d'azote brut sont d'environ 2 % du gaz naturel. Il s'ensuit donc que, si l'on rapporte l'émanation à l'azote brut, celui-ci en contient une proportion au plus égale à 1 millimicrocurie par litre. Pratiquement, donc, ces grisous, ou même l'azote brut de ces grisous, ne sont pas radioactifs.

(b) *Radium et thorium dans les houilles.*—A l'époque où nous exécutions nos expériences sur les gaz rares des grisous, aucun dosage d'éléments radioactifs dans les houilles n'avait encore été publié. A cause de l'importance fondamentale de cette donnée pour l'interprétation de nos résultats relatifs aux gaz rares, nous avons entrepris la recherche et le dosage du radium et du thorium dans les houilles avoisinant les soufflards ou les trous de sondes d'où provenaient les grisous par nous étudiés.

Pour doser le radium et le thorium dans la houille, nous nous sommes adressés aux méthodes usuelles basées sur la propriété des émanations du radium et du thorium. Nous avons d'abord isolé puis, suivant la technique de Shutt, amené en solution la partie minérale de la houille (cendres); ensuite, cette très longue opération effectuée, nous avons mesuré l'émanation du radium accumulée dans la solution après que celle-ci avait été conservée en vase clos pendant un temps défini, et nous avons déduit de cette mesure la teneur en radium de la houille. Enfin, à la solution privée d'émanation du radium, nous avons appliqué, pour le dosage du thorium, la méthode de Joly, basée sur l'utilisation du courant d'émanation.

Voici le résultat de nos mesures :

TABLE X.

Radium et thorium dans les houilles.

Origine.	Poids de houille traité, en grammes.	cendres pour 100.	Radium en 10^{-12} g. dans 1 g.		Thorium en 10^{-6} g. dans 1 g.	
			de cendres.	de houille.	de cendres.	de houille.
Agrappe (près Mons)	2000	2.3	<0.5	<0.01	1.2	0.02
Anzin	2000	3.5	<0.5	<0.01	<0.5	<0.01
Frankenholz ...	2000	2	2	0.04	1.5	0.03
Lens	500	11	8.8	0.97	3	0.33
Liévin	200	46	<0.5	<0.2		

Il y aura lieu de compléter les déterminations de radium et de thorium dans la houille par l'étude, au même point de vue, des roches *encaissantes*, qui sont, en général, des grès et des schistes. On sait, par de nombreuses mesures dues à divers savants, que leur teneur moyenne est : en radium, de l'ordre $1.5 \cdot 10^{-12}$ g. de radium par gramme de roche et, en thorium, de $1.2 \cdot 10^{-6}$ g. de thorium par gramme de roche.

C.—Observations Diverses—Conclusions.

Nous avons rassemblé ci-dessus les résultats bruts de nos mesures. Il s'agit maintenant de déduire, de ces données nouvelles et de leur comparaison avec celles que nous a fournies l'étude des gaz thermaux, les enseignements qu'elles comportent et les conclusions qui en découlent.

(a) *Remarques sur la composition des grisous.*—Laissant de côté la partie combustible, que nous nous sommes bornés à déterminer en bloc et qui est toujours très largement prédominante dans les grisous, nous ferons les remarques suivantes :

1. Nous avons trouvé nos grisous complètement exempts d'oxygène à l'exception d'un seul (Frankenholz), pour lequel on est ainsi en droit de supposer une introduction accidentelle d'air dans l'échantillon examiné. Tous les grisous doivent sans doute être exempts d'oxygène.

Si l'on rapproche de ces résultats le fait que l'oxygène est complètement ou presque complètement absent dans la grande majorité des gaz des sources thermales, on ne peut s'empêcher de remarquer le contraste qui existe, eu égard à la teneur en oxygène, entre l'atmosphère interne de la Terre et son atmosphère externe, qui en contient un *cinquième*.

2. D'après nos recherches et celles de Schloesing, il y a au plus quelques centièmes d'anhydride carbonique dans les grisous. Un de nos échantillons (Lens) en était même totalement dépourvu. Une faible teneur paraît être le cas général pour les mélanges naturels

riches en gaz combustibles. On se rappelle que dans les sources thermales, au contraire, l'anhydride carbonique est souvent très abondant.

3. Les grisous renferment toujours une partie non combustible, laquelle, en dehors de l'anhydride carbonique, est constituée par l'azote et les gaz rares (mélange que nous appellerons *azote brut*).

La proportion d'azote brut, toujours très notablement inférieure à celle de la partie combustible, peut varier néanmoins dans d'assez larges limites. Un de nos grisous n'en contenait que 3·7 millièmes, et, chez les autres, la proportion était, en moyenne, voisine de 2 centièmes.

4. (a) En ce qui concerne la composition qualitative de cet azote brut, nos recherches présentent un accord très complet. Outre l'azote lui-même, les cinq gaz rares : hélium, néon, argon, krypton, xénon, ont été nettement caractérisés dans nos divers échantillons de grisou.

De son côté, Schloesing a mis en évidence l'argon dans ceux de ses échantillons de grisou (Anzin, Plat-de-Gier, Saint-Etienne) où il l'a recherché.

L'argon et l'hélium ont, en outre, été recherchés et reconnus par nous dans le grisou de Liévin, et l'hélium dans ceux d'Anzin et de Plat-de-Gier.

Ajoutons enfin que Czako a caractérisé l'hélium dans le grisou de Zeche Gneisenau.

Bref, les cinq gaz rares ont pu être reconnus dans tous les grisous où on les a recherchés. On peut en déduire qu'ils sont présents dans tous les grisous.

(b) Quant aux proportions des gaz rares, elles sont toujours beaucoup plus faibles que celles de l'azote. Le mélange global des gaz rares, dans celui de nos grisous où il est le plus abondant, est de 6·5 dix-millièmes (Anzin). Dans les grisous étudiés par Schloesing, il a varié de 1·2 (Firminy) à 60 (Plat-de-Gier) dix-millièmes.

Nous ne connaissons pas, pour le moment, les teneurs de nos grisous en néon. Nous pouvons dire seulement qu'elles sont très faibles et, de plus, qu'elles pourront généralement, dans ces gaz, être négligées devant celles de l'hélium.

Toujours infimes, les teneurs en krypton et xénon y seront, de même, négligeables devant celles de l'argon.

Les proportions d'hélium, dans nos grisous, vont de 3 millièmes (Lens) à 5 dix-millièmes (Agrappe, près Mons). Dans le grisou de Leche Gneisenau, Czako a trouvé une teneur en hélium de 67 millièmes. Nous reviendrons ci-dessous sur les débits d'hélium des grisous (voir en b).

Les teneurs en argon sont comprises, dans nos grisous, entre 3 cent-millièmes (Agrappe, près Mons) et 4 dix-millièmes (Liévin).

(b) *Hélium des grisous et radioactivité.*—L'hélium, d'après ce qui précède, est un des éléments constitutifs des grisous, comme il l'est des gaz thermaux. Ce fait est en complet accord avec nos prévisions. L'hélium, en effet, se produit dans la désintégration des substances radioactives, et des traces de celles-ci se rencontrent en tous lieux dans le sol et le sous-sol. On doit donc y rencontrer partout l'hélium.

Ce point étant acquis, diverses considérations trouveront ici leur place :

1. Il résulte de nos recherches que les grisous peuvent renfermer des proportions relativement importantes d'hélium (5 dix-millièmes à Agrappe). Si l'on tient compte des forts débits qu'ils présentent généralement, on s'aperçoit que des quantités considérables d'hélium sont déversées par cette voie dans l'atmosphère. La mine d'Anzin (0.04 pour 100 d'hélium) en dégage 12 mètres cubes par jour, soit 4380 mètres cubes par an, et celle de Frankenholtz (0.027 pour 100) 10 mètres cubes par jour, soit 3650 mètres cubes par an. Ces débits sont énormes, et ils surpassent de beaucoup ceux que nous avons rencontrés dans les sources thermales les plus riches (Santenay, 18 mètres cubes par an; Nérès, 34 mètres cubes par an). Il convient toutefois de ne pas oublier, à ce propos, que les dégagements gazeux des sources thermales sont constants et durables, tandis que les soufflards des grisous s'épuisent généralement en quelques années. Et nous ignorons lequel, de l'hélium des sources ou de celui des grisous, l'emporterait si l'on considérait une longue période de temps.

Rappelons ici l'intérêt que présentent, à un autre point de vue, les dégagements gazeux de certaines sources thermales. Si les débits des sources de Maizières et de Santenay apparaissent relativement faibles devant ceux des grisous (respectivement 1 mètre cube et 18 mètres cubes par an), les concentrations en hélium y sont, par contre, très élevées; le gaz spontané brut renferme, à Maizières, près de 6 pour 100 d'hélium, et, à Santenay, 10 pour 100.

2. Nous avons reconnu des traces de radium et de thorium dans les houilles d'où proviennent nos grisous (moyennes $0.2 \cdot 10^{-12}$ gr. de radium et $0.1 \cdot 10^{-5}$ gr. de thorium par gramme de houille). En dehors de nos déterminations, les seules, à notre connaissance, qui aient été faites relativement à la radioactivité des houilles, sont dues à Lloyd et Cunningham, de l'Université d'Alabama (Etats-Unis-d'Amérique), qui ont dosé le radium dans dix échantillons de houille provenant de différentes localités et dans un lignite; la moyenne des teneurs était de $0.166 \cdot 10^{-12}$ gr. de radium

par gramme de houille. Ces résultats, comme on le voit, sont en parfaite concordance avec ceux de nos dosages de radium.

Si nous n'avons pas trouvé radioactifs les grisous eux-mêmes, cela tient, sans aucun doute, à l'insuffisance de la sensibilité de notre méthode de mesure. Minimales, en effet, sont les quantités d'émanation que les faibles traces de radium des houilles, pour ne parler que de cet élément radioactif, dont l'émanation est à destruction lente, doivent déverser dans les grisous.

Les infimes teneurs des houilles ou des grisous en matières radioactives peuvent-elles rendre compte des énormes débits d'hélium des soufflards? Nous donnerons à cet égard, à titre d'exemple, le calcul suivant, relatif au grisou de Frankenholz.

Le grisou qui se dégage de cette mine amène au jour, quotidiennement, 9 mètres cubes d'hélium. Pour fixer les idées, nous supposerons que la quantité totale d'hélium qu'elle aura déversée dans l'atmosphère, lorsqu'elle sera épuisée, est équivalente à celle qu'elle fournirait, avec le débit actuel, et le gaz ayant partout et toujours la même teneur en hélium (0.027 pour 100), pendant 20 ans, ce qui donnerait le volume de 73000 mètres cubes. Admettons pour un instant, en outre, que cette quantité d'hélium représente la totalité de celle qui a été produite par les matières radioactives de la houille (dont nous supposerons encore, pour simplifier, que la masse n'a pas diminué) depuis la période carbonifère, que nous ferons remonter, pour prendre un chiffre moyen parmi ceux qui ont été proposés, à 100 millions d'années. Connaissant les teneurs de la houille de Frankenholz en radium ($0.04 \cdot 10^{-12}$ gr. de radium par gramme de houille) et en thorium ($0.03 \cdot 10^{-5}$ gr. de thorium par gramme de houille), ainsi que les lois de production de l'hélium par le radium et le thorium, on trouve qu'il a été produit $2.2 \cdot 10^{-3}$ millimètres cubes d'hélium par gramme de houille, et que, par conséquent, le poids de houille d'où proviendraient les 73000 mètres cubes d'hélium serait de 33 milliards de tonnes (soit 22 milliards de mètres cubes; c'est environ 1000 fois la production annuelle de la France). Mais n'est-il pas probable que l'hélium engendré reste, en grande partie, occlus dans la houille, et qu'une fraction très petite doit seule s'en échapper, en sorte que la masse de houille qui aurait été réellement nécessaire pour que la mine puisse répandre dans l'atmosphère 73000 mètres cubes d'hélium serait très supérieure à 33 milliards de tonnes (peut-être 100 fois ou 1000 cette quantité, peut-être beaucoup plus encore)? Il semble donc, d'après ces évaluations, qu'il n'y ait qu'une très petite fraction de l'hélium des grisous qui doive être issue des matières radioactives de la houille.

On pourrait envisager le même problème en considérant aussi

les roches encaissantes, dans la substance desquelles sont également disséminées des matières radioactives. D'après les plus récentes études, les teneurs moyennes des roches sédimentaires sont, pour le radium, $1.5.10^{-12}$ gr. de radium par gramme de roche, et, pour le thorium, $1.16.10^{-5}$ gr. de thorium par gramme de roche, soit environ 40 fois les teneurs en radium et en thorium des houilles. On voit donc qu'un raisonnement semblable au précédent conduirait à des chiffres du même ordre de grandeur et, par conséquent, à une conclusion analogue.

Quoi qu'il en soit, étant donné les énormes quantités d'hélium dont il s'agit, il est hors de doute qu'il n'y en a qu'une minime fraction qui soit de formation récente, de l'hélium *jeune* ; on peut dire, en toute assurance, que la presque totalité est, au contraire, de l'hélium ancien, de l'hélium *fossile*, et qu'une partie au moins (sans doute de beaucoup la plus importante) n'est pas issue des matières radioactives de la houille. Comment, par quel mécanisme, cet hélium étranger a-t-il pu être amené dans la masse des houilles grisouteuses ? Nous nous contenterons, pour l'instant, de poser la question. Elle se présente, en effet, de la même manière pour les autres gaz rares, qui, comme nous savons, font également partie constitutive des grisous. Nous l'examinerons plus loin dans son ensemble.

(c) *Constance de certains rapports.*—Nous avons montré précédemment que les rapports, en volumes, du krypton à l'argon, du xénon à l'argon, du xénon au krypton, et de chacun de ces gaz à l'azote, dans les gaz spontanés des sources thermales, présentent un caractère de constance tout à fait évident, que leurs valeurs respectives *moyennes* sont très voisines (légèrement supérieures) des valeurs des rapports correspondants dans l'air atmosphérique. Cette constance remarquable nous a paru s'expliquer au moyen d'une hypothèse très simple, laquelle, remontant jusqu'à la nébuleuse génératrice du système solaire, s'appuie sur l'inertie chimique des éléments considérés, ainsi que sur leur faculté de conserver l'état gazeux dans un large champ de variation des conditions physiques.

Ayant dosé l'azote et les gaz rares dans les grisous, recherchons si la loi de constance s'étend aussi à ces mélanges gazeux, absolument différents des précédents.

Nous avons calculé, pour les échantillons de grisou étudiés, les rapports *argon-azote*, *krypton-argon*, *xénon-argon* et *xénon-krypton*. Les valeurs de quelques rapports ont, en outre, pu être déterminées dans deux échantillons d'*argon brut* (ce que nous appelons mélange global des gaz rares) de grisous, obligeamment mis à notre disposition par Th. Schloesing fils.

Dans le Tableau suivant, nous donnons les valeurs respectives, en volumes, de ces divers rapports, la valeur que chacun d'eux présente dans l'air atmosphérique étant conventionnellement prise pour unité. Nous y ajoutons, à titre d'indication, les valeurs absolues, multipliées par 100, des rapports *argon-azote* :

TABLE XI.

Provenance du grisou	$\frac{Ar}{N_2} 10^3$	$\frac{Ar}{N_2}$ (grisou).	$\frac{Kr}{Ar}$ (grisou).	$\frac{Xe}{Ar}$ (grisou).	$\frac{Xe}{Kr}$ (grisou).
		$\frac{Ar}{N_2}$ (air).	$\frac{Kr}{Ar}$ (air).	$\frac{Xe}{Ar}$ (air).	$\frac{Xe}{Kr}$ (air).
Air	1.18	1	1	1	1
Agrappe (près Mons)	0.97	0.82	1.3	2.1	1.6
Anzin	1.15	0.97	1	1.1	1.1
Frankenholz	1.003	0.85	1.1	1.2	1.1
Lens	2.03	1.72	0.5	0.3	0.7
Liévin	1.63	1.38	1.4	1.2	0.9
Spittel (Sarre et Moselle)	1.492	1.248			
Th. Schloesing (échantillon No. 1)			1	1	1
Th. Schloesing (échantillon No. 2).			1.4	2	1.4

(a) On voit que les divers rapports, lorsque l'on prend le rapport dans l'air pour unité, sont assez voisins les uns des autres, et qu'ils s'éloignent relativement peu de l'unité. Ils sont d'ailleurs tous (sauf trois des rapports du grisou de Lens) compris entre les limites extrêmes atteintes par les rapports correspondants des mélanges gazeux naturels précédemment étudiés. Il nous paraît donc légitime d'affirmer que la loi de constance des rapports entre les gaz chimiquement inertes dans les mélanges gazeux naturels s'applique certainement aussi aux grisous.

(b) Nous ne pouvons cependant pas ne pas observer que, malgré le petit nombre de cas étudiés, les variations de ces divers rapports se montrent beaucoup plus étendues dans les grisous que dans les gaz thermaux. Il convient de remarquer, en outre, que la plupart des valeurs des rapports ci-dessus sont inférieures aux valeurs moyennes des rapports correspondants pour les gaz thermaux; et l'on voit, en particulier, combien faibles sont les valeurs de trois des rapports dans les grisous de Lens (0.5; 0.3; 0.7). Nous reviendrons plus loin sur ces divers points.

Cas de l'hélium. Variabilité des rapports.—Dans ce qui vient d'être dit sur les rapports mutuels des gaz inertes, nous n'avons mis en cause que l'argon, le krypton, le xénon et l'azote, laissant de côté l'hélium et le néon. La raison en est, pour le néon, en ce que les données analytiques quantitatives nous font totalement défaut; nous sommes en mesure, par contre, de traiter le cas de l'hélium.

(a) Il résulte de nos déterminations, en ce qui concerne l'hélium, que son rapport avec l'un quelconque des autres gaz inertes ne présente aucune régularité. Dans le Tableau suivant, nous donnons, à titre d'exemples, les rapports *hélium-argon* dans nos grisous, les valeurs de ces rapports quand on prend la valeur dans l'air pour unité, et les rapports *hélium-azote* en valeurs absolues et calculés également par rapport à l'air.

TABLE XII.

Provenance.	$\frac{\text{He}}{\text{Ar}}$	$\frac{\text{He}}{\text{Ar}}$ (grisou).	$\frac{\text{He}}{\text{N}^2}$	$\frac{\text{He}}{\text{N}^2}$ (grisou).
		$\frac{\text{He}}{\text{Ar}}$ (air).		$\frac{\text{He}}{\text{N}^2}$ (air).
Agrappe (près Mons)	16.67	31,095	0.1576	23,100
Anzin	2.095	3,909	0.0237	3,470
Frankenholz	1.286	2,400	0.0133	1,950
Lens	0.00817	15.25	0.00021	30
Liévin	0.325	606.3	0.0054	790
Spittel (Sarre et Moselle)	0.149	257	0.00228	322

L'absence de toute constance est évidente. L'hélium se sépare ici nettement des autres gaz inertes. On voit, en outre, que ces rapports sont tous très supérieurs à ce qu'ils sont dans l'air. Le rapport *hélium-argon*, par exemple, dans le cas où il est le moins fort, à Lens, l'est cependant encore 15 fois plus que dans l'air; et à Mons, il l'est 31000 fois plus.

On remarquera la valeur très élevée du rapport *hélium-azote* du grisou d'Agrappe (près Mons); cette valeur correspond à 13 pour 100 d'hélium dans l'azote brut. L'azote brut de ce grisou est, à notre connaissance, le plus riche en hélium parmi tous les azotes bruts des mélanges gazeux naturels qui ont été étudiés jusqu'ici.

(b) Quant à l'explication de l'absence de toute uniformité dans les rapports entre l'hélium et les autres gaz inertes dans les grisous, elle ne peut être qu'identique à celle que nous avons donnée dans le cas des gaz thermaux. Si de l'hélium est engendré sans cesse et partout dans l'écorce terrestre par les corps radioactifs, le dégagement de ce gaz des roches où il est occlus dépend de divers facteurs : nature et âge des roches, perméabilité, température, pression, etc.; et, par suite, les valeurs des rapports entre la teneur en hélium et celles des autres gaz inertes dans les mélanges naturels ne sauraient être que fort capricieuses.

III.—Les Gaz Rares de mélanges naturels divers riches en Gaz Combustibles.

Outre les gaz thermaux et les grisous, d'autres gaz naturels devaient aussi attirer l'attention. Nous avons, M. Lepape et moi,

étudié avec soin l'azote brut de quelques-uns d'entre eux, et, en outre, divers auteurs, se sont occupés de gaz naturels riches en gaz combustibles, spécialement en vue de la recherche de l'hélium.

Nous résumerons d'abord nos recherches, qui, tout en ne portant que sur un petit nombre de gaz naturels, forment un tout complet et apportent de nouvelles données précieuses pour la question des gaz rares prise dans son ensemble.

A.—Les Gaz Rares des Mines de Pétrole et de Potasse d'Alsace, et de quelques autres Gaz Naturels.

Nos expériences ont porté sur quatre gaz des mines de pétrole de Pechelbronn (Bas-Rhin), et un gaz des mines de potasse de Wittelsheim (Haut-Rhin), deux gaz de sondages faits à Lesquin (Nord) et à Vaux-en-Bugey (Ain) et deux gaz provenant de dégagements naturels secs à Molières (Drome) et à St. Barthélemy-en-Goa (Fontaine Ardente, Ysère). Chaque gaz a été traité, en principe, suivant les méthodes analytiques précédemment décrites.

Voici les résultats de nos études :

TABLE XIII.

Composition centésimale, en volumes, des Gaz des Mines de Pétrole et de Potasse d'Alsace et de quelques autres Gaz Naturels.

Ces nouveaux résultats expérimentaux viennent confirmer en tous points les conclusions déduites de nos recherches sur les gaz rares des gaz thermaux et des grisons.

1. Au point de vue *qualitatif*, nous constatons, dans les gaz d'Alsace, la présence constante de l'azote et des cinq gaz rares.*

2. Au point de vue *quantitatif*, si nous envisageons la composition de l'*azote brut* (azote + gaz rares), nous observons que les relations établies par nous antérieurement concernant les rapports mutuels entre les proportions de l'azote et des gaz rares sont également vérifiées. On trouve, en effet, que le rapport *argon-azote* ne varie (lorsqu'on prend pour unité sa valeur pour l'air) qu'entre 0.29 et 1.68, limites relativement étroites et d'ailleurs comprises entre les valeurs extrêmes (0.25 et 3.39) précédemment trouvées.

Toutes données nous font défaut sur les proportions de néon, de krypton et de xénon, mais nous pouvons affirmer que ces proportions sont négligeables devant celles de l'argon : elles sont très petites, et l'on ne saurait douter que les rapports *krypton-argon*, *xénon-argon* et *xénon-krypton* ne soient en accord avec la loi de constance que nous avons antérieurement établie.

Quant à l'hélium, nous constatons, ici comme partout ailleurs, la *grande variabilité* des rapports *hélium-azote* et *hélium-argon*.

On voit que ces observations apportent une pleine confirmation à la règle générale que nous avons formulée relativement à la composition qualitative et quantitative de l'azote brut des gaz naturels.

B.—L'*Hélium de divers gaz naturels* (Allemagne, Etats-Unis, Canada, etc.).

En dehors de nos recherches personnelles, que nous venons de résumer, un grand nombre de gaz naturels ont été étudiés par différents auteurs, mais toujours d'une manière assez sommaire. C'est surtout de l'hélium qu'on s'est le plus souvent occupé, en raison de l'intérêt exceptionnel qu'il présente. Je me bornerai à mentionner les principaux de ces travaux parvenus à notre connaissance.

Dans quelques gaz naturels (Erdgasen) d'Allemagne et d'Autriche-

* Avant nos recherches, l'hélium et le néon avaient déjà été mis en évidence dans un gaz de mine de potasse (Léopoldshall, He : 0.17%) par Erdmann et dans deux gaz de pétrole de Pechelbronn par Czakó.

Hongrie, Czako a trouvé des proportions d'hélium comprises entre 0.0014 et 0.38 pour 100 du mélange brut. Le débit du gaz de Neuengamme est très important. La quantité d'hélium qu'il fournit annuellement dépasse 25000 mètres cubes; il est notablement plus élevé que le plus élevé de ceux que nous avons signalés (Anzin, 4380 mètres cubes).

P. Cady et MacFarland ont étudié de nombreux gaz naturels des Etats-Unis d'Amérique; les teneurs en hélium étaient comprises entre 0.009 pour 100 et 1.84 pour 100 du mélange brut. MacLennan et ses collaborateurs (Satterly, Patterson, etc.) ont également étudié un grand nombre de gaz naturels du Canada; les teneurs en hélium maxima observées étaient 0.3 pour 100. Les débits sont souvent considérables, et nous verrons plus loin que des extractions industrielles sont en cours tant au Canada qu'aux Etats-Unis.

L'azote brut a le plus souvent été dosé, de même qu'on a parfois recherché et reconnu la présence de l'argon, plus rarement du néon. Avec les données des auteurs, nous avons pu calculer les rapports *hélium-azote*, et, comme il était à prévoir, ils se sont trouvés essentiellement variables.

On voit que si une multitude de gaz naturels riches en gaz combustibles ont été étudiés, il n'en est pas qui aient fait l'objet de recherches aussi complètes que les nôtres sur quelques-uns de ces gaz. Néanmoins, toutes sommaires que sont les données expérimentales des auteurs, elles suffisent à nous montrer que tous les résultats partiels concordent parfaitement avec ceux que nous avons nous-mêmes obtenus. Et l'on peut en inférer, en toute certitude, que l'azote et les cinq gaz rares sont présents dans tous les gaz souterrains riches en gaz combustibles.

IV.—*Les gaz rares des gaz de roches et des gaz volcaniques.*

De très nombreuses recherches ont été exécutées sur les gaz de roches et les gaz volcaniques. Ce sont généralement des mélanges complexes, où dominent souvent les gaz combustibles (hydrogène, oxyde de carbone, hydrogène sulfuré, méthane) accompagnés principalement d'azote et de gaz carbonique.

A.—C'est en calcinant la clévéite que Ramsay découvrit l'hélium (1895). Ce gaz, ainsi que l'argon, a été également rencontré par Ramsay et Travers dans différents autres minéraux.

Des recherches très étendues de Strutt (1908 et années suivantes) ont montré que l'hélium accompagne généralement les traces de substances radioactives présentes dans les roches communes, ignées ou sédimentaires, et le même sujet a aussi été étudié peu après par Piutti.

L'hélium est le seul des gaz rares qui aient fait l'objet de véritables dosages dans les roches.

B.—L'argon et l'hélium ont été déterminés par Nasini, Anderlini et Salvadori dans les suffioni de Larderello (Toscane), les gaz des solfatares de Ponzsoles et les gaz hydrocarbonés de Salsomaggiore (1898-1900). Porlezza et Norzi ont étudié aussi, au même point de vue, les gaz de Larderello.

Moissan (1902) a trouvé l'argon dans une fumerolle du Mont-Pelé (Martinique), ainsi que dans deux fumerolles de la Guadeloupe.

Moireu et Lepape (1909) ont reconnu la présence des cinq gaz rares dans un gaz de Vésuve et les y ont dosés (sauf le néon). Les rapports argon-azote, krypton-argon, xénon-argon ont été trouvés très voisins de leur valeur pour l'air (respectivement 1.15—1.1—1.2, le rapport dans l'air étant pris pour unité).

Thorkeisson a dosé l'argon et l'hélium dans les gaz des geysers d'Islande (1910). Les proportions dans les mélanges argon + azote étaient comprises entre 0.62 et 2.25 pour cent.

En 1912, des gaz recueillis au cratère du Kilauea (Iles Hawaï) ont été étudiés par Day et Shepherd, qui n'y ont pas trouvé d'argon.

En 1919, Shepherd, examinant d'autres gaz de la même origine, y a trouvé des proportions très variables d'argon, allant jusqu'à 19.11 pour cent. de l'azote brut (azote + gaz rares).

Allen et Zies, plus récemment, ont dosé l'argon dans des fumerolles d'Alaska; les proportions de ce gaz dans l'azote brut étaient comprises entre 0.9 et 1.55.

Comme on le voit, les gaz volcaniques examinés jusqu'à présent, sauf ceux du Kilauea, présentent pour le rapport argon-azote (le seul que les données expérimentales permettent de calculer) des valeurs s'accordant parfaitement avec celles qui ont été trouvées pour les autres gaz naturels. Le cas exceptionnel du gaz du Kilauea nous paraît pouvoir s'expliquer par les considérations que nous avons déjà présentées à propos des gaz thermaux et des grisons (toute relation de l'azote, surtout dans les conditions géochimiques très particulières qui se trouvent réalisées au lac de lave fondue du Kilauea).*

V.—Conclusions.

I. Il est impossible, en considérant dans leur ensemble les nombreux faits relatifs à l'azote brut (azote + gaz rares), de ne pas apercevoir l'étroite analogie de composition qui s'en dégage entre l'azote brut

* On trouvera de nombreuses données numériques et des considérations très intéressantes sur les gaz volcaniques dans une belle étude d'ensemble du sujet publiée par E. T. Allen dans le *Journal of the Franklin Institute*, t. 193, p. 129 (1922).

des grisous ou autres mélanges naturels riches en gaz combustibles, d'une part, et celui des gaz thermaux, d'autre part. Partout l'azote brut a la même composition qualitative : azote, hélium, néon, argon, krypton et xénon. Partout la proportion d'azote est largement prédominante; partout également les deux gaz rares les plus abondants sont l'argon et l'hélium, devant lesquels le krypton et le xénon sont toujours, et le néon presque toujours, négligeables. Partout encore, nous trouvons que les rapports *krypton-argon* sont voisins les uns des autres, ainsi que les rapports *xénon-argon* et *xénon-krypton*, et aussi ceux de chacun de ces gaz avec l'azote. Dans les diverses catégories de mélanges gazeux, enfin, nous constatons la même irrégularité dans les rapports entre l'hélium, d'un côté, et, de l'autre, l'azote, l'argon, le krypton et le xénon.* contrastant manifestement avec la fixité des rapports mutuels de ces derniers éléments.

Une telle ressemblance ne peut se comprendre que si tous ces azotes bruts ont une origine commune.

Considérons, en effet, pour fixer les idées, l'azote brut des grisous et celui des gaz thermaux. Si ces deux azotes bruts avaient une origine différente, la similitude dans la composition qualitative pourrait, à la grande rigueur, se concevoir; mais comment s'expliquerait-on la constance des rapports mutuels entre l'azote, l'argon, le krypton et le xénon dans tous les mélanges? Il faut donc que l'origine des azotes bruts soit commune.

2. Une conséquence de cette manière de voir est que l'azote des grisous ne peut provenir de la houille. S'il en était ainsi, en effet, la houille devrait être la source de tous les azotes bruts, puisque les azotes bruts doivent avoir nécessairement tous la même origine; et l'azote avec les gaz rares, dont il resterait à trouver la provenance, devrait donc passer des houilles grisouteuses dans les sources thermales. Or cela est inadmissible, attendu que les terrains houillers ne constituent qu'une minime fraction de l'écorce terrestre et qu'il y a des sources thermales dans toutes les contrées, houillères ou non. L'azote du grisou n'est donc pas issu de la houille. C'est de l'azote minéral qui, sans aucun doute possible, vient d'ailleurs, ainsi que les gaz rares qui l'accompagnent.

On prouverait par le même raisonnement que l'azote des gaz de

* Nous rappelons que les données quantitatives précises nous manquent en ce qui concerne le néon. Nous pouvons affirmer toutefois que dans tous les mélanges naturels il n'y en a jamais que de très faibles proportions et que, de plus, elles sont généralement négligeables devant celles de l'hélium. Nous pouvons donc prévoir, pour le moins, que si les rapports du néon avec l'argon (ou avec le krypton, le xénon ou l'azote) se montrent variables, ils ne peuvent l'être qu'entre des limites beaucoup moins étendues que dans le cas de l'hélium.

pétrole a également une origine minérale et que, comme les gaz rares, il vient aussi d'ailleurs.

On peut donc dire que chaque valeur des rapports mutuels entre l'azote, l'argon, le krypton et le xénon, sensiblement la même dans tous les mélanges gazeux naturels, caractérise l'azote brut de ces mélanges et en est comme la *marque de fabrique*. L'air atmosphérique, rappelons-le, ne fait pas exception à la règle, puisque les divers rapports y présentent des valeurs voisines de celles qu'on trouve dans les mélanges souterrains. Et l'analogie qui apparaît, à ce point de vue, entre l'atmosphère externe et l'atmosphère interne de la Terre, ne laisse pas que d'être fort suggestive.*

3. Cet azote brut, dont nous venons ainsi de prouver la communauté d'origine pour tous les mélanges gazeux naturels, d'où provient-il ?

Nous remonterons ici encore, comme nous l'avons fait lorsque nous nous sommes proposé d'expliquer la constance de nos rapports, jusqu'à la nébuleuse solaire.

La masse gazeuse incandescente devait être un mélange relativement homogène dans ses différentes parties. Le fragment constitutif de la Terre s'étant détaché, celle-ci comprend bientôt trois régions concentriques : une masse en fusion, une écorce solide hétérogène et l'atmosphère gazeuse. Au cours de l'évolution continue de la Planète, tandis que les autres éléments contractaient des combinaisons mutuelles, les gaz rares, en vertu de leur inertie chimique, et aussi en grande partie, l'azote, élément *relativement* inerte, sont demeurés libres, et comme ils sont difficilement liquéfiables, ils ont conservé l'état gazeux ; et leurs rapports quantitatifs mutuels, dans l'atmosphère externe comme dans les mélanges gazeux souterrains qui furent emprisonnés ou occlus dans les roches de l'écorce au moment de sa solidification, ont dû se maintenir peu différents de ce qu'ils étaient au début.†

Bref, notre *azote brut* (azote + gaz rares) a gardé intact son cachet d'origine depuis l'époque de la nébuleuse jusqu'à nos jours.

4. L'azote brut occlus est susceptible d'être dégagé par diverses causes, parmi lesquelles l'action des eaux profondes n'est sans doute pas la moins importante.‡ Celui qui est emprisonné (dans des

* Observons que l'azote brut de l'air atmosphérique s'écarte de la plupart des azotes bruts des mélanges souterrains par sa faible teneur en hélium (1,42%).

† Hormis ce qui regarde l'hélium, dont nous savons qu'il y a production continue aux dépens des corps radioactifs dans l'écorce terrestre, et qui est plus ou moins abondant dans les mélanges souterrains, par rapport aux autres gaz inertes, suivant la nature des terrains traversés.

‡ Armand Gautier a émis l'idée que la plus grande partie des gaz thermaux doit provenir du noyau terrestre incandescent (*Revue Scientifique*, 2 et 9 novembre 1907).

poches plus ou moins volumineuses) peut être libéré sous l'influence des mouvements d'ensemble ou locaux de l'écorce : tremblements de terre, éruptions volcaniques, etc., amenant des ruptures et des dislocations. Quels que soient les mécanismes, l'azote brut, une fois mis en liberté, se répandra de proche en proche, à travers les fissures, entraîné par les eaux, par diffusion, etc., dans les différents milieux de l'écorce.* Il pénétrera, notamment, dans la houille, et ira se mêler au méthane du grison. Il rencontrera également les pétroles et, avec les hydrocarbures volatils de ces derniers, il s'échappera dans l'atmosphère.

On prévoit, ainsi, que tous les gaz issus du sein de la terre; gaz thermaux, grisons, gaz de pétroles, gaz volcaniques, etc., devront contenir une certaine proportion de cet azote brut, et c'est là une prévision que l'expérience vérifie complètement.

5. L'azote brut des mélanges naturels, nous ne saurions trop le répéter, se reconnaît partout et toujours à sa marque de fabrique : l'inertie chimique de l'azote, de l'argon, du krypton et du xénon, et la propriété que possèdent ces gaz d'être difficilement liquéfiables, font que chacun de leurs rapports quantitatifs mutuels présente, dans les différents mélanges, une valeur toujours voisine de la valeur moyenne correspondante. Cette loi de constance ne peut être altérée que par des processus physiques : occlusion, dissolution, diffusion, etc., c'est à dire entre des limites peu étendues.

Nous avons observé, en fait, quelques écarts relativement notables dans les grisons. Cela n'a rien qui doive nous surprendre, puisque le charbon est une matière susceptible d'absorber les différents gaz dans des proportions fort inégales et, par suite, de leur faire subir un véritable fractionnement.† Ailleurs, le fractionnement naturel peut être opéré par diffusion, par dissolution, etc., et les effets produits varieront suivant les conditions de température et de pression, suivant la nature du solvant, etc.

À la réflexion, on voit donc que ce serait la constance rigoureuse des rapports qui devrait nous surprendre.

6. Nous venons, en ce qui concerne les légères variations des

* En pleine concordance avec cette manière de voir, un soufflard d'azote nous fut signalé en février 1912 par M. Barrois à Lesquin, près de Lille, à la profondeur de 45 mètres, dans le forage No. 1 de la Société Thomson-Houston. Nous lui trouvâmes la composition centésimale suivante : anhydride carbonique, 0.97; oxygène, néant; gaz combustibles, néant; azote, 97.75; gaz rares en bloc, 1.274; argon, 0.350; hélium, 0.924. Le débit était de 18 mètres cubes à l'heure, ce qui portait le débit quotidien d'hélium à 3970 litres. Le soufflard était encore en activité en 1914; se trouvant dans la zone des opérations militaires, il a disparu dans le bouleversement des terrains.

† On se souvient que c'est précisément sur cette propriété que reposent nos méthodes de détermination qualitative et quantitative des différents gaz rares.

rapports mutuels entre l'azote, l'argon, le krypton et le xénon, de considérer les mélanges naturels dans leur ensemble. Un intérêt particulier s'attache à la comparaison, au même point de vue, des mélanges souterrains et de l'air atmosphérique.

On sait que l'atmosphère externe de la Terre se raréfie à mesure que l'on s'élève. La distribution de chaque gaz en hauteur obéit, théoriquement, à une loi exponentielle, laquelle, avec des coefficients différents, est de même forme pour tous. Conformément à cette loi, la teneur de l'air en gaz légers croît avec l'altitude, tandis que les gaz lourds se concentrent dans les basses régions. D'un autre côté, ainsi que la Mécanique permet de le démontrer, toutes les molécules qui, dans les couches extérieures de notre atmosphère, sont animées d'une vitesse d'au moins 11,2 kilomètres par seconde et se dirigent vers l'espace, doivent échapper à l'attraction terrestre. Or, les gaz les plus légers étant ceux dont la vitesse moyenne des molécules est la plus élevée et dont la concentration dans ces régions est en même temps la plus forte, on voit que les molécules susceptibles de quitter l'atmosphère sont plus nombreuses pour ces gaz que pour les gaz plus lourds. Il se produit donc ainsi une distillation continue et fractionnée de gaz des basses régions vers les hautes régions, et de celles-ci vers les espaces célestes. On comprend qu'en vertu de ce mécanisme la teneur de l'air en gaz lourds doit croître avec temps.* Si cette manière de voir est exacte, le rapport xénon-argon, par exemple, doit être plus grand dans l'air actuel qu'il ne l'était dans l'air initial.

Or, d'après notre hypothèse astrophysique, l'azote brut des mélanges gazeux souterrains n'est autre que celui de l'air initial; il semble donc que les rapports dans l'air actuel devraient être supérieurs à ceux de cet azote brut. Il n'en est rien, du moins en général; et l'on observe, au contraire, que les valeurs moyennes des rapports dans les gaz souterrains surpassent les valeurs des mêmes rapports dans l'air.

Nous estimons qu'on ne saurait voir là une infirmation de notre hypothèse. La déduction qui précède suppose, en effet, que la composition de l'azote brut initial n'a pu s'altérer d'aucune manière au cours de l'évolution de la Planète. Et cela est manifestement invraisemblable, étant données les causes physiques multiples de variabilité auxquelles est perpétuellement soumise la composition des mélanges gazeux naturels.

En réalité le problème est probablement très complexe. D'im-

* On peut ajouter que l'atmosphère ultime de la Terre, nécessairement très raréfiée, devra être constituée surtout par le gaz le plus lourd, qui est le xénon (nous faisons abstraction ici de l'émanation du radium ou niton, gaz qui est plus dense encore que le xénon).

portantes données, qui nous font encore défaut, seraient indispensables pour une discussion fructueuse. Il conviendrait, notamment, d'étudier l'azote brut des mélanges gazeux dissous dans les eaux (eaux superficielles, eaux de la mer, eaux thermales) et dans les pétroles, ainsi que celui qui est occlus dans les diverses variétés de roches (roches primitives, roches sédimentaires, charbons, etc.).

7. *Les gaz rares autres que l'hélium au regard des corps radioactifs.*— Les relations simples que nous venons de mettre en évidence entre les proportions de quelques éléments dans la Nature apportent à la Géophysique et à l'Astrophysique des données inattendues—car ici, comme il arrive généralement, l'expérience a précédé la théorie—et il est vraisemblable qu'elles pourront servir de base à des travaux ultérieurs d'ordre théorique ou expérimental.

Par ailleurs, elles éclairent, d'une manière aussi utile qu'imprévue, une question toute différente. Si une étroite parenté rattache l'hélium aux substances radioactives, on ne connaît encore, d'une manière *positive*, rien d'analogue relativement aux quatre autres gaz rares : néon, argon, krypton, xénon, présents, comme lui, dans l'atmosphère externe et dans l'atmosphère interne de la Terre. Comme je l'ai dit précédemment, la grande similitude de propriétés qui existe entre ces cinq éléments porterait à supposer que le néon, l'argon, le krypton et le xénon sont, peut-être, de même que l'hélium, issus également des corps radioactifs, connus ou inconnus, qui seraient plus ou moins répandus dans les profondeurs de la Terre, et qui subiraient des métamorphoses du même ordre que celles du radium ou du thorium engendrant de l'hélium. Cependant, pour fixer les idées, envisageons l'argon et le krypton. Il y a proportionnalité entre ces deux gaz dans les mélanges gazeux naturels; et ce fait est difficile à concilier avec l'hypothèse d'après laquelle ces gaz—ou seulement l'un d'eux—se produiraient *actuellement* par la désintégration d'autres atomes. Si l'argon et le krypton ont une telle origine, celle-ci doit sans doute remonter à une phase de l'Evolution de la matière antérieure à la formation de l'écorce terrestre. Quoiqu'il en soit, leur situation vis-à-vis des corps radioactifs apparaît comme très différente de celle de l'hélium.

Applications Pratiques Des Gaz Rares.

Nous savons que toute découverte scientifique, si exclusivement contemplatif que paraisse d'abord son intérêt, ne peut manquer de conduire, tôt ou tard, à des applications pratiques. L'on peut dire, en ce qui concerne les gaz rares, que les plus grandes espérances sont permises.

L'argon s'emploie dans les lampes à incandescence, et des essais d'éclairage au néon se sont montrés fort encourageants.

On se propose de gonfler les ballons à l'hélium, qui seront ainsi rendus ininflammables. Quels progrès en perspective pour l'Aéronautique ! On prévoit aussi l'utilisation de l'hélium pour l'éclairage, soit qu'on l'introduise, comme l'argon, dans les lampes à incandescence, soit, comme dans le cas du néon, qu'on illumine le gaz raréfié. L'emploi de l'hélium pour la réalisation de très basses températures paraît également appelé à un brillant avenir. En vue de ces applications et d'autres encore qui pourront être envisagées, la fabrication industrielle de l'hélium est déjà en voie de développement. Au moment de l'armistice (11 novembre 1918), grâce aux efforts concertés de MM. Moore, Cottrell, Burrell, Manning, etc., on avait extrait des gaz naturels, aux Etats-Unis, en vue le l'aérostation militaire, 147,000 pieds cubes d'hélium. Au Canada, M. MacLennan avec le concours de MM. Satterly, Patterson, etc., a également installé une fabrication d'hélium. En France, on se préoccupe aussi de cet intéressant problème. En Juin 1919, le Ministre de la Marine institua une " Commission de l'hélium," chargée de rechercher les sources exploitables d'hélium pouvant exister en France et dans les Colonies, et c'est sous ses auspices que nous avons, M. Lepape et moi, étudié les gaz naturels d'Alsace.

Messieurs,

Je ne saurais clore cette conférence sans faire observer toute la variété des problèmes qu'on est conduit à envisager quand on étudie la dissémination des gaz rares dans la Nature. La raison en est dans la situation toute privilégiée qu'occupent l'argon et ses congénères vis-à-vis des autres éléments. Leur complète inertie, qui les place, pour ainsi dire, en marge de la Chimie, leur permet de résister, en restant sains et saufs, à tous les cataclysmes de l'Astronomie et de la Géologie ; elle leur assure une éternelle inviolabilité. Grâce, en outre, à la propriété dont ils jouissent d'être difficilement liquéfiables, ils ont accès dans tous les fluides et dans toutes les atmosphères, où les cinq membres de la famille voyagent librement et toujours de compagnie. Un autre gaz, relativement inerte, l'azote, les accompagne partout ; il est leur diluant constant. C'est un rôle bien suggestif que celui de l'hélium dans les processus de l'Evolution de la Matière, et quelle destinée exceptionnelle que celle de ces divers éléments dans les phénomènes de la Physique du Globe et de l'Evolution des Mondes !

Nombreuses et importantes sont les lacunes expérimentales qui apparaissent de tous côtés quand on médite ces vastes questions. A les combler, nous invitons tous ceux qu'intéresse l'Histoire de la Terre.

CCXIII.—*The Molecular Configurations of Polynuclear Aromatic Compounds. Part IV. 6:6'-Dichlorodiphenic Acid; its Synthesis and Resolution into Optically Active Components.*

By GEORGE HALLATT CHRISTIE, CUTHBERT WILLIAM JAMES, and JAMES KENNER.

IN pursuing the inquiry into the nature of the configuration of diphenyl derivatives discussed in previous papers of this series (T., 1922, 121, 614; this vol., p. 779), it is of importance to ascertain to what extent their resolvability into optically active components is affected by variation of the nature of the substituents or their orientation.

In connexion with the former of these questions, we have investigated 6:6'-dichlorodiphenic acid (X), of which the synthesis is represented by the following scheme:

The only difficulties encountered in this series of reactions arose from the mobility of the halogen atom in 2-iodo-*m*-toluidine (III) and in 2-iodo-*m*-aminobenzoic acid (VI). On this account, the preparation of the former from the corresponding nitro-compound must be carried out either by means of ferrous sulphate and ammonia (Wheeler and Liddle, *Amer. Chem. J.*, 1909, 42, 441), or, if stannous chloride and hydrochloric acid be employed, only at a low temperature (compare Burton and Kenner, T., 1922, 121, 675). Similarly, the hydrolysis of 2-iodo-3-acetylamino-6-methoxybenzoic acid (V) by means of hydrochloric acid must not be carried out above 100°, and even at this temperature iodine will be liberated if the reaction be too prolonged. Again, the amino-acid could not be prepared

by ~~acid~~ reduction of 2-iodo-3-nitrobenzoic acid owing to elimination of the iodine. In regard to the question as to whether the mobility of the halogen is favoured by salt formation (Burton and Kenner, *loc. cit.*) it may be noted that the iodotoluidine may be distilled in steam from alkaline solution without decomposition, and the hydrochloride of the amino-acid loses iodine at its melting point, whilst *iodoacetylaminobenzoic acid* (V) shows no tendency to decomposition under these conditions. This point is, however, one requiring further investigation.

The resolution of 6:6'-dichlorodiphenic acid was accomplished by fractional crystallisation of its brucine salts. The free acids respectively liberated from the two salts furnished sodium salts, solutions of which exhibited specific rotations of $+21.43^\circ$ and -20.18° , respectively.

These results confirm the correctness of the assumption that the cause of the stereoisomerism of the various nitrodiphenic acids previously investigated by two of us is not to be sought in any property peculiar to the nitro-group. It remains to be seen whether a racemic acid, isomeric with that now described, is obtainable from the corresponding dichlorophenanthraquinone.

EXPERIMENTAL.

2-Iodo-3-acetylaminobenzoic Acid.—2-Iodo-*m*-toluidine was prepared in good yield by gradual addition of a solution of 2-iodo-3-nitrotoluene (20 grams) in glacial acetic acid (134 grams) to a solution of stannous chloride (160 grams) in concentrated hydrochloric acid (160 c.c.) below 25° . The double tin salt which had separated after twelve hours was worked up in the usual manner.

A suspension of 2-iodoaceto-*m*-toluidide (10 grams) in boiling water (1200 c.c.), containing magnesium sulphate (9.3 grams), was oxidised by gradual addition of potassium permanganate (15.4 grams). The 2-iodo-3-acetylaminobenzoic acid thus prepared formed colourless needles, m. p. 199° . It was hydrolysed by heating 20 grams with concentrated hydrochloric acid (80 c.c.) at 100° until vapours of iodine appeared in the flask; on cooling, the hydrochloride of 2-iodo-3-aminobenzoic acid (7.5 grams), m. p. $262-263^\circ$ (with evolution of iodine), separated (Found: N = 4.76, equivalent = 145. $C_7H_6O_2NI \cdot HCl$ requires N = 4.68 per cent; equivalent = 149.5).

3-Chloro-2-iodobenzoic Acid.—This compound, prepared from the above amino-acid in the usual manner, separates from water in plates, m. p. $137-138^\circ$ (Found: C = 29.49; H = 1.58. $C_7H_4O_2ClI$ requires C = 29.78; H = 1.42 per cent.). The methyl ester (Found: C = 32.91; H = 2.00. $C_8H_5O_2ClI$ requires C = 32.38; H = 2.03

per cent.) boils at $182^{\circ}/28$ mm., and the *ethyl* ester $175^{\circ}/15$ mm.

6:6'-Dichlorodiphenic Acid.—The methyl ester of this acid was prepared by gradual addition of copper powder to an equal weight of methyl chloriodobenzoate at 180° , and subsequent heating of the mixture at 230 – 240° for one hour. The *ethyl* ester is prepared in a similar manner.

r-6:6'-Dichlorodiphenic acid, $C_{12}H_8Cl_2(CO_2H)_2$, crystallises from alcohol in feathery clusters of needles, m. p. 288° (Found: C = 54.04; H = 2.16. $C_{14}H_8O_4Cl_2$ requires C = 54.02; H = 2.57 per cent.). The *methyl* ester separates from benzene in almost rectangular prisms, m. p. 156° , whilst the *ethyl* ester crystallises from alcohol in rhombic plates, m. p. 103 – 104° (Found: C = 58.88; H = 4.12. $C_{16}H_{16}O_4Cl_2$ requires C = 58.81; H = 4.36 per cent.).

Resolution of r-6:6'-Dichlorodiphenic Acid.

By repeated fractional crystallisation of the mixture of salts prepared from 2 grams of the racemic acid and 6 grams of hydrated brucine, 2.3 grams of the pure, less soluble salt, and 1.35 grams of the pure, more soluble salt were separated with moderate ease.

Brucine 1-6:6'-dichlorodiphenate, $C_{14}H_8O_4Cl_2 \cdot 2C_{25}H_{26}O_4N_2 \cdot 3H_2O$, consists of rectangular prisms, m. p. 235° , and is the less soluble of the two salts thus obtained. For a 1.23 per cent. solution in chloroform, $[\alpha]_D^{25} + 1.97^{\circ}$ (Found: $H_2O = 4.66$. $C_{60}H_{60}O_{12}N_4Cl_2 \cdot 3H_2O$ requires $H_2O = 4.68$ per cent. Found: for the anhydrous material dried at 120° , N = 5.18. $C_{60}H_{60}O_{12}N_4Cl_2$ requires N = 5.09 per cent.).

Brucine d-6:6'-dichlorodiphenate, $C_{14}H_8O_4Cl_2 \cdot 2C_{25}H_{26}O_4N_2 \cdot 1\frac{1}{2}H_2O$, forms rectangular plates, m. p. 163° (decomp.). For a 1.16 per cent. solution in chloroform, $[\alpha]_D^{25} - 58.62^{\circ}$ (Found: $H_2O = 2.43$. $C_{60}H_{60}O_{12}N_4Cl_2 \cdot 1\frac{1}{2}H_2O$ requires $H_2O = 2.40$ per cent. Found: for the anhydrous material dried at 120° , N = 5.17. $C_{60}H_{60}O_{12}N_4Cl_2$ requires N = 5.09 per cent.).

d-6:6'-Dichlorodiphenic acid, $C_{12}H_6Cl_2(CO_2H)_2$, from the brucine salt, forms rectangular plates, m. p. 259° . For a 0.69 per cent. solution of the sodium salt, $[\alpha]_D^{25} - 20.18^{\circ}$. The acid recovered from this solution furnished a dextrorotatory solution in ether, which, however, was too dilute for anything more than qualitative observation.

l-6:6'-Dichlorodiphenic acid, $C_{12}H_6Cl_2(CO_2H)_2$, rectangular plates, m. p. 259° , furnished a sodium salt for which $[\alpha]_D^{25} + 21.43^{\circ}$ in a 1.01 per cent. aqueous solution.

One of us (G.H.C.) expresses grateful acknowledgment of a grant from the Department of Scientific and Industrial Research which

has enabled him to collaborate in this work, whilst another (C.W.J.) is similarly indebted to Messrs. The British Dyestuffs Corporation, Limited. Further, we wish to thank the Research Fund Committee of the Chemical Society for a grant towards the expenses of this investigation.

CCXIV.—*The Viscosity of some Cellulose Acetate Solutions.*

By ERNEST WALTER JOHN MARDLES.

THE subject of the viscosity of colloidal solutions has received considerable attention, especially with the object of establishing a quantitative relation between viscosity and concentration.* In most cases, however, the concentrations of the sols were never high; for example, Baker (T., 1913, 103, 1653), with cellulose nitrate solutions, seldom used concentrations above 4 per cent. The characteristic rapid rise of viscosity with increase of concentration is such that the higher-concentration sols are very viscous and intractable, and the capillary type of viscometer cannot readily be used. With the falling-sphere viscometer (Gibson and Jacobs, T., 1920, 117, 472), however, it was found possible to extend the viscosity measurements over a wide range of concentration. The exploration of the region of highly viscous sols, apart from the interest attaching to the relation between viscosity and concentration or temperature, is of importance with regard to the stability of the higher-concentration sols and the existence of a saturation concentration as with crystalloids.

The cellulose acetate solutions, which were clear and exhibited only a faint Tyndall cone in the majority of cases, were kept for some days before the viscosity was determined, there being viscosity changes with time for a short period after dissolution (compare Masson and McCall, T., 1920, 117, 819).

The viscosity values recorded are those for the true sols in absence of any gelation, there having been little or no aggregation of the dispersed particles, and therefore the values are largely independent of time, thermal history, mechanical treatment, etc.

* For reviews and bibliography of the subject, see "Colloids and their Viscosity," a general discussion held by the Faraday Society (*Trans. Faraday Soc.*, 1913, 9); "General Review on the Viscosity of Colloids," by E. Hatschek, First Report on Colloid Chemistry, 1917; "Grundriss der Kolloidchemie," Wo. Ostwald, 1919, p. 179 (English translation, 1918, p. 145).

Many of the sols were found to give identical results after an interval of eight months, when examined under the same conditions, indicating absence of the chemical changes which occur with hydrosols of proteins, especially on warming.

Incipient gelation of the sols can be detected by the increase of viscosity with time, and when equilibrium is attained the viscosity of the system is abnormal, being variable with rate of shear and dependent on mechanical treatment and thermal history, factors which affect the structure of aggregated particles (compare *Mardles, Trans. Faraday Soc.*, 1923, 18, 327; *de Jong, Rec. trav. chim.*, 1923, 42, 1).

Apart from gelation, the presence of coarser particles in the sols causes variability of viscosity, so that different values are obtained by using a variety of viscometers. Hatschek and Humphreys (*Proc. Physical Soc.*, 1916, 28, 274) showed the dependence of viscosity on the rate of shear in suspensions of rice starch in mixtures of carbon tetrachloride and toluene of the same density.

With the cellulose acetate sols, the variation in viscosity as measured by the use of different viscometers and by the deviation from Stokes's law for falling spheres, amounted to within 2 per cent. for sols with a viscosity less than 5 (C.G.S. units), and to 5 per cent. for sols of viscosity up to 10, whilst with the very viscous solutions the variation sometimes reached 15 per cent., the coarser particles having accumulated.

EXPERIMENTAL.

The cellulose acetate employed was obtained from the Société Chimique des Usines du Rhône. It charred at 208° and contained 0.23 per cent. of ash and 6.5 per cent. of water. The acetyl content, 39.6 per cent., corresponded with that of the average cellulose acetate represented by the formula $C_{12}H_{18}O_5(O\cdot CO\cdot CH_3)_5$ (compare Fenton and Berry, *Proc. Camb. Phil. Soc.*, 1920, 20, i, 16).

The material, as in the case of the parent substance cellulose, is not a chemical individual, but a complex mixture or solid solution of various acetates of similar chemical character but differing widely in viscosity.

In Table I are given the relative viscosity values of various fractions of cellulose acetate obtained by the repeated fractional precipitation of the original material from acetone solution by means of water. A portion of the material which remained in fine suspension in the aqueous acetone was not recovered.

It is possible that the fractionation of the cellulose acetate was accompanied by some degradation; when two fractions were

TABLE I.

Fraction a gave the highest content of ash.

mixed, the viscosity of the mixture was not the mean of those of the constituents.

The cellulose acetate was dehydrated before use, by heating it in a steam-oven for four to five hours and then keeping it in a vacuum desiccator until its weight was constant. The density of the material in film form, after drying, was 1.317 at 25°. The densities of the solutions were determined to four places of decimals (corrected for air buoyancy) in the case of the lesser concentrated, and to three places for the higher concentrations.

The solutions were prepared by allowing the colloid and dispersion medium to stand in a warm place with occasional shaking. In the case of the more concentrated solutions, several months elapsed before dissolution was complete.

The lower-concentration sols were examined by means of a chain of viscometers of the Ostwald type, water being used as the standard. The fall of the steel spheres, sizes $\frac{1}{16}$ ", $\frac{3}{32}$ ", and $\frac{1}{8}$ ", and of the specially prepared aluminium spheres in the case of the more viscous sols, was followed by means of a travelling microscope.

In Table II are given the results obtained at 25° with *cyclohexanone*, b. p. 155.5°, d_4^{25} 0.9423, and *acetone*, b. p. 56.5°, d_4^{25} 0.7847 (dehydrated with calcium oxide and fractionally distilled through a Young and Thomas six-unit still-head) as solvents.

Discussion.

There does not appear to be any simple relation between the viscosity and the concentration of the solutions examined. The relations between the logarithm of the viscosity and the concentration, and between $\log \eta/\eta_0$, where η is the viscosity of the sol and η_0 that of the dispersion medium, and the logarithm of the concentration, are represented by smooth curves, and the

curvilinear character will remain if the concentrations be expressed as percentage by volume or by weight of the total system. Similarly there does not appear to be any simple relation between fluidity and concentration. The various empirical and rational formulae connecting viscosity and concentration established with a certain measure of success in the case of various hydrosols over a limited range of concentration, are not applicable to the results obtained with cellulose acetate.

The empirical formula proposed by Baker (*loc. cit.*) for cellulose nitrate solutions, namely, $\eta/\eta_0 = (1 + ac)^2$, although applicable to cellulose acetate solutions of concentrations below 10 per cent. (compare Visser, "Aeronautical Research Committee Reports and Memoranda," No. 758, 1920), fails over wider ranges.

The possibility of establishing a generally valid formula connecting the viscosity and the concentration of colloidal solutions seems remote, since there are so many contributing factors. The relative specific characters of the colloid, and medium, have a profound influence on the viscosity values. The degree of dispersion and accordingly the degree of solvation of the dispersed particle are complex functions of the concentration, whilst the influence of the degree of dispersion on viscosity is not well known. Further, most naturally-occurring colloids are heterogeneous and the size of the dispersed particle is not uniform.

An examination of the viscosity-temperature data indicates that, in general, the temperature coefficient increases rapidly with fall in temperature or rise in concentration, to an extent depending on the specific character of the ester. In some cases there is a bend in the viscosity-temperature curve, such as in the case of hydrosols of gelatin (compare Davies and Oakes, *J. Amer. Chem. Soc.*, 1922, 44, 46).

There is a definite upper limit to the ratio of solute to solvent in ordinary solutions, namely, the saturation concentration, but colloidal solutions, other than the suspensoids, are generally regarded as mixtures of mutually soluble components, or complex concentration-variable systems (Wo. Ostwald, "Grundriss der Kolloidchemie," 1919, pp. 39, 168), thus, gelatin or silicic acid with water, and cellulose acetate with benzyl alcohol, will, with proper regulation of temperature, take up progressively greater or smaller amounts of dispersion medium without separating out in a coarsely disperse form.

On the other hand, the fact that many of the sols gelate at high concentration or at low temperatures indicates that the limit of stability of the sol, corresponding to a saturation concentration,

the cellulose acetate was precipitated from solution as an opalescent mass instead of the jelly formation having occurred.

Thus we may regard a sol which is stable with no signs of gelation as being below the saturation limit. By cooling the cyclohexanone sols to -10° , and the benzyl alcohol sols to about 15° , with stirring, the cellulose acetate was precipitated from solution, whilst with the higher-concentration sols gelation occurred. There was also evidence of incipient gelation, after several months, with the triacetin sol of concentration 20/100.

The fluid character of the acetone sols at 25° persisted until the concentration reached at least 36.5/100, but by allowing the sol to concentrate by spontaneous evaporation there was eventually a transition to the gel state.

If it be admitted that gelation is a consequence of the saturation concentration having been exceeded (compare von Weimarn, "Grundzüge der Dispersoid Chemie," Dresden, 1911), then the curve connecting gelation temperature or "setting" point with concentration is analogous to the solubility curve of a crystalloid.

For permission to include results obtained during researches at the Royal Aircraft Establishment, acknowledgment is made to the Director of Research, Air Ministry.

CCXV.—Mercaptans of the Purine Group. Part I.

By SIR PRAFULLA CHANDRA RÂY, GOPÂL CHANDRA CHAKRAVARTI,
and PRAFULLA KUMÂR BOSE.

THE action of potassium hydrosulphide on 2:6-dichloro-8-hydroxypurine has been investigated with a view to the synthesis, and study of the corresponding possible mercaptans. It was, however, found that potassium hydrosulphide in boiling alcoholic solution did not react with the dichloropurine in the way expected, the hydrosulphide being simply decomposed with the separation of the potassium salt of the oxypurine, whilst in aqueous solution at 100° the interaction led to a mixture of various products from which the mercaptan could not be isolated in a pure condition. At a higher temperature, however, and under pressure, both the chlorine atoms were replaced by thiol groups and 2:6-dithiol-8-hydroxypurine (I) was obtained.

The action of potassium hydrosulphide on several chloropurines has been studied by Fischer and his co-workers (*Ber.*, 1899, 31, 431), who have shown that in the cases of trichloropurine and 2:6-dichloro-7-methylpurine, the reaction proceeds very smoothly even in the cold. The difficulty observed in our case in replacing the chlorine atoms by thiol groups was supposed to be due to the presence of the acidic hydroxyl group in position 8. Accordingly, 2:6-dichloro-8-hydroxypurine was methylated to 2:6-dichloro-8-oxy-7:9-dimethylpurine (Fischer, *Ber.*, 1898, 30, 2208), whereby the substance completely lost its acidic nature. On treatment with hot alcoholic potassium hydrosulphide, one of the chlorine atoms of the dimethyl derivative was replaced by a thiol group, thus showing that the chlorine atom is rendered more labile by the suppression of the acid character of the oxypurine. The thiolpurine has probably the constitution (II), as Fischer (*Ber.*, 1898, 30, 2226; 1899, 31, 104, 431, etc.) has shown that the chlorine atom in position 6 is more reactive than that at 2. The extreme reactivity of substituents in position 6 is further corroborated by the fact that the methyl ether of the above-mentioned thiolpurine, when boiled with potassium hydrosulphide in alcohol, is hydrolysed to the parent mercaptan instead of yielding the 2-thiol derivative as expected.

2:6-Dithiol-8-oxy-7:9-dimethylpurine (III) has been obtained from both 2:6-dichloro-8-oxy-7:9-dimethylpurine and 2-chloro-6-thiol-8-oxy-7:9-dimethylpurine by heating with aqueous potassium hydrosulphide under pressure at 130°. These mercaptans possess a strongly acid character and form beautifully crystalline potassium and sodium salts. The hydrogen atoms of the thiol groups are readily replaced by alkyl groups, producing alkyl ethers. 2-Chloro-6-thiol-8-oxy-7:9-dimethylpurine gives with mercuric chloride a chloromercaptide which crystallises with four molecules of ethyl alcohol; the chloromercaptide also combines with one molecule of mercuric chloride, as might well have been expected from the basic property due to the presence of several tertiary nitrogen atoms. 2-Chloro-6-thiol-8-oxy-7:9-dimethylpurine reacts with phenylhydrazine, the chlorine atom being replaced by the phenylhydrazino-group.

It is known that tautomerism of the type $\text{C}(\text{OH})\text{N} \rightleftharpoons \text{CO}\text{NH}$ is exhibited by many hydroxypurines, but a similar tautomeric

behaviour in the case of thiolpurines has not been noticed by any investigator. The dithiolpurines described above were expected to give the corresponding dipotassium salts, but they actually yield the monopotassium ones. It seems, therefore, very likely that one of the thiol groups is in the keto-form, the other being reactive as usual. Thus,

The fact that titration with iodine indicates the presence of two thiol groups in the molecule might militate against the existence of the thiolpurines in the ketonic form, but instances of the enolising action of halogens are not rare (compare Dawson and Powis, T., 1909, 95, 1860; 1910, 97, 2048; 1912, 101, 1503; Lapworth, T., 1904, 85, 30, etc.). It is thus evident that keto-enol tautomerism of the type indicated above may occur in the thiolpurines, differing from that of the corresponding hydroxypurines in degree, but not in kind.

EXPERIMENTAL.

2 : 6 - *Dithiol* - 8 - *hydroxypurine* (I).—2 : 6 - Dichloro - 8 - hydroxypurine (1 mol.), dissolved in a minimum of a dilute solution of caustic potash, was treated with a 10 per cent. aqueous solution of caustic potash (6—7 mols.) which had been saturated with hydrogen sulphide in the cold, and the mixture was heated at 140—150° for three hours. The precipitate obtained on acidifying the cold, filtered solution was washed with water and dissolved in the least quantity of a hot saturated solution of sodium carbonate. The solution, decolorised by animal charcoal, was filtered hot and, on cooling, the sodium salt crystallised in fine, colourless needles (Found : Na = 9.77. $\text{C}_5\text{H}_3\text{ON}_4\text{S}_2\text{Na}$ requires Na = 10.36 per cent.).

On acidifying an aqueous solution of the sodium salt, the free mercaptan was precipitated in very small, yellow nodules [Found : S = 31.19; N = 27.78; SH (by titration with iodine) = 32.30. $\text{C}_5\text{H}_4\text{ON}_4\text{S}_2$ requires S = 32.00; N = 28.00; SH = 33.00 per cent.].

The mother-liquor from the above sodium salt, on being treated with dilute hydrochloric acid, gave a small quantity of a precipitate, which was filtered off. The filtrate, when acidified with concentrated hydrochloric acid, deposited a substance in not very well-defined crystals (needle-shaped), insoluble in ordinary solvents but slightly soluble in boiling water, from which it separated as a flocculent precipitate. It was dissolved in sodium carbonate solution and reprecipitated by adding a large excess of concentrated

hydrochloric acid, a crystalline product being obtained (Found : N = 26.62; Cl = 19.70, 17.79; S = 29.99, 31.14 per cent.). The percentage of nitrogen shows that the ring evidently remains intact, but the high percentage of chlorine indicates that the substance is a mixture of 2:6-dithiol-8-hydroxypurine and 2-chloro-6-thiol-8-hydroxypurine.

The *dimethyl* ether of 2:6-dithiol-8-hydroxypurine was prepared by heating under reflux on the water-bath an aqueous solution of the sodium salt with an excess of methyl iodide. The precipitated ether was collected and washed with water. It separates from acetone in minute crystals melting with decomposition at 285–288° (Found : N = 25.08. $C_7H_8ON_4S_2$ requires N = 24.56 per cent.).

2-Chloro-6-thiol-8-oxy-7:9-dimethylpurine (II).—To 5 grams of potassium hydroxide in 100 c.c. of alcohol saturated with hydrogen sulphide in the cold were added 10 grams of finely divided 2:6-dichloro-8-oxy-7:9-dimethylpurine suspended in about 100 c.c. of alcohol. The mixture was boiled under reflux for nearly fifteen minutes, when a white, crystalline precipitate consisting of a mixture of potassium chloride and the potassium salt of the mercaptan separated out. The precipitate was removed and dissolved in water and the filtered solution treated with dilute hydrochloric acid in excess. The precipitated mercaptan was washed with hot water, dried, and then twice heated under reflux with carbon disulphide to dissolve any adhering traces of sulphur. It was finally purified by crystallisation from glacial acetic acid, in which it was only slightly soluble. It was also very sparingly soluble in ethyl or amyl alcohol, from which it separated in brownish-yellow, rhombic crystals (Found : S = 13.85; Cl = 16.36; N = 24.25. $C_7H_7ON_4ClS$ requires S = 13.88; Cl = 15.40; N = 24.29 per cent.). It is a strong monobasic acid and readily dissolves in dilute aqueous solutions of alkalis, alkali carbonates, and bicarbonates. It is odourless, bitter to the taste, and does not give the murexide reaction. When heated, it decomposes without melting. The *potassium* salt was obtained in colourless needles by cooling a hot filtered solution of the mercaptan in dilute alcoholic potash (Found : K = 14.53. $C_7H_8ON_4ClSK$ requires K = 14.53 per cent.). The *ammonium* salt, prepared by dissolving the mercaptan in boiling alcoholic ammonia and diluting the filtered solution with ether, formed fine, silky crystals.

Interaction of 2-Chloro-6-thiol-8-oxy-7:9-dimethylpurine and Mercuric Chloride.—To the hot filtered solution of the mercaptan in amyl alcohol was added, with constant stirring, an excess of an alcoholic solution of mercuric chloride. The white, curdy precipitate

was removed when cool, and extracted with hot amyl alcohol, the chloromercaptide remaining as a white residue (A); the other product of the reaction (*vide supra*) crystallised from the hot filtrate in colourless needles (B). This was recrystallised from amyl alcohol, washed with absolute alcohol, and dried in a vacuum desiccator. The above experiment was repeated using an ethyl-alcoholic solution of the mercaptan. The precipitate (C) was collected, washed with absolute alcohol, and dried [Found: (A) C = 25.70; * H = 3.06; Hg = 30.40; Cl = 10.47. (C) Hg = 30.83. $C_7H_6ON_4Cl_2SHg_2 \cdot 4C_2H_5 \cdot OH$ requires C = 27.73; H = 4.62; Hg = 30.80; Cl = 10.90 per cent. Found: (B) Hg = 53.00. $C_7H_6ON_4Cl_2SHg_2$ requires Hg = 54.34 per cent.]. It is thus evident that compounds (A) and (C) are identical and are pure chloromercaptides. The compound (B) is not formed when ethyl alcohol is used instead of amyl alcohol.

Disulphide.—2-Chloro-6-thiol-8-oxy-7:9-dimethylpurine was dissolved in aqueous potash and treated with a solution of iodine in potassium iodide until the brown colour of iodine persisted. The precipitate was collected and dried. The *disulphide* was obtained from hot toluene as colourless needles melting at 259° (Found: S = 13.77; Cl = 15.92. $C_{14}H_{12}O_2N_8Cl_2S_2$ requires S = 13.96; Cl = 15.46 per cent.).

Methyl Ether of 2-Chloro-6-thiol-8-oxy-7:9-dimethylpurine.—An aqueous solution of the potassium salt of the mercaptan was heated under reflux on the water-bath with excess of methyl iodide for fifteen to twenty minutes. The *methylthiol*, which separated in needles, was crystallised from absolute alcohol, in which it is very soluble, and melted at 179° (Found: N = 23.49. $C_8H_9ON_4ClS$ requires N = 22.90 per cent.).

The corresponding *ethyl ether* crystallises from 60 per cent. methyl alcohol in colourless needles melting at 133°. The *n-propyl ether* is soluble in hot absolute alcohol and melts at 120° (Found: S = 12.09. $C_{10}H_{13}ON_4ClS$ requires S = 11.74 per cent.).

Interaction of 2-Chloro-6-thiol-8-oxy-7:9-dimethylpurine and Phenylhydrazine.—A solution of about 2 grams of phenylhydrazine hydrochloride and an equal quantity of sodium acetate in about 25 c.c. of water was heated on the water-bath with about 0.3 gram of the finely divided mercaptan for seven to eight hours with frequent stirring. The condensation product, which separated in needles, was washed successively with hot water, alcohol, and chloroform, and dried in a steam-oven. It was found to be insoluble in all

* The percentages of carbon and hydrogen come out slightly low owing to traces of alcohol escaping oxidation, as it is often found to be the case when compounds containing alcohol of crystallisation are analysed.

the ordinary organic solvents (Found: N = 28.16. $C_{13}H_{14}ON_4S$ requires N = 29.37 per cent.).

2:6-Dithiol-8-oxy-7:9-dimethylpurine (III).—About 50 c.c. of an aqueous solution of potassium hydroxide (2*N* approx.) were saturated with hydrogen sulphide in the cold, 1 gram of 2:6-dichloro-8-oxy-7:9-dimethylpurine was added, and the mixture heated in a bomb furnace at 130–140° for three hours. The reaction product, a liquid, was filtered from any impurities and acidified with dilute hydrochloric acid, when a yellow precipitate was obtained. It was crystallised from glacial acetic acid (Found: S = 27.98. $C_7H_8ON_4S_2$ requires S = 28.07 per cent.). The purine is a yellow, crystalline substance, melting with decomposition above 300°. It is a stronger acid than the monothiolpurine described above, but resembles it in not giving the murexide reaction. This dithiolpurine has also been obtained from 2-chloro-6-thiol-8-oxy-7:9-dimethylpurine in exactly the same way.

The potassium salt is best prepared by adding a cold, concentrated aqueous solution of potassium hydrosulphide to the finely divided mercaptan with vigorous shaking. The silky needles of the potassium salt are washed with absolute alcohol and dried in a vacuum desiccator. It reacts quantitatively with iodine (Found: K = 14.76; SH = 24.39. $C_7H_7ON_4S_2K$ requires K = 14.66; SH = 24.81 per cent.).

The dimethyl ether crystallises from carbon disulphide in colourless prisms melting at 172–173° (Found: N = 21.28. $C_9H_{12}ON_4S_2$ requires N = 21.87 per cent.). The diethyl ether separates from dilute alcohol in colourless needles melting at 104° (Found: N = 19.99. $C_{11}H_{16}ON_4S_2$ requires N = 19.72 per cent.). The dibenzyl ether crystallises from a mixture of benzene and ether in rhombic prisms melting at 158° (Found: N = 14.06. $C_{21}H_{26}ON_4S_2$ requires N = 13.72 per cent.). These ethers were prepared in the same way as the other purine ethers described above.

UNIVERSITY COLLEGE OF SCIENCE, CALCUTTA. [Received, April 16th, 1923.]

CCXVI.—The Isomeric 1-Menthyl Phenylchloroacetates.

By ALEX. MCKENZIE and ISOBEL AGNES SMITH.

THE contrast between phosphorus pentachloride and thionyl chloride in their behaviour towards esters of optically active hydroxy-acids was first observed with ethyl *l*-atrolactinate:

(McKenzie and Clough, T., 1910, 97, 2564). Again, when the hydroxy-group in ethyl *l*-mandelate was displaced by chlorine, a change of sign of rotation occurred when phosphorus pentachloride was employed as the chlorinating agent, a dextro-ethyl phenylchloroacetate being formed :

(Walden, *Ber.*, 1895, 28, 1287). When thionyl chloride was used in place of phosphorus pentachloride, the resulting chloro-ester was laevo :

(McKenzie and Barrow, T., 1911, 99, 1910).

The action of phosphorus pentachloride on ethyl *l*-mandelate was attended by considerable racemisation, the chloro-ester having $[\alpha]_D + 25.19^\circ$, whereas the ester resulting from the action of thionyl chloride possessed a rotatory power which was much higher, namely $[\alpha]_D - 64^\circ$.

One of the problems of the present investigation was to find if any difference would be exhibited by the two chlorinating agents when applied to *l*-menthyl *l*-mandelate (T., 1904, 85, 1249). Would the action of phosphorus pentachloride lead to a mixture of *l*-menthyl *d*-phenylchloroacetate and *l*-menthyl *l*-phenylchloroacetate with a preponderance of the former, and would the action of thionyl chloride give *l*-menthyl *l*-phenylchloroacetate exclusively? Also, with *l*-menthyl *d*-mandelate, would the actions proceed in this manner :

Those questions provided us with an intricate topic in the study of displacement racemisation, more especially as the substitution of chlorine for the hydroxy-groups is effected under an asymmetric environment, namely, that of the *l*-menthyl group.

The preparation of the isomeric chloro-esters in a state of optical purity was accordingly essential, and this was accomplished by resolving *l*-menthyl *d*-phenylchloroacetate by crystallisation from rectified spirit, a method which we were led to adopt in the light of the success of Wren and his co-workers in the resolutions of *r*-tartaric, *r*-atrolactic, and *r*- α -hydroxy- β -phenylpropionic acids by *l*-menthol or *l*-borneol (T., 1920, 117, 191; 1921, 119, 798). The temperature at which the crystallisation is effected apparently

has an influence: low temperatures seem to favour the separation of the partly racemic ester. Under suitable conditions of temperature, *l*-menthyl *d*-phenylchloroacetate was obtained, this ester melting at 56–57° and having $[\alpha]_D + 5.6^\circ$ ($c = 4.1732$) in ethyl-alcoholic solution. *l*-Menthyl *l*-phenylchloroacetate was also isolated; it melts at 44.5–45.5°, and has $[\alpha]_D - 149.8^\circ$ ($c = 3.9912$) in ethyl-alcoholic solution. Those esters may also be prepared from the corresponding *d*- and *l*-chloro-acids which were obtained by resolving *r*-phenylchloroacetic acid by morphine (McKenzie and Clough, *T.*, 1908, 93, 811; 1909, 95, 777). *l*-Menthyl *dl*-phenylchloroacetate thus behaved differently from the closely-related *l*-menthyl *r*-mandelate, which one of us failed to resolve by repeated crystallisation* (*T.*, 1904, 85, 378), and is a partly racemic compound and non-resolvable at any temperature above –15° (compare Findlay and Hickmans, *T.*, 1907, 91, 905; 1909, 95, 1386).

In view of an interesting paper (Shimomura and Cohen, *T.*, 1921, 119, 1816) which will be discussed later, the hydrolysis of the *l*-menthyl esters of the phenylchloroacetic acids has also been investigated. Previous work (compare, *inter alia*, *T.*, 1904, 85, 378, 1249; 1905, 87, 1004; 1907, 91, 789, 1814; 1909, 95, 1105; 1915, 107, 702; 1919, 115, 602; 1920, 117, 680) enabled the prediction to be made with confidence that racemisation would be detected when the esters of the active chloro-acids are hydrolysed by alcoholic alkali, no matter how great is the care exercised or how mild the experimental conditions are. The esters in question have the phenyl group in direct attachment to the asymmetric carbon atom, and they also have a migrational hydrogen atom in the α -position relatively to the $-\text{CO}_2\cdot\text{C}_{10}\text{H}_{19}$ group, those being precisely the factors which, as is now known, render it inevitable that racemisation will occur on hydrolysis of the esters with alcoholic alkali. The racemisation observed on hydrolysing *l*-menthyl *l*-phenylchloroacetate with a slight excess of alcoholic alkali at the ordinary temperature was profound: the resulting acid gave the feeble levorotation of $[\alpha]_D - 1.6^\circ$ in ethyl-alcoholic solution, whereas *l*-phenylchloroacetic acid has the high rotatory power of $[\alpha]_D - 155.8^\circ$ in the same solvent. This slight activity of $[\alpha]_D - 1.6^\circ$ is to be ascribed to the presence only of a trace of the

* Shimomura and Cohen (*T.*, 1921, 119, 1816) in their reference to those attempts state that partial resolution was not effected because the mandelic acid recovered by hydrolysis was quite inactive. The behaviour of the recrystallised ester on hydrolysis is, however, no criterion of its homogeneity, since unequal amounts of the diastereoisomeric *l*-menthyl mandelates can give *r*-mandelic acid on hydrolysis (*T.*, 1904, 85, 1249).

l-chloro-acid, the main product consisting of the *r*-chloro-acid. But it should be noticed that the product did not consist of those phenylchloroacetic acids alone, as a small quantity of mandelic acid was unavoidably present owing to the action of water on the chloro-acid in the course of the manipulation. Since the displacement racemisation attending the conversion of *l*-phenylchloroacetic acid into *l*-mandelic acid is very pronounced (McKenzie and Clough, *loc. cit.*), it is highly improbable that the slight optical activity noted is to be attributed to *l*-mandelic acid.

The nearest parallel to the above example of profound racemisation by alcoholic alkali is afforded by the hydrolysis of *l*-bornyl *d*-phenyl-*p*-tolylacetate at the ordinary temperature (McKenzie and Widdows, *T.*, 1915, 107, 702).

The hydrolysis of *l*-menthyl *d*-phenylchloroacetate under experimental conditions identical with those adopted in the case of its isomeride led to a result which is novel. That a feebly active acid would result was not unexpected, but we anticipated that its rotation would be dextro-, and not lævo- as we found it to be. In one experiment, for example, the small value of $[\alpha]_D - 1.3^\circ$ in ethyl-alcoholic solution was observed, and in another experiment the acid had $[\alpha]_D - 3.3^\circ$ in benzene. As this slight optical activity is not to be attributed to a trace of menthol, the following interpretation is submitted. An examination of the fractional esterification of *r*-phenylchloroacetic acid by *l*-menthol at 150° according to the method of Marckwald and McKenzie showed that the unesterified acid was dextrorotatory. The velocity of formation of *l*-menthyl *d*-phenylchloroacetate (I) is accordingly less than that of *l*-menthyl *l*-phenylchloroacetate (II).

Since of two isomeric esters the one which is formed the more quickly will also be hydrolysed the more quickly, the deduction is legitimate that II will undergo hydrolysis faster than I. Starting with I in the presence of an excess of alcoholic potassium hydroxide at the ordinary temperature, catalytic racemisation comes speedily into play by interchange of groups round the asymmetric carbon atom C*, and I passes into a mixture of I and II. As the hydrolysis progresses, II is hydrolysed more quickly than I, giving a preponderance of potassium *l*-salt; the excess of I again passes into a mixture of I and II, and therefore the potassium *l*-salt preponderates when the hydrolysis is ended.

If this interpretation is valid, it ought to be possible to obtain

a slight preponderance of potassium salt when a mixture of equal quantities of I and II is hydrolysed by an excess of alcoholic alkali. This expectation was experimentally realised. *l*-Menthyl *dl*-phenylchloroacetate was synthesised by mixing equal quantities of the pure diastereoisomerides. It melts at 28–29°, and has $[\alpha]_D -72.2^\circ$ ($c = 3.9216$) in ethyl-alcoholic solution. On hydrolysing this synthetic ester with an excess of alcoholic alkali, the resulting acid had a slight levorotation.

Thus each of the three isomeric *l*-menthyl phenylchloroacetates gives on hydrolysis a levorotatory acid after the complete removal of the menthol in each case.

The action of thionyl chloride on the isomeric *l*-menthyl mandelates was also studied. Designating *l*-menthyl *d*-phenylchloroacetate as I, and *l*-menthyl *l*-phenylchloroacetate as II, the results were the following :

Displacement racemisation had therefore occurred at the mandelic complex, the *l*-menthyl group remaining intact throughout. The action of thionyl chloride does not, therefore, lead to the formation of a homogeneous *l*-menthyl phenylchloroacetate. The extent of the racemisation was nearly identical in each of the above cases, but not quite. The product from the complete action of thionyl chloride on *l*-menthyl *r*-mandelate should, therefore, contain a very slight preponderance of II. The experimental result accords, thus :

The action of phosphorus pentachloride on the *l*-menthyl mandelates takes a different course :

* As an alternative, the ester mixture from the action of thionyl chloride on *l*-menthyl *d*-mandelate may consist of a mixture of the partially racemic ester and I. Throughout this paper, the constitution of the ester mixtures is, however, expressed in percentage amounts of the diastereoisomerides, the question still remaining an open one as to whether the partly racemic ester is stable at the ordinary temperature.

Thus the mixture of chloro-esters here contains a preponderance of the *lævo*-ester, whereas with thionyl chloride it is the dextro-ester which is in excess. Similarly with *l*-menthyl *l*-mandelate,

the dextro chloro-ester is in excess, whereas thionyl chloride leads to an excess of the *lævo*-ester. With phosphorus pentachloride, the extent of the displacement racemisation is also slightly different, and from the above figures the deduction was drawn that the complete action of phosphorus pentachloride on *l*-menthyl *r*-mandelate should lead to the formation of a mixture of chloro-esters with a slight preponderance of II. The experimental result accords, thus :

The displacement reactions studied in the above examples may be considered from three points of view. In the action of thionyl chloride, for example, on *l*-menthyl *d*-mandelate, it might be suggested (1) that *l*-menthyl *d*-phenylchloroacetate is first formed, and then undergoes partial inversion by the subsequent action of thionyl chloride. This is, however, untenable (see experimental part); (2) that catalytic racemisation of the *d*-mandelate might take place prior to chlorination; (3) that displacement racemisation might occur during the actual displacement.

The above results with thionyl chloride and phosphorus pentachloride also present us with a type of Walden inversion, but it is impossible at present to state which of the two chlorinating agents causes the configurative change. It is very striking that although the two chlorinating agents are thus quite different in their behaviour towards the diastereoisomeric *l*-menthyl mandelates, the final result of each action on the partly racemic mandelate is similar in this respect that the product consists in each case of a mixture of I and II with a slight preponderance of II.

In the paper by Shimomura and Cohen entitled "A New Method for the Resolution of Asymmetric Compounds" (T., 1921, 119, 1816), the argument on which their method is based is the following. An inactive mixture *C*(*abcd*) is combined with an active group, and then one of the groups (for example, *d*) is displaced by *e* under asymmetric conditions, giving *C*(*abce*); if the active group is then removed, then *C*(*abce*) should be optically active. Of the various actions investigated to test the validity of this principle, three were regarded as providing positive results. *d**L*-Phenyl-

chloroacetyl-L-tyrosine was acted on by ammonia, the amino compound was treated with nitrous acid, and the L-tyrosine was then removed. The mandelic acid isolated had $[\alpha]_D^{25} + 11.5^\circ$ ($c = 0.13$, $l = 2$). For one reason alone, this result cannot be accepted as convincing, as the concentration employed is so small that the observed angle of rotation when calculated from the above data provided by the authors, is only $\alpha_D + 0.03^\circ$ in a 2-dm. tube. In the other two actions, active phenylchloroacetic acid was obtained by the action of thionyl chloride and phosphorus pentachloride respectively on L-menthyl *r*-mandelate, the product in the first case giving $[\alpha]_D^{25} - 10^\circ$, and in the second $[\alpha]_D^{25} - 8.1^\circ$. In accordance with the above principle, it is assumed that a mixture of unequal amounts of I and II is produced, and II is assumed to be in excess because the acid from the hydrolysis is levorotatory.

It may at once be stated that the present authors have been forced to the conclusion that the principle of Shimomura and Cohen is erroneous. Take the case of a partly racemic L-menthyl ester of an inactive acid, $R\cdot CH(OH)\cdot CO_2H$. When such an ester is submitted to chemical action, it will behave as if it consisted of

in equal quantities. When acted on by an excess of thionyl chloride, and on the assumptions that the action of the thionyl chloride is carried to a completion and that no displacement racemisation occurs, III will be entirely converted into the chloro-ester (V), and IV will be entirely converted into the chloro-ester (VI):

Although V and VI will be formed at different rates, at the end of the action they will be formed in *equal* quantities (on the above assumptions).

The principle adduced by Shimomura and Cohen implies that *unequal* quantities of V and VI would be produced when the action of thionyl chloride is carried to a completion.

Now the proof is given in the present paper that by the action either of thionyl chloride or of phosphorus pentachloride on L-menthyl *r*-mandelate, a mixture of *unequal* quantities of I and II is actually formed with a slight preponderance of II. This is not, however, a confirmation of the validity of the reasoning of Shimo-

mura and Cohen, as the result is due to displacement racemisation. *l*-Menthyl *r*-mandelate, from the experience of one of us, behaves in its chemical reactions as if it were a mixture of VII and VIII in equal quantities :

When the action of thionyl chloride on this partly racemic ester is carried to a completion, VII gives I and II (with an excess of I), whilst VIII gives I and II (with an excess of II). The displacement racemisation is slightly greater with VII than with VIII, and the product of the action of thionyl chloride on *l*-menthyl *r*-mandelate is accordingly a mixture of I and II (with a slight excess of II).

When the action of phosphorus pentachloride on *l*-menthyl *r*-mandelate is carried to a completion, VII gives a mixture with 69 per cent. of II, and VIII gives a mixture with 65 per cent. of I. The product of the action of phosphorus pentachloride on *l*-menthyl *r*-mandelate is accordingly a mixture of I and II (with a slight excess of II).

Even if the principle of Shimomura and Cohen were admitted to be correct, their experimental evidence gives, in our opinion, no support to it. A mixture of I and II in *unequal* quantities gives a slightly *lævorotatory* acid as a result of hydrolysis by alcoholic alkali irrespective of which of the esters is in excess in the mixture, and the same result is also obtained when the quantities of I and II are *equal*.

We are unable, therefore, to agree with Shimomura and Cohen when they claim that their method is new, since their experimental results can be interpreted by methods which are already known, and which have been elaborated by one of us and his co-workers. Shimomura and Cohen have omitted from their discussion the consideration of two very important aspects : (1) the displacement racemisation which occurs both when the hydroxy-esters are converted into the chloro-esters, and when the phenylchloroacetic acid is isolated from the products of the hydrolysis, and (2) the catalytic racemisation which occurs by the action of alcoholic alkali on the chloro-esters. In any explanation offered with reference to the action of thionyl chloride and of phosphorus pentachloride on *l*-menthyl *r*-mandelate, those factors are vital, and cannot be disregarded.

EXPERIMENTAL.

Resolution of 1-Menthyl di-Phenylchloroacetate into its Diastereoisomerides.

A current of dry hydrogen chloride was passed for fifteen minutes into a molten mixture of *r*-phenylchloroacetic acid (10 grams) and *l*-menthol (30 grams), and heating on a water-bath was continued for four hours. After further treatment of the mixture with hydrogen chloride and subsequent heating for one and a half hours, the ethereal solution of the oil was washed first with water, and then with a dilute solution of sodium hydrogen carbonate. The ether and menthol were removed, the latter by distillation with steam, and the residual oil solidified after twenty-four hours in the ice-chest. Yield 17.3 grams; m. p. 24–29°. After crystallisation from rectified spirit at –5°, the crystals (11.7 grams) melted over a larger range, namely 28.5–51.5°, and gave $[\alpha]_D - 63.5^\circ$ for $c = 4.3808$ in ethyl-alcoholic solution. The resolution proceeded slowly when the crystallisation was conducted at temperatures below 0°, since a further crystallisation at –7° gave a product (10.4 grams) which was only slightly less optically active than before, the value being $[\alpha]_D - 60.9^\circ$ for $c = 4.2184$ in ethyl-alcoholic solution. The next crystallisation from rectified spirit took place at the ordinary temperature, and the resulting crystals (3.8 grams) were now slightly dextro-, giving $[\alpha]_D + 1.5^\circ$ for $c = 4.3264$ in ethyl-alcoholic solution, whilst the crystals (1.3 grams) which separated from the filtrate were strongly laevo-, giving $[\alpha]_D - 141.1^\circ$ for $c = 4.0736$ in ethyl-alcoholic solution. The dextro-product with $[\alpha]_D + 1.5^\circ$ gave the pure ester of the *d*-acid after one further crystallisation; yield = 3 grams.

1-Menthyl d-phenylchloroacetate, $C_6H_5 \cdot CHCl \cdot CO_2 \cdot C_{10}H_{18}$, separates from aqueous ethyl alcohol in fine needles, and melts at 56–57° (Found: Cl = 11.5. $C_{18}H_{25}O_2Cl$ requires Cl = 11.5 per cent.). In ethyl alcohol: $l = 2$, $c = 4.1732$, $\alpha_D^{18.5} + 0.47^\circ$, $[\alpha]_D^{18.5} + 5.6^\circ$; $\alpha_D^{13.5} + 0.66^\circ$, $[\alpha]_D^{13.5} + 7.9^\circ$.* This ester was also prepared directly from *d*-phenylchloroacetic acid, which was obtained by resolving the *r*-acid with morphine in ethyl-alcoholic solution (McKenzie and Clough, T., 1909, 95, 777). The acid was esterified by *l*-menthol by means of hydrogen chloride, and the resulting ester after crystallisation from rectified spirit was found to be identical with the above; m. p. 56–57° (Found: Cl = 11.6; calc., 11.5 per

* The determinations of optical rotatory power of solid substances made in this and in all other cases recorded in the present paper were conducted with products which were dried over sulphuric acid at the ordinary temperature and under diminished pressure until the weight was constant.

cent.). In ethyl alcohol: $l = 2$, $c = 4.3672$, $\alpha_D^{15} + 0.50^\circ$, $[\alpha]_D^{15} + 5.7^\circ$; $\alpha_{361}^{15} + 0.70^\circ$, $[\alpha]_{361}^{15} + 8.0^\circ$. By fractional crystallisation of the products from the preceding resolution, the diastereoisomeride was also isolated.

l-Menthyl *l*-phenylchloroacetate, $C_6H_5 \cdot CHCl \cdot CO_2 \cdot C_{10}H_{19}$, separates from aqueous ethyl alcohol in fine needles, and melts at $44.5\text{--}45.5^\circ$ (Found: Cl = 11.7. $C_{18}H_{25}O_2Cl$ requires Cl = 11.5 per cent.). In ethyl alcohol: $l = 2$, $c = 3.9912$, $\alpha_D^{15} - 11.96^\circ$, $[\alpha]_D^{15} - 149.8^\circ$.

The homogeneity of this ester was controlled by its preparation from *l*-phenylchloroacetic acid, which was obtained by resolving the *r*-acid with morphine in methyl-alcoholic solution (McKenzie and Clough, T., 1908, 93, 811). On esterification with *l*-menthol in the presence of hydrogen chloride, this acid gave an ester which, after crystallisation from rectified spirit, melted at $44.5\text{--}45.5^\circ$. In ethyl alcohol: $l = 2$, $c = 4.0748$, $\alpha_D^{15} - 12.23^\circ$, $[\alpha]_D^{15} - 150.1^\circ$; $\alpha_{361}^{15} - 14.65^\circ$, $[\alpha]_{361}^{15} - 179.8^\circ$.

Synthesis of l-Menthyl *dl*-Phenylchloroacetate from its Diastereoisomerides.

A mixture of equal weights of *l*-menthyl *d*-phenylchloroacetate and *l*-menthyl *l*-phenylchloroacetate was dissolved in anhydrous ether, and the solvent was then allowed to evaporate spontaneously. The resulting solid, which melted at $28\text{--}29^\circ$, gave the following rotations in ethyl-alcoholic solution: $l = 2$, $c = 3.9216$, $\alpha_D^{15} - 5.66^\circ$, $[\alpha]_D^{15} - 72.2^\circ$; $\alpha_{361}^{15} - 6.74^\circ$, $[\alpha]_{361}^{15} - 85.9^\circ$. The values calculated from the rotations of the diastereoisomeric esters are $[\alpha]_D - 72.15^\circ$ and $[\alpha]_{361} - 85.9^\circ$.

The transition temperature at which the partly racemic *l*-menthyl *r*-phenylchloroacetate is transformed into the mixture of equal quantities of the diastereoisomerides has not yet been determined, but from the manner in which the resolution proceeded it would appear that this temperature lies below the ordinary.

Interaction of dl-Phenylchloroacetyl Chloride and *l*-Menthol.

The ester obtained by Shimomura and Cohen (*loc. cit.*) by this action melted at $30\text{--}41^\circ$, and it is suggested by them that a partial resolution of the compound into diastereoisomerides is possible, since by repeated crystallisation from alcohol an ester with $[\alpha]_D^{15} - 92.25^\circ$ in alcoholic solution was obtained, which on hydrolysis gave a slightly laevorotatory phenylchloroacetic acid. As will be seen from the following account, we obtained a different result, the dextrorotatory ester being the more sparingly soluble of the two esters, as we expected from our experience of the resolution already described. The description of Shimomura and Cohen implies that

the *l*-ester is the more sparingly soluble of the two. It is possible that those authors had neglected the first deposit of crystals, but had examined a product from the alcoholic filtrate; this would explain the discrepancy.

Equimolecular quantities of *dl*-phenylchloroacetyl chloride and *l*-menthol were heated at 110° for two and a half hours, and then at 150° for one hour. After the ethereal solution of the oil had been washed with water and then with a dilute solution of sodium carbonate, it was dried, and the ether expelled. The ester was distilled twice under diminished pressure, and gave values for its boiling point and for its rotation in the liquid condition in close agreement with those of Shimomura and Cohen. After remaining at the ordinary temperature for five and a half hours, the oil solidified, and then melted at 28–32°. In ethyl alcohol: $l = 2$, $c = 4.1612$, $\alpha_D^{25} = 5.85^\circ$, $[\alpha]_D^{25} = 70.3^\circ$; $\alpha_{D_{461}}^{25} = 6.91^\circ$, $[\alpha]_{D_{461}}^{25} = 83.0^\circ$. On dissolving this product in rectified spirit, an oil separated on cooling, and this had not crystallised after remaining over-night at the ordinary temperature. It was nucleated with *l*-menthyl *d*-phenylchloroacetate, and it then solidified. After two further crystallisations, the pure *l*-menthyl *d*-ester separated; its melting point was sharp, and it had $[\alpha]_D^{25} + 5.3^\circ$ ($l = 2$, $c = 3.7616$, $\alpha_D^{25} + 0.40^\circ$) in ethyl-alcoholic solution.

Another object in studying the product of the action of *dl*-phenylchloroacetyl chloride on *l*-menthol was to find out if its optical activity varied from that of the synthetic *dl*-ester. For two reasons, it was by no means certain that those esters would be identical. First, if the interaction of the acid chloride and menthol were incomplete, the method of Marckwald and McKenzie (*Ber.*, 1899, 32, 2130, etc.) would come into play, and the product would consist of a mixture of unequal amounts of the diastereoisomerides. Secondly, it was possible that the diastereoisomerides could be partly racemised by the heating of the acid chloride with menthol and by the subsequent distillation under diminished pressure in such a manner that the optical inversion would take place round the asymmetric carbon atom to which the groups, phenyl, hydrogen, and chlorine are attached, whilst no inversion would take place in the menthyl group. Such an instance of partial racemisation has already been recorded by McKenzie and Thompson (*T.*, 1905, 87, 1004), who proved that when *l*-menthyl *d*-mandelate and *l*-menthyl *l*-mandelate were heated at 155°, inversion round the mandelic complex took place to different extents in each case. In the present instance, however, the values $[\alpha]_D^{25} = 70.3^\circ$ and $[\alpha]_{D_{461}}^{25} = 83.0^\circ$ differ only very slightly from those of the synthetic ester, which are $[\alpha]_D^{25} = 72.2^\circ$ and $[\alpha]_{D_{461}}^{25} = 85.9^\circ$. The esterification

by means of the acid chloride and menthol was therefore practically complete. It was also not to be expected from those figures that the diastereoisomerides would alter much in activity on being heated, and experiment bore this out. No partial inversion was observed when the *l*-menthyl *d*-phenylchloroacetate was heated at 150° for four hours, the rotation of the ester after heating being $[\alpha]_D^{25} + 5.8^\circ$ ($l = 2$, $c = 4.0784$, $\alpha_D^{18} + 0.47^\circ$) in ethyl-alcoholic solution. With the *l*-menthyl *l*-ester, a very slight alteration only (to the extent of about 2° in the specific rotation) was observed when the heating was conducted under exactly the same conditions as with the isomeride, the value in alcoholic solution being: $l = 2$, $c = 4.0244$, $\alpha_D^{18} - 11.92^\circ$, $[\alpha]_D^{18} - 148.1^\circ$.

Hydrolysis of l-Menthyl d-Phenylchloroacetate.

Complete Hydrolysis with Excess of Alcoholic Alkali.—Eleven c.c. of ethyl-alcoholic potassium hydroxide (0.6849*N*) were added to a solution of 2 grams of the ester in 20 c.c. of ethyl alcohol, the amount of alkali theoretically required for complete hydrolysis being 9.5 c.c. After remaining at the ordinary temperature for a week, the alcohol was allowed to evaporate under diminished pressure at the ordinary temperature. A very dilute aqueous solution of sodium hydrogen carbonate was added to the residue, and the menthol was removed completely by extraction with ether nine times. The aqueous solution was acidified by dilute sulphuric acid, and the chloro-acid was extracted three times with ether. The ethereal solution was dried with anhydrous magnesium sulphate, and the ether was allowed to evaporate under diminished pressure over sulphuric acid at the ordinary temperature. The resulting acid (0.99 gram) melted at 56–73°, and consisted mainly of *r*-phenylchloroacetic acid, but some mandelic acid was also unavoidably present, so that on analysis the percentage of halogen was found to be low (Found: Cl = 18.1. $C_8H_7O_2Cl$ requires Cl = 20.8 per cent.). This mixture of acids was slightly levorotatory in ethyl-alcoholic solution: $l = 2$, $c = 3.5372$, $\alpha_D^{18} - 0.09^\circ$, $[\alpha]_D^{18} - 1.3^\circ$.

The result was confirmed. Ester, 2 grams; ethyl alcohol, 25 c.c.; standard alcoholic alkali, 11 c.c. (calc. 9.5 c.c.); at ord. temp. for 27 hours; allowed to evaporate as before: acid obtained, 1.02 grams. Rotation in benzene: $l = 2$, $c = 5.598$, $\alpha_D^{18} - 0.34^\circ$, $[\alpha]_D^{18} - 3.0^\circ$; $\alpha_{589}^{18} - 0.37^\circ$, $[\alpha]_{589}^{18} - 3.3^\circ$.

For comparison, the activity of pure *l*-phenylchloroacetic acid was determined in ethyl-alcoholic solution: $l = 2$, $c = 2.002$, $\alpha_D^{18} - 6.24^\circ$, $[\alpha]_D^{18} - 155.8^\circ$. In benzene, the acid has $[\alpha]_D - 191.8^\circ$ (*loc. cit.*).

The *dextrorotatory* ester with $[\alpha]_D + 5.5^\circ$ thus gave on complete hydrolysis a slightly *laevorotatory* acid.

Partial Hydrolysis with Insufficiency of Alcoholic Alkali.—10.5 C.c. of ethyl-alcoholic potassium hydroxide (0.6849*N*) were added to a solution of 4 grams of *l*-menthyl *d*-phenylchloroacetate in 40 c.c. of ethyl alcohol, the amount of alkali required for complete hydrolysis being 18.9 c.c. After remaining at the ordinary temperature for a week, the alcohol was removed as before, and a very dilute aqueous solution of sodium carbonate was added to the product. Extraction with ether was carried out eight times, and the final ethereal extract on polarimetric examination was found to be quite inactive. The acid (0.94 gram) was obtained from the aqueous solution as before. It melted at 59–76°, and was again found to be slightly *laevorotatory*. In ethyl alcohol: $l = 2$, $c = 4.2$, $\alpha_D^{25} - 0.18^\circ$, $[\alpha]_D^{25} - 2.1^\circ$.

The ether was removed from the solution containing the mixture of unhydrolysed ester and menthol, and the residue was distilled for two hours in a current of steam. Under those conditions, practically no ester was left behind in the distilling flask, the unhydrolysed ester being obviously slightly volatile with steam, as it was present along with the menthol in the distillate.

Hydrolysis of l-Menthyl l-Phenylchloroacetate.

Complete Hydrolysis with Excess of Alcoholic Alkali.—The quantities used were the same as those employed in the case of the isomeric acid, and the procedure was identical. Acid recovered = 0.98 gram, m. p. 52–75° (Found: Cl = 18.1. $C_8H_7O_2Cl$ requires Cl = 20.8 per cent.). This mixture of phenylchloroacetic and mandelic acids was slightly *laevorotatory* in ethyl-alcoholic solution: $l = 2$, $c = 3.4536$, $\alpha_D^{25} - 0.11^\circ$, $[\alpha]_D^{25} - 1.6^\circ$.

Partial Hydrolysis with Insufficiency of Alcoholic Alkali.—Conditions as with the isomeric ester. Acid recovered = 0.84 gram, m. p. 55–69°. This acid was slightly *laevo*- in ethyl-alcoholic solution: $l = 2$, $c = 4.255$, $\alpha_D^{25} - 0.18^\circ$, $[\alpha]_D^{25} - 2.1^\circ$.

The *laevorotatory* ester with $[\alpha]_D - 149.8^\circ$ thus resembled its *dextrorotatory* isomeride in giving on hydrolysis an acid with a slight *laevorotation*.

Hydrolysis of l-Menthyl dl-Phenylchloroacetate.

The hydrolysis was carried out with an excess of alcoholic alkali. Two grams of synthetic ester: conditions identical with those described for *l*-menthyl *d*-phenylchloroacetate: menthol completely removed: acid obtained = 1.01 grams. The acid was slightly

laevorotatory in ethyl-alcoholic solution: $l = 2$, $c = 3.7396$, $\alpha_D^{17} = -0.17^\circ$, $[\alpha]_D^{17} = -2.3^\circ$; $\alpha_D^{15} = -0.20^\circ$, $[\alpha]_D^{15} = -2.7^\circ$.

In another experiment with 2 grams of the synthetic ester the conditions were the same as before except that the solution after the addition of the alkali remained at the ordinary temperature for twenty-four hours before the ethyl alcohol was evaporated under diminished pressure. The resulting acid gave the following values in ethyl-alcoholic solution: $l = 2$, $c = 6.04$, $\alpha_D^{17} = -0.27^\circ$, $[\alpha]_D^{17} = -2.2^\circ$; $\alpha_D^{15} = -0.33^\circ$, $[\alpha]_D^{15} = -2.7^\circ$.

*Fractional Esterification of r-Phenylchloroacetic Acid with
l-Menthol.*

The method of Marckwald and McKenzie (*Ber.*, 1899, 32, 2130) was applied, 6 grams of the *r*-acid being used. The unesterified acid (3 grams) was dextrorotatory in ethyl-alcoholic solution: $l = 2$, $c = 4.412$, $\alpha_D^{17} = +0.38^\circ$, $[\alpha]_D^{17} = +4.3^\circ$.

Action of Thionyl Chloride on l-Menthyl r-Mandelate.

Three grams of *l*-menthyl *r*-mandelate (*T.*, 1904, 85, 378) were heated with 20 grams of thionyl chloride under reflux on a water-bath for two and a quarter hours. The excess of thionyl chloride was removed under diminished pressure, and the ethereal solution of the residue after washing with a dilute solution of sodium hydrogen carbonate was dried with anhydrous magnesium sulphate. After removal of the ether by evaporation at the ordinary temperature, the oil solidified on being cooled in a freezing mixture. The product (2.8 grams) melted at $25-34^\circ$, and gave the following values in ethyl-alcoholic solution: $l = 2$, $c = 4.0776$, $\alpha_D^{17} = -6.05^\circ$, $[\alpha]_D^{17} = -74.2^\circ$; $\alpha_D^{15} = -7.20^\circ$, $[\alpha]_D^{15} = -88.3^\circ$.

The whole of this ester mixture, which contains a slight preponderance of the *l*-menthyl *l*-phenylchloroacetate (51 per cent.), was dissolved in 20 c.c. of ethyl alcohol to which were added 15.2 c.c. of ethyl-alcoholic potassium hydroxide (0.6849*N*), the calculated amount of alkali required for complete hydrolysis being 13.2 c.c. After remaining at the ordinary temperature for seven days, the alcohol was allowed to evaporate under diminished pressure at the ordinary temperature. A very dilute solution of sodium carbonate was then added, the precipitated solid (menthol) removed, and the filtrate extracted with ether eight times to ensure the complete removal of the menthol; the eighth ethereal extract was examined polarimetrically, and found to be quite inactive. The aqueous solution was acidified by dilute sulphuric acid, and extracted with ether three times. The ethereal extract was dried, and the ether was removed. The solid acid (1.2 grams) gave the following

value in ethyl-alcoholic solution: $l = 2$, $c = 4.791$, $\alpha_D^{18} = 0.34^\circ$, $[\alpha]_D^{18} = 3.5^\circ$.

The acid obtained under those conditions did not consist of phenylchloroacetic acid only, as some mandelic acid was necessarily formed owing to the ease with which the chlorine was displaced by the hydroxy-group (compare McKenzie and Clough, T., 1908, 93, 811; 1909, 95, 777). The percentage of chlorine is thus low (Found: Cl = 16.1. $C_8H_7O_2Cl$ requires Cl = 20.8 per cent.).

In another experiment in which the chlorination was conducted in a similar manner, 3 grams of the mandelate gave 2.8 grams of chloro-ester, which again contained a slight preponderance of the ester of the *L*-acid, the values obtained under the same conditions as before being $[\alpha]_D = -74.2^\circ$ and $[\alpha]_{565} = -88.2^\circ$ respectively (Found: Cl = 11.4. $C_{10}H_{15}O_2Cl$ requires Cl = 11.5 per cent.). The saponification of this product was carried out by following the procedure of Shimomura and Cohen. To a solution of 2.64 grams of the ester in 20 c.c. of ethyl alcohol, 14.45 c.c. of alcoholic potassium hydroxide (0.6849*N*) were added, the calculated amount being 12.5 c.c. The solution was kept at the ordinary temperature for a week, the alcohol was removed at the ordinary temperature, and a very dilute solution of sodium carbonate was added. The precipitated menthol was removed by filtration. The filtrate, after being extracted with ether several times, was acidified by hydrochloric acid, and then evaporated by heating on the water-bath for one hour. The acid was then extracted with ether and dried. Yield 1.06 grams. In ethyl alcohol: $l = 2$, $c = 4.779$, $\alpha_D^{18} = 0.18^\circ$, $[\alpha]_D^{18} = 1.9^\circ$ (Found Cl = 11.2. $C_8H_7O_2Cl$ requires Cl = 20.8 per cent.). In this case, more mandelic acid was produced than in the first experiment described, where the percentage of chlorine in the acid mixture was 16.1. This result was not unexpected, since the product (after acidification) had been heated in contact with water, the rise of temperature above the ordinary increasing the velocity of the displacement of the halogen by the hydroxy-group. The above value, $[\alpha]_D = 1.9^\circ$, was the highest we obtained when the directions given by Shimomura and Cohen were followed; in three other cases the acid was practically inactive. We were therefore never able to obtain an acid so active as $[\alpha]_D^{18} = 10^\circ$ ($c = 4.65$, $l = 2$) as found by Shimomura and Cohen.

Action of Thionyl Chloride on l-Menthyl d-Mandelate.

1.5 Grams of *l*-menthyl *d*-mandelate (T., 1904, 85, 1249) were heated with 10 grams of thionyl chloride for two hours. 1.43 Grams of a mixture of the chloro-esters were obtained (Found: Cl = 11.3. Calc., 11.5 per cent.). In ethyl alcohol: $l = 2$, $c = 4.1444$,

$\alpha_D^{15.5^\circ} - 3.65^\circ$, $[\alpha]_D^{15.5^\circ} - 44.0^\circ$; $\alpha_{5461}^{15.5^\circ} - 4.33^\circ$, $[\alpha]_{5461}^{15.5^\circ} - 52.2^\circ$. A second experiment under similar conditions gave a chloro-ester mixture melting at $25-50^\circ$. In ethyl alcohol: $l = 2$, $c = 4.3412$, $\alpha_D^{15^\circ} - 3.75^\circ$, $[\alpha]_D^{15^\circ} - 43.2^\circ$; $\alpha_{5461}^{15^\circ} - 4.37^\circ$, $[\alpha]_{5461}^{15^\circ} - 50.3^\circ$. From those figures the product of the action of thionyl chloride on *l*-menthyl *d*-mandelate consisted of *l*-menthyl *d*-phenylchloroacetate (68 per cent.) and *l*-menthyl *l*-phenylchloroacetate (32 per cent.).

The partial inversion, which has been shown to occur here, must have taken place during the action of the thionyl chloride on the mandelate and not by the subsequent action of the thionyl chloride on the dextrorotatory ester alone, since the latter, when heated with thionyl chloride for two hours and then recovered, gave a product identical in optical activity with that of the original ester.

Action of Thionyl Chloride on l-Menthyl l-Mandelate.

1.5 Grams of *l*-menthyl *l*-mandelate (T., 1904, 85, 1249) were heated with 10 grams of thionyl chloride for two hours. 1.47 Grams of a mixture of the chloro-esters were obtained (Found: Cl = 11.4. Calc., 11.5 per cent.). In ethyl alcohol: $l = 2$, $c = 4.0848$, $\alpha_D^{15.5^\circ} - 8.48^\circ$, $[\alpha]_D^{15.5^\circ} - 103.8^\circ$; $\alpha_{5461}^{15.5^\circ} - 10.15^\circ$, $[\alpha]_{5461}^{15.5^\circ} - 124.2^\circ$.

This result was confirmed by heating 1.22 grams of the mandelate with 10 grams of thionyl chloride for two and a half hours. The mixture of chloro-esters (1.25 grams) melted at $25-31^\circ$. In ethyl alcohol: $l = 2$, $c = 4.2856$, $\alpha_D^{17^\circ} - 8.89^\circ$, $[\alpha]_D^{17^\circ} - 103.7^\circ$; $\alpha_{5461}^{17^\circ} - 10.51^\circ$, $[\alpha]_{5461}^{17^\circ} - 122.6^\circ$.

The product of the action of thionyl chloride on *l*-menthyl *l*-mandelate thus consisted of a mixture of *l*-menthyl *l*-phenylchloroacetate (70 per cent.) and *l*-menthyl *d*-phenylchloroacetate (30 per cent.).

Action of Phosphorus Pentachloride on l-Menthyl r-Mandelate.

Several experiments were carried out in which the mandelate was acted on by phosphorus pentachloride according to Shimomura and Cohen. Determinations of halogen in the resulting oil gave values which were much too high, and the values which we obtained for the specific rotations have accordingly no significance, and need not be quoted. On hydrolysing such oils, the resulting acid was either optically inactive or feebly laevorotatory. We never succeeded in obtaining an acid so active as that of Shimomura and Cohen, who found $[\alpha]_D^{25^\circ} - 8.1^\circ$ ($c = 3.274$, $l = 2$), our highest value being $[\alpha]_D - 1.8^\circ$ ($c = 3.9144$, $l = 2$).

The chlorination was accordingly carried out in the presence of chloroform as follows. Twenty grams of phosphorus pentachloride were added in instalments to a solution of 10 grams of *l*-menthyl

r-mandelate in 50 grams of chloroform. When the action had subsided, heating was continued for two hours. The product was washed several times with water and then with dilute sodium hydrogen carbonate. After drying, the chloroform was removed, and the ester distilled under diminished pressure. 8.6 Grams were obtained, b. p. 211°/20 mm. (Found: Cl = 11.5. Calc., 11.5 per cent.). Rotation of the solid in ethyl alcohol: $l = 2$, $c = 4.3288$, $\alpha_D^{15} - 6.64^\circ$, $[\alpha]_D^{15} - 76.7^\circ$; $\alpha_{5461}^{15} - 7.99^\circ$, $[\alpha]_{5461}^{15} - 92.3^\circ$.

The product therefore consisted of *l*-menthyl *d*-phenylchloroacetate (47 per cent.) and *l*-menthyl *l*-phenylchloroacetate (53 per cent.). In another experiment where the distillation under diminished pressure was omitted, the ester mixture was found to contain 48 per cent. of the *d*-ester and 52 per cent. of the *l*-ester.

Hydrolysis of the Ester Mixture.—2.96 Grams were dissolved in 20 c.c. of ethyl alcohol, and 15.5 c.c. of standard alcoholic potassium hydroxide added (calc., 14 c.c.). The mixture remained for a week at the ordinary temperature. Acid recovered = 1.5 grams. In ethyl alcohol: $l = 2$, $c = 5.8176$, $\alpha_D^{15} - 0.44^\circ$, $[\alpha]_D^{15} - 3.8^\circ$.

Action of Phosphorus Pentachloride on l-Menthyl d-Mandelate.

l-Menthyl *d*-mandelate (1.6 grams), phosphorus pentachloride (3.2 grams), chloroform (20 c.c.); time of heating, six and a half hours. Distillation under diminished pressure was not adopted. 1.5 Grams were obtained (Found: Cl = 11.6. Calc., 11.5 per cent.). Rotation of the solid ester in ethyl alcohol: $l = 2$, $c = 4.0212$, $\alpha_D^{15} - 8.17^\circ$, $[\alpha]_D^{15} - 101.6^\circ$; $\alpha_{5461}^{15} - 9.68^\circ$, $[\alpha]_{5461}^{15} - 120.4^\circ$. The product therefore contained 31 per cent. of the *d*-ester, and 69 per cent. of the *l*-ester.

Action of Phosphorus Pentachloride on l-Menthyl l-Mandelate.

l-Menthyl *l*-mandelate (3 grams), phosphorus pentachloride (6 grams), chloroform (30 grams); time of heating, six and a half hours; distillation under diminished pressure not adopted. Yield of solid ester = 2.8 grams (Found: Cl = 11.5; calc., 11.5 per cent.). In ethyl alcohol: $l = 2$, $c = 4.1316$, $\alpha_D^{15} - 4.03^\circ$, $[\alpha]_D^{15} - 48.8^\circ$; $\alpha_{5461}^{15} - 4.76^\circ$, $[\alpha]_{5461}^{15} - 57.6^\circ$. The product thus contained 65 per cent. of the *d*-ester and 35 per cent. of the *l*-ester.

The progress of this research has been facilitated by the generosity of the Carnegie Trust, to whom we express our thanks.

CCXVII.—*The Determination of the Degree of Hydration of Salts by a Radioactive Method.*

By HENRY TERREY and VICTOR GEORGE JOLLY.

DURING some experiments on the determination of the degree of hydration of platinocyanides, considerable difficulty was experienced in drying the crystals prior to dehydration. Owing to the tendency of these salts to retain large quantities of mother-liquor, particularly at high temperatures, it was found impossible to evaluate the hydration by the ordinary methods. Organic dyes were successfully employed as indicators, but the results were not sufficiently accurate, and therefore it was decided to attempt a similar method, replacing the dye by some radioactive material. For this purpose, it was necessary to select some radioactive compound which would go entirely into the mother-liquor and not be adsorbed on, or form compounds or solid solutions with the solid phase. Mesothorium in the form of its very soluble chloride was selected for the series of experiments, chiefly because it provided a strong source of γ -radiation equal to that of radium. This element falls in the same group of the periodic table as the metals of the alkaline earths, which were selected for the trial experiments because of their probable freedom from sulphates, carbonates, etc., which would tend to precipitate the mesothorium and bring it down in the solid phase. As will be seen later, the method breaks down in the case of the dihydrates, and finally the hydrates of sodium bromide were used as a means of testing the applicability of the method to a series of hydrates.

Briefly, the method was as follows: A hot solution of strontium chloride containing a few drops of a solution of mesothorium chloride was allowed to crystallise in a specially-constructed vessel (see Fig. 1), maintained at a constant temperature in a thermostat, the crystals and mother-liquor being well stirred mechanically for two to six hours, according to the time necessary for the attain-

FIG. 1.

ment of equilibrium. By releasing the ground glass stopper, the contents were filtered at the temperature of the bath and the phases thus separated. Weighed quantities of the solution and of the crystals with adhering mother-liquor were dehydrated at 130° , and their respective activities measured by means of an ordinary γ -ray electroscope.

A comparison of the β - or $\alpha + \beta$ -radiations from the two phases gave results approximating to those obtained for γ -radiation measurements, but the former were not sufficiently accurate, for the intensity of α - and β -radiations depends on the area of the solid exposed, absorption taking place if it has considerable depth. The γ -radiations were selected for the comparison owing to their superior penetrative power, depth of solid having no effect. Since a gram or more of solid cannot be concentrated at a point, errors arise from this source; however, by placing the phases at a distance of three inches or more from the electroscope the risk of appreciable error is eliminated. The bulk of the phases was kept at a minimum by evaporation in small, air-tight, glass capsules.

The comparison was made by noting the time required for the gold leaf to cross a definite number of divisions of the scale of a reading-microscope, and applying a correction for the natural leak of the instrument. The electroscope was of such material, brass, lead, or tinned iron, that the radiations compared were practically γ only.

The comparison indicates how much mother-liquor adheres to the solid phase and thus enables a value to be obtained for the water of hydration, which is distinct from the water containing active matter. The following results, obtained with strontium chloride hexahydrate at 28.7° , illustrate clearly the method of calculating the water content. The salt used was purified by recrystallisation.

0.6016 Gram of the liquid phase gave 0.2211 gram of anhydrous solid.

0.5338 Gram of the solid phase gave 0.2713 gram of anhydrous solid.

Activity of the solid phase = 0.3378 (average of 0.3269, 0.3218,

Activity of the liquid phase
0.3479, 0.3546).

Therefore the amount of the liquid phase adhering to the solid phase = $0.3378 \times 0.6016 = 0.2032$ gram, and the amount of anhydrous solid resulting from the adhering mother liquor = $0.3378 \times 0.2211 = 0.0747$ gram.

Therefore the amount of hydrate = $0.5338 - 0.2032 = 0.3306$ gram, and the amount of anhydrous solid from the hydrate = $0.2713 - 0.0747 = 0.1966$ gram.

Percentage of water = $100 \times 0.1340 / 0.3306 = 40.5$ (theor. = 40.53).

DEGREE OF HYDRATION OF SALTS BY A RADIOACTIVE METHOD. 1981

In the dihydrate region, that is, above 66.5°, the use of mesothorium as an indicator breaks down owing to the probable isomorphism of the mesothorium chloride dihydrate with the dihydrates of strontium and barium chlorides. The failure of the method in this case is evident from the following results :

Temp. 71.3°.

1.1461 Grams of the liquid phase gave 0.5537 gram of the anhydrous salt.

0.6907 Gram of the solid phase gave 0.4327 gram of the anhydrous salt.

$\frac{\text{Activity of the solid phase}}{\text{Activity of the liquid phase}} = 3.332$ (that is, the solid phase is far too active).

Temp. 82.9°.

0.9251 Gram of the liquid phase gave 0.4490 gram of the anhydrous salt.

0.7175 Gram of the solid phase gave 0.4227 gram of the anhydrous salt.

$\frac{\text{Activity of the solid phase}}{\text{Activity of the liquid phase}} = 1.878$ (again giving an impossible result).

The method was therefore applied in the case of sodium bromide, with which the mesothorium would probably not unite, and the results show that the degrees of hydration of the penta- and dihydrates and of the anhydrous salt could be evaluated with a fair degree of accuracy. In the case of the anhydrous salt, owing to its fine state of sub-division, slight adsorption took place, but this was eliminated by the addition, after the anhydrous salt had separated out, of a small amount of water, which dissolved the finer particles responsible for the adsorption. The bromide used was purified by recrystallisation.

Dihydrate.	26.4°.	37.0°.
Wt. of liquid phase	2.2193 grams	1.1446 grams
Anhydrous salt from the liquid phase	1.0361 "	0.5815 gram
Wt. of solid phase	1.0977 "	0.8959 "
Anhydrous salt from the solid phase.....	0.6680 gram	0.5697 "
Ratio of the activities of the solid and of the liquid phase	0.2457 "	0.3388 "
Calculated water of hydration	25.2%	20.6%
Theoretical water of hydration		23.9%
Anhydrous salt.	64.5°.	64.7°.
Wt. of liquid phase	1.0436 grams	1.2624 grams
Anhydrous salt from the liquid phase	0.5624 gram	0.6808 gram
Wt. of solid phase	0.8210 "	0.7967 "
Anhydrous salt from the solid phase	0.0485 "	0.6233 "
Ratio of the activities of the solid and of the liquid phase.....	0.3552 "	0.3050 "
Actual wt. of anhydrous salt taken	0.4502 "	0.4117 "
Wt. of anhydrous solid resulting	0.4488 "	0.4157 "

Within the range of experimental error, the above pairs of values indicate that the method is practicable. In the 64.7° determination, adsorption was avoided by adding solid to activated water already at the temperature of the thermostat.

Attempts to obtain sodium bromide pentahydrate, which exists within the somewhat narrow temperature range of -24° to -28° , by stirring the dihydrate at -26° (this temperature was obtained by cooling calcium chloride solution with solid carbon dioxide) for six hours proved fruitless, owing to the difficulty of keeping the bath at constant temperature for a sufficient length of time, and to the very slow attainment of equilibrium. It was found practicable to obtain the pentahydrate by taking a large bulk of solution of such composition that, on cooling, this hydrate only could crystallise out.

Pentahydrate. Temp. -26° .

9.5551 Grams of the liquid phase gave 3.7146 grams of the anhydrous solid.

8.6020 Grams of the solid phase gave 3.7086 grams of the anhydrous solid.

$$\frac{\text{Activity of the solid phase}}{\text{Activity of the liquid phase}} = 0.6543.$$

Water of crystallisation = 45.6 (theor. 46.6 per cent.).

This method is very convenient for the determination of the degree of hydration of salts crystallising at low temperatures, especially those which lose water quickly or dissolve in their water of crystallisation at the ordinary temperature.

The best thanks of the authors are due to Mr. W. E. Garner, M.Sc., who suggested the possibility of using radioactive indicators in the case of the hydrated platinocyanides.

CCXVIII.—*The Action of Bromine on p-Hydroxy- and p-Methoxy-sulphonic Acids.**

By ANDREW NORMAN MELDRUM and MADHAVLAL SUKHLAL SHAH.

MUCH work has been done on the halogenation of aromatic sulphonic acids, with the result, in many cases, that the sulphonic acid radicle is found to be replaced by a halogen atom. Such replacement has

* A preliminary note on the subject of this paper was read in the Chemistry Section of the Indian Science Congress, Lucknow meeting, January, 1923.

been observed by Kelbe in the case of cymenesulphonic acid (*Ber.*, 1882, **15**, 39) and by Meyer in the cases of α - and β -anthraquinone-sulphonic acids (*Monatsh.*, 1915, **36**, 719). Similarly, chloroalizarin is produced from alizarin- β -sulphonic acid by the Farbenfabriken vorm. F. Baeyer & Co. (Brit. Pat. 1822, 1908). Datta and Mitter (*J. Amer. Chem. Soc.*, 1919, **41**, 2028) have studied the action of chlorine on a number of hydroxy-sulphonic acids: *o*-cresol-5-sulphonic acid gives 5-chloro-*o*-cresol, and sulphasalicylic acid gives 3:5-dichlorosalicylic acid, whilst anisolesulphonic acid produces tetrachloroketodihydrobenzene. Blanksma (*Rec. trav. chim.*, 1910, **29**, 377) has made use of this property, that is, the readiness with which the sulphonic group in the ortho- or para-position with respect to the amino- or hydroxy-group is displaced by bromine, in settling the constitution of sulphoamino- and sulphohydroxybenzoic acid. Sudborough and Lakumalani (T., 1917, **111**, 41), by observations on the bromination of ortho- or para-amino-sulphonic acids, have shown that the reactivity, that is, the replacement of the sulphonic acid radicle by bromine, is usually greater if the sulphonic acid radicle is present in the ortho-position than if in the para-position.

The authors have studied the bromination of phenol-*p*-sulphonic acid, *o*-cresolsulphonic acid, sulphasalicylic acid, and their respective methyl ethers. In each case, the phenolic substance gives a bromo-sulphonic acid, the bromine atom being in the ortho-position to the hydroxyl group, whilst the methyl ether gives the bromomethoxy-derivative, the bromine atom having replaced the sulphonic acid radicle.

On bromination of phenol-*p*-sulphonic acid, Senhofer (*Annalen*, 1870, **156**, 105) obtained 2-bromo- and 2:6-dibromo-*p*-phenol-sulphonic acids.

When the authors brominated anisole-*p*-sulphonic acid, an oily liquid separated which was found to be *p*-bromoanisole. The authors obtained this substance also by brominating anisole in acetic acid solution; Autenrieth and Mühlinghaus (*Ber.*, 1906, **39**, 4098) prepared it by the action on anisole of phosphorus pentabromide.

Claus and Jackson (*J. pr. Chem.*, 1888, [ii], **38**, 334) found that the action of bromine on *o*-cresol-5-sulphonic acid led to 3-bromo-*o*-cresol-5-sulphonic acid.

When 2-methoxytoluene-5-sulphonic acid was brominated, the product was 5-bromo-2-methoxytoluene. The same substance was obtained by the action of bromine on *o*-tolyl methyl ether in acetic acid solution. In each case, the product melted at 74° and crystallised with $1\frac{1}{2}$ molecules of water of crystallisation. 5-Bromo-2-

methoxytoluene on oxidation gave Peratoner's 5-bromo-2-methoxybenzoic acid.

The authors have shown (following paper) that when sulphosalicylic acid is brominated the product is 3-bromosulphosalicylic acid.

The methyl ether of sulphosalicylic acid, when treated with bromine, yields 5-bromo-2-methoxybenzoic acid. The same bromo-acid is obtained by the action of bromine on the methyl ether of salicylic acid in acetic acid solution. It was found to have the melting point 121° and to give a barium salt, $(C_8H_7O_3Br)_2Ba \cdot 3H_2O$, in agreement with Peratoner (*Gazzetta*, 1887, 16, 409), who obtained it from 5-bromosalicylic acid by using methyl iodide and potassium hydroxide, and found the melting point to be 119° .

EXPERIMENTAL.

In each case, the reaction was carried out by passing the bromine (1 mol.), as vapour mixed with air, into a solution of the sulphonic acid (1 mol.) in water. The temperature was kept from rising, and, at the end, any excess of bromine was removed by a current of air.

p-Bromoanisole from Anisole-*p*-sulphonic Acid.—A solution of anisole-*p*-sulphonic acid, prepared from phenol (5 grams), was treated with the vapour of bromine (3.8 grams). The reaction proceeded slowly; an oily liquid formed which was separated, dried, and distilled (b. p. 216 – 217°). Yield = 2 grams (Found: Br = 43.10. Calc. for C_7H_7OBr , Br = 42.77 per cent.).

p-Bromoanisole was prepared also from anisole (11 grams) in acetic acid solution by the action of bromine. Yield = 15 grams. B. p. 216° .

5-Bromo-2-methoxytoluene from (a) 2-Methoxytoluene-5-sulphonic Acid, (b) *o*-Tolyl Methyl Ether.—(a) The anhydrous sodium salt of 2-methoxytoluenesulphonic acid (2.3 grams) was dissolved in water (100 c.c.), a little sulphuric acid added, and the vapour of bromine (1.6 grams) passed in slowly. The oil that had separated finally became solid. The product was collected, washed, and dried (yield = 1.8 grams).

5-Bromo-2-methoxytoluene has an aromatic odour. It is insoluble in cold water, sparingly soluble in hot water, moderately soluble in cold alcohol or acetone, and dissolves readily in cold acetic acid, benzene, toluene, or chloroform. For analysis, it was crystallised from solution in dilute acetic acid and obtained as shining, thin, six-sided plates, m. p. 74° . The crystals contained one and a half molecules of water of crystallisation (Found: H_2O = 11.57; Br = 35.33, 35.74. $C_8H_9OBr \cdot 1\frac{1}{2}H_2O$ requires H_2O = 11.84; Br = 35.06 per cent.).

(b) *o*-Tolyl methyl ether (11 grams), dissolved in acetic acid (50 c.c.) and water (10 c.c.), was treated with the vapour of bromine (16 grams). When the bromination had ended, water (200 c.c.) was added to complete the precipitation (yield = 18 grams). After purification as above, it melted at 74–75°. The melting point of the mixture with the substance obtained under (a) was 74°.

5-Bromo-2-methoxybenzoic Acid.—This substance was prepared in three ways, (a) by brominating sulphosalicylic acid methyl ether, (b) by brominating 2-methoxybenzoic acid, and (c) by oxidising 5-bromo-2-methoxytoluene.

(a) The anhydrous sodium salt of sulphosalicylic acid methyl ether (4 grams) was dissolved in sulphuric acid (5 c.c.) and water (100 c.c.) and then treated with the vapour of bromine (3 grams). Needle-shaped crystals separated which were collected, washed, and dried (yield = 3.2 grams).

The substance is insoluble in cold water and moderately soluble in hot. It is very soluble in most organic solvents. For analysis, it was crystallised from solution in petrol, when it separated as long needles, m. p. 121° (Peratoner, *loc. cit.*, gives 119°) (Found: Br = 34.58; equivalent = 230.2. Calc. for $C_8H_7O_3Br$, Br = 34.63 per cent.; equivalent = 230.9). The barium salt was obtained in clusters of needles. It had the same composition, $(C_8H_4O_3Br)_2Ba \cdot 3H_2O$, as was found by Peratoner.

It seemed possible that if bromination were carried out at a low temperature, the sulphonic acid radicle might remain intact and bromine might occupy the ortho-position to the methoxyl group. By experiment it was found that bromination at 0–5° led to 50 per cent. conversion into 5-bromo-2-methoxybenzoic acid, and about 50 per cent. of the original sulphosalicylic acid methyl ether, as the characteristic acid sodium salt, was recovered unchanged.

(b) *o*-Methoxybenzoic acid (2 grams) was dissolved in acetic acid (20 c.c.) and water (100 c.c.), and the vapour of bromine (2 grams) was passed in. The product when purified, melted at 121.5°. Mixed with the substance obtained under (a), there was no depression of the melting point.

(c) 5-Bromo-2-methoxytoluene (5 grams) was heated under reflux with potassium hydroxide (0.5 gram) dissolved in water (200 c.c.). Potassium permanganate (8 grams), dissolved in water (400 c.c.), was added. Oxidation went on very slowly and part only of the 5-bromo-2-methoxytoluene was oxidised after twenty-four hours' heating. Unchanged 5-bromo-2-methoxytoluene and precipitated manganese dioxide were removed and the excess of the potassium permanganate solution in the liquid was reduced by boiling with alcohol. When the solution became colourless,

the precipitated manganese dioxide was removed and the clear filtrate, after evaporating to small bulk, was acidified with hydrochloric acid. 5-Bromo-2-methoxybenzoic acid separated in short needles melting at 121° (Found: equivalent = 230.1. $C_8H_7O_3Br$ requires equivalent = 230.9).

A mixture with 5-bromo-2-methoxybenzoic acid prepared by another method showed no depression of the melting point.

CCXIX.—*The Constitution of Sulphosalicylic Acid and of Related Substances.*

By ANDREW NORMAN MELDRUM and MADHAVLAL SUKHLAL SHAH.

THE work described in this paper was undertaken with the view of determining the constitution of sulphosalicylic acid and of certain substances that are closely related to it, namely, the acid obtained by sulphonating *o*-methoxybenzoic acid and the sulphonic acid of *o*-tolyl methyl ether.

Attempts to ascertain the constitution of sulphosalicylic acid by the method that is usually employed in studying sulphuric acid have failed. Remsen (*Annalen*, 1875, **179**, 107) fused sulphosalicylic acid with potassium hydroxide and obtained salicylic acid and phenol, instead of the dihydroxybenzoic acid that he expected. The authors also have obtained salicylic acid by fusing sulphosalicylic acid with potassium hydroxide. Moreover, they obtained salicylic acid on fusing sulphosalicylic acid methyl ether with sodium hydroxide, with potassium hydroxide, and with sodium methoxide.

The authors therefore attacked the problem in other ways. Before their work could be prepared for publication the constitution of sulphosalicylic acid was proved by Stewart (*T.*, 1922, **121**, 2556). The result of the authors' work is to confirm Miss Stewart's proof and also to show that the constitutions of the other substances that they studied are represented by formulæ I and II, respectively.

The authors were able to ascertain the constitution of sulphosalicylic acid in the following way: when bromine vapour is passed into a solution in water of sulphosalicylic acid, molecular proportions being taken, reaction takes place readily and the only organic substance that is produced is a bromosulphosalicylic acid which must be *3-bromo-5-sulpho-2-hydroxybenzoic acid* since it is converted into 3-bromosalicylic acid on elimination of the sulpho-group by the agency of superheated steam.

The bromination of the methyl ether of sulphosalicylic acid proceeds in a different manner (see preceding paper).

The authors have devised a method for preparing pure sulphosalicylic acid, more straightforward than the methods laid down hitherto (Mendius, *Annalen*, 1857, **103**, 45; Remsen, *loc. cit.*; Pisonello, *Gazzetta*, 1888, **18**, 346; and Hirsch, *Ber.*, 1900, **33**, 3238), which consists in mixing salicylic acid with fuming sulphuric acid (3 per cent. of sulphur trioxide), when reaction proceeds without the application of heat, and sulphosalicylic acid separates, the yield being large and there being no sign of any other product; when purified by crystallisation from water, it separates as the substance $C_7H_5O_6S \cdot 2H_2O$. The acid potassium salt was found to contain three molecules of water of crystallisation, instead of two as found by Mendius (*loc. cit.*).

Sulphosalicylic acid methyl ether (I) was prepared in three ways: (A) by sulphonating *o*-methoxybenzoic acid; (B) by methylating sulphosalicylic acid; and (C) by oxidising *o*-tolyl methyl ether sulphonic acid (II).

(A) In preparing *o*-methoxybenzoic acid by the methylation of salicylic acid, an improved method was devised for separating that substance from the unchanged salicylic acid. For this separation Graebe recommended continued treatment with milk of lime, which converts calcium salicylate into the insoluble substance $C_7H_5O_3Ca$ (*Annalen*, 1866, **139**, 138; 1905, **340**, 209). The authors find that when salicylic acid is submitted to methylation, the product should be converted into the ordinary calcium salts, when the salt of the methyl ether acid separates first from solution, being much less soluble than calcium salicylate.

After sulphonating *o*-methoxybenzoic acid (no indication was found of more than one sulphonic acid being formed), the authors separated the sulphonic acid as a sparingly soluble acid sodium salt, $C_7H_5O_6SNa \cdot 3H_2O$; the acid potassium salt, $C_7H_5O_6SK \cdot 2H_2O$, is much more soluble. The free sulphonic acid melts at 152° .

(B) Sulphosalicylic acid was methylated, and the product identified with the substance described under (A) by means of the acid sodium and potassium salts. Thus the sulphonic acid obtained from *o*-methoxybenzoic acid must have the constitution (I).

(C) On sulphonating *o*-tolyl methyl ether, prepared from *o*-toluidine, Bromwell obtained a sulphonic acid, the constitution of which he left unsettled (*Amer. Chem. J.*, 1897, **19**, 569). The authors, on sulphonating *o*-tolyl methyl ether—prepared from *o*-cresol—obtained two products: (i) Bromwell's sulphonic acid in large amount and (ii), in small amount, a substance, m. p. 138° , which is reserved for further investigation.

Having oxidised Bromwell's sulphonic acid, the authors isolated an acid sodium salt and an acid potassium salt that proved to be identical with those obtained by methods (A) and (B). Thus Bromwell's acid has the constitution II. Moreover, the relationship between the substances I and II was shown in another way. Bromwell converted his acid *via* the sulphonyl chloride into the sulphonamide III and on oxidising the latter obtained the sulphonamide carboxylic acid (IV). Walker fused this carboxylic acid with potassium hydroxide and found that the product was salicylic acid sulphonamide (V), so that the sulphonamide group had remained intact and the methoxy-group had been hydrolysed (*Amer. Chem. J.*, 1897, 19, 578). The authors converted sulphosalicylic acid methyl ether (I) into the corresponding sulphonamide, and then fused this with potassium hydroxide, obtaining another sulphonamide. The first sulphonamide melted at 212–213° and was evidently identical with Bromwell's sulphonamide, which melted at 210°. By fusion with potassium hydroxide, a substance was obtained melting at 230° and evidently identical with Walker's compound, which melted at 231°. Thus Bromwell's *o*-tolyl methyl ether sulphonic acid must have the constitution II and Walker's salicylic acid sulphonamide the constitution V.

EXPERIMENTAL.

Sulphosalicylic Acid.—The following process is more convenient for making sulphosalicylic acid than that employed by Hirsch and workers previous to him. Salicylic acid (100 grams) was dissolved in sulphuric acid containing 3 per cent. of sulphur trioxide (200 c.c.), the temperature of the solution rising to about 75°. The mixture was cooled and crystallisation set in after half an hour; after one hour, the hard mass was broken up. After filtering through flannel, the mother-liquor, on addition of a little water, gave a further yield of the crystalline substance. The crystalline mass was well-

pressed, washed with dilute sulphuric acid, and dried by means of porous tile.

The crude substance was recrystallised from water (yield = 160 grams). The crystals, when rapidly formed, are needle-shaped; when slowly formed, they are rectangular plates. The composition is $C_7H_5O_6S, 2H_2O$ and the melting-point is 113° . Desiccation leads to material that shrinks when heated from 115° upwards and melts with decomposition at about 180° (Found: $H_2O = 14.10$; equivalent = 126.8. $C_7H_5O_6S, 2H_2O$ requires $H_2O = 14.17$ per cent.; equivalent = 127.0). The acid potassium salt crystallises in slender needles (Found: $K = 12.46$; equivalent = 309.8, 310.3. $C_7H_5O_6SK, 3H_2O$ requires $K = 12.77$ per cent.; equivalent = 310.2). Mendius described an acid potassium salt of the composition $C_7H_5O_6SK, 2H_2O$.

3-Bromo-5-sulpho-2-hydroxybenzoic Acid.—Sulphosalicylic acid (32 grams) was dissolved in water (200 c.c.) in a flask which was connected with a flask containing bromine (21 grams). Air containing bromine vapour was passed into the solution, and the bromine was rapidly absorbed. At the end, traces of unchanged bromine were removed by a current of air. The solution was then evaporated on a water-bath until hydrogen bromide was no longer evolved, and the residue was kept in a desiccator containing sodium hydroxide for two days. The product crystallised in shining needles and was found to be insoluble in most organic solvents, but soluble in ethyl acetate or nitrobenzene. When heated, it shrinks from 110° upwards and melts at 140° ; on further heating, it solidifies and melts again at about 182° (Found: equivalent = 152.8, 154.1. $C_7H_3O_6BrS, \frac{1}{2}H_2O$ requires equivalent = 153).

In preparing salts of the acid, the solution obtained on bromination was used without evaporation for removal of hydrogen bromide.

Acid Potassium Salt.—The solution was neutralised with potassium hydroxide solution, evaporated to small bulk, and acidified with strong hydrochloric acid, when the acid potassium salt separated in flocculent needles. The substance loses $2\frac{1}{2}$ molecules of water when heated at 110° (Found: $H_2O = 11.69$ at 110° ; $K = 10.03$; equivalent = 385.2. $C_7H_4O_6SBrK, 3H_2O$ requires $H_2O = 11.57$ ($2\frac{1}{2}$ molecules H_2O); $K = 10.05$ per cent.; equivalent = 389.1.]

Acid Sodium Salt.—The solution was neutralised with sodium hydroxide solution and treated as above, the acid sodium salt separating in clusters of soft, silky needles. It is more soluble than the acid potassium salt (Found: $H_2O = 21.02$; $Na = 5.58$. $C_7H_4O_6SBrNa, 5H_2O$ requires $H_2O = 22.0$; $Na = 5.62$ per cent. Equivalent of the anhydrous salt = 321.8. $C_7H_4O_6SBrNa$ requires 319.1).

Barium Salt.—The hot dilute solution was digested with barium carbonate, the mixture filtered, and the filtrate evaporated. Two kinds of crystals were obtained, (a) needles on rapid crystallisation, and (b) short needles on slow crystallisation.

(a) This substance did not lose in weight when heated at 110° for two hours (Found : Ba = 30.56. $C_7H_3O_6SBrBa \cdot H_2O$ requires Ba = 30.51 per cent.).

(b) This substance, when heated at 110° , lost 4 out of 5 molecules of water [Found : H_2O = 13.00; Ba = 26.32. $C_7H_3O_6SBrBa \cdot 5H_2O$ requires H_2O = 13.78 (4 molecules of water); Ba = 26.30 per cent.].

Strontium Salt.—This was prepared similarly to the barium salt, and was obtained as microscopic needles. It did not lose in weight when heated at 110° (Found : Sr = 21.44. $C_7H_3O_6SBrSr \cdot H_2O$ requires Sr = 21.86 per cent.).

Lead Salt.—The solution was digested with lead carbonate, filtered, and the filtrate evaporated to small bulk. The salt separated in clusters of minute needles. The lead bromide that was formed at the same time was much more soluble in hot water and was easily removed (Found : H_2O = 9.17; Pb = 37.40. $C_7H_3O_6SBrPb \cdot 3H_2O$ requires H_2O = 9.71; Pb = 37.25 per cent.).

3-Bromosalicylic Acid.—It was mentioned that 3-bromosulphosalicylic acid, when heated, melts at 140° , and that the liquid on further heating gives a solid that melts at 182° . In a small-scale experiment, by heating 3-bromosulphosalicylic acid that contained half a molecule of water of crystallisation, it was found that 3-bromosalicylic acid is produced. It is obtained in large yield as follows :

3-Bromosulphosalicylic acid (10 grams) and syrupy phosphoric acid (50 grams) were heated together at 130° for about thirty minutes. Superheated steam was then passed in and the temperature raised to 155 – 160° (it ought not to be raised further). Part of the 3-bromosalicylic acid volatilised with the steam, and more was obtained on adding water to the liquid in the flask (yield = 5.5 grams).

The substance dissolves readily in methyl alcohol, acetone, or acetic acid. It is moderately soluble in hot water, benzene, toluene, chloroform, or petrol. For analysis, it was purified by recrystallisation first from dilute acetic acid and then from 50 per cent. methyl alcohol : it formed long needles, m. p. 184.5° (Lellmann and Grothmann, *Ber.*, 1884, 17, 2715, record m. p. 184° . Compare also Müller, *Ber.*, 1909, 42, 3702) (Found : Br = 36.77; equivalent = 217.4, 216.8. Calc. for $C_7H_5O_2Br$, Br = 36.86 per cent.; equivalent = 217.0).

The *sodium*, *potassium*, and *ammonium* salts crystallise in short, shining needles.

Barium Salt.—3-Bromosalicylic acid dissolved in water was digested with barium carbonate in slight excess. The mixture was filtered, and the filtrate evaporated and filtered again. The filtrate gave small prisms, slightly red, and charcoal did not remove the red colour [Found: $H_2O = 9.25$; $Ba = 21.96$. Calc. for $(C_7H_4O_3)_2Ba \cdot 3H_2O$, $H_2O = 8.70$; $Ba = 22.10$ per cent.]. Lellmann and Grothmann (*loc. cit.*) described a barium salt of the same composition that crystallised in red prisms.

3-Bromo-2-methoxybenzoic Acid.—3-Bromosalicylic acid (2 grams) was methylated with methyl sulphate and sodium hydroxide. After being heated to decompose the ester and the excess of methyl sulphate, the liquid was acidified, when a white, crystalline precipitate formed (yield = 1.5 grams). The substance is sparingly soluble in hot water, but is readily soluble in hot organic solvents. It separates as curly, fibre-like crystals from benzene, toluene, or ethyl alcohol, and as clusters of needles from petrol. A sample gave no coloration with ferric chloride solution, and melted at 136° . Its isomeride, 5-bromo-2-methoxybenzoic acid, melts at 121° , and a mixture of the two at 100° (Found: equivalent = 232.1. $C_8H_7O_3Br$ requires equivalent = 231.0).

o-Methoxybenzoic Acid.—Salicylic acid having been methylated, the crude mixture of salicylic acid and the methoxybenzoic acid was dissolved in ammonia and the neutral solution was treated with concentrated calcium chloride solution in excess. Calcium salts separated on cooling, which were collected, washed, and dissolved in hot water. The solution on cooling gave crystals of calcium o-methoxybenzoate, and the mother-liquor on evaporation gave a further yield. When the deposit gave a violet coloration with ferric chloride, indicating that calcium salicylate was separating, the process was stopped. The acid was prepared from the calcium salt and was crystallised from water [yield, from 100 grams of salicylic acid, (1) o-methoxybenzoic acid, m. p. 100.5° , 77 grams; (2) residual salicylic acid and o-methoxybenzoic acid, 22 grams].

Methyl Ether of Sulphosalicylic Acid, (I).—This substance was obtained by different methods, (A), (B), and (C).

(A) A mixture of salicylic acid methyl ether (5 grams) and fuming sulphuric acid (3 per cent. SO_3 ; 10 c.c.) was kept at 50° for two hours. Next day, water was added carefully and the diluted solution neutralised with sodium hydroxide. Sodium sulphate crystals were removed and the liquid was strongly acidified with hydrochloric acid. An acid sodium salt separated which was recrystallised and obtained as soft, lustrous needles (yield = 9 grams).

(Found: Na = 7.49; H_2O = 17.44; equivalent = 306.9, 307.6. $C_8H_7O_6SNa \cdot 3H_2O$ requires Na = 7.46; H_2O = 17.52 per cent.; equivalent = 308.0).

The *acid potassium* salt was prepared in a similar way to the acid sodium salt and obtained as short needles (Found: K = 12.82; H_2O = 11.67; equivalent = 304.0, 304.1. $C_8H_7O_6SK \cdot 2H_2O$ requires K = 12.78; H_2O = 11.76 per cent.; equivalent = 306.1).

The *barium* salt was prepared from the acid sodium salt by neutralisation with ammonium hydroxide solution and addition of barium acetate solution in excess. A crystalline precipitate formed which was separated, redissolved, and recrystallised. It was obtained in minute needles (Found: Ba = 37.34. $C_8H_6O_6SBa$ requires Ba = 37.39 per cent.).

The Sulphonic Acid.—A weighed quantity of the barium salt was dissolved in boiling water and the equivalent amount of dilute sulphuric acid was added. The filtrate from barium sulphate, evaporated to small bulk on a water-bath, when kept in a desiccator, yielded long, shining needles. The substance is deliquescent and melts in the anhydrous state at 152° (Found: equivalent = 115.4. $C_8H_8O_6S$ requires equivalent = 116.0).

(B) Sulphosalicylic acid was methylated and the product was isolated as the acid sodium salt (yield from 50 grams of $C_7H_7O_6S \cdot 2H_2O$ 56 grams of $C_8H_7O_6SNa \cdot 3H_2O$). The acid sodium salt, the acid potassium salt, and the barium salt were found on analysis to be identical with those obtained by (A). The anhydrous sulphonic acid melted at 152° , alone or mixed with the acid obtained by (A).

(C) (i) *Preparation of 5-Sulpho-o-tolyl Methyl Ether* (II).— o -tolyl methyl ether (25 grams), cooled to 10° , fuming sulphuric acid (3 per cent. SO_3 ; 45 c.c.) was added in small amounts, with shaking, so that the temperature did not rise above 15° . When the acid had been added, the mixture was kept at 15° for fifteen minutes and was then carefully diluted with water (200 c.c.). The substance separated in microscopic needles, which were collected, washed with water, and dried (yield = 2.5 grams). It was insoluble in water, but was readily soluble in organic solvents and was obtained in long needles, m. p. 138° . The substance, which contains sulphur, and remains unchanged when boiled with sodium hydroxide solution, is reserved for further investigation.

The filtrate was treated with barium carbonate so as to give the barium salt of the acid (II). The sodium and potassium salts were also prepared. Each salt was found to have the composition given by Bromwell. The sulphonic acid was prepared and found to melt at 210° (Bromwell gives m. p. 212°).

(C) (ii) *Preparation of the Methyl Ether of Sulphosalicylic Acid.*—The sodium salt of the acid (II) (5 grams) and potassium hydroxide (0.5 gram) were dissolved in water (200 c.c.) and solution was heated to boiling and treated with a solution of potassium permanganate (7 grams) in water (200 c.c.). After about five hours the colour of the permanganate had disappeared. The solution was filtered, and the filtrate evaporated to small bulk and acidified with hydrochloric acid, when an acid sodium salt identical in composition with that obtained by methods (A) and (B) was obtained. Again, the potassium salt of the acid (II) was oxidised, and an acid potassium salt was obtained, identical with that given by methods (A) and (B). Of these two acid salts, the sodium salt is much the less soluble, for it was found by the cobaltinitrite test to be free from potassium, although potassium hydroxide and permanganate were used in preparing it.

The Sulphonyl Chloride.—A mixture of the anhydrous acid sodium salt of the methyl ether of sulphosalicylic acid (I) (15 grams) and phosphorus pentachloride (35 grams) was gradually heated and kept at near 100° for two hours, the product being then poured into ice-cold water (800 c.c.). After about twelve hours, the hydrolysis of the $-\text{COCl}$ group being complete, the oil had changed to a solid mass, which was collected, washed, and dried (14.6 grams). The sulphonyl chloride readily dissolves in hot benzene, toluene, or chloroform. From solution in toluene it was obtained in transparent, well-shaped rhombohedra, m. p. 148.5° [Found: $\text{Cl} = 14.09$; equivalent (using excess of NaOH solution and titrating back) = 82.3. $\text{C}_8\text{H}_7\text{O}_2\text{ClS}$ requires $\text{Cl} = 14.15$ per cent.; equivalent (if $-\text{SO}_2\text{Cl}$ becomes $-\text{SO}_3\text{H}$ and HCl) = 83.5].

2-Methoxybenzoic Acid 5-Sulphonamide. (IV).—The above sulphonyl chloride dissolved in strong ammonium hydroxide solution, and on acidification the sulphonamide was precipitated. On purification, it was obtained in long, shining needles melting at $212\text{--}213^{\circ}$ (Bromwell gives m. p. 211°) (Found: equivalent = 231.4. Calc. for $\text{C}_8\text{H}_6\text{O}_5\text{NS}$ equivalent = 231.0).

Salicylic Acid 5-Sulphonamide (V).—The sulphonamide (IV) was fused with potassium hydroxide, and the sulphonamide (V) obtained. The pure substance gave a violet coloration with ferric chloride and melted at 230° . Walker gives m. p. 231° .

CCXX.—*Studies in the Anthracene Series. Part V.*By EDWARD DE BARRY BARNETT, JAMES WILFRED COOK, and
MARCUS AURELIUS MATTHEWS.

THE centre of activity of the anthracene ring system lies in the "bridge" bond joining the two *meso*-carbon atoms, and recently (Ingold, T., 1922, 121, 1133; Ingold, Seeley, and Thorpe, this vol., p. 853) evidence has been adduced in favour of the view that aromatic characteristics in any compound are due to the formation of a reactive "bridge" bond in one of the phases of an intra-annular tautomeric change. The idea of the "bridge" bond is, of course, an old one and was originally proposed by Dewar (*Proc. Roy. Soc. Edin.*, 1866—1867, 84) in his formula for benzene, and at a later date was revived by Baly, Edwards, and Stewart (T., 1905, 87, 1347) as representing one of the extreme phases of their pulsating ring formula, the second extreme showing two *meta*-bonds and two carbon atoms in a transiently trivalent state. Ingold's formula would seem only to differ from that of Baly, Edwards, and Stewart by postulating the Kekulé formula as one of the extreme phases of the isodynamic change, but whereas according to Baly, Edwards, and Stewart the reactivity of the nucleus is due to the transiently trivalent carbon atoms, Ingold attributes the reactivity to the "bridge" bond. If the "bridge" bond is the centre of activity of an aromatic compound, then the oxidation of a monohydric phenol should lead to a *p*-dihydric phenol, and a phenolic ether should behave in much the same way:

Although reactions of this nature take place in some cases, in the majority the oxidation product of a phenol is a diphenol, and phenolic ethers are usually stable towards mild oxidising agents. An alternative explanation, and one which appears to be much more in accord with the facts as known at present, lies in the assumption that the first action of the oxidising agent consists in the removal of the phenolic hydrogen atom, leaving a free radicle in which the oxygen atom is in the univalent state. Since oxygen atoms have but little tendency to unite with one another, these radicles do not combine to form a peroxide,* but rather stabilise

* In the case of mercaptans, owing to the greater tendency of sulphur atoms to unite, the product is a disulphide.

themselves by changing over into free radicles with tervalent carbon atoms, the union of these with subsequent enolisation leading to the diphenol :

The conception of univalent oxygen radicles being formed by the oxidation of a phenol had previously been suggested by Goldschmidt (*Ber.*, 1922, 55, [B], 3194, 3197) to explain the production of very reactive substances by the oxidation of guaiacol and quinol mono-methyl ethers and phenanthraquinol monomethyl and monoethyl ethers, and, previous to this, Pummerer and Frankfurter (*Ber.*, 1914, 47, 1472), by oxidising hydroxydinaphthylene oxide, obtained a product which behaved towards quinol as if in solution it passed rapidly from a univalent oxygen radicle to a tervalent carbon radicle :

Strong support of the above view of the mechanism of the oxidation of the phenols would be afforded by the isolation of the ketonic product which must be supposed to be formed by the union of the tervalent carbon radicles. In the benzene and naphthalene series this has not been achieved, probably owing to the very slight tendency of the phenols to assume the ketonic form. In the anthracene series, however, the case is different, as anthrone and anthranol are distinct substances, and dianthrone (I) and dianthranol (II), although interconvertible, are only so with difficulty. Anthranol on oxidation invariably gives dianthrone, the enolic dianthranol never being obtained. In view of the comparative difficulty with which dianthranol is ketonised—prolonged boiling with an alcoholic solution of hydrogen chloride is necessary—it is very improbable that the dianthrone is a secondary product formed by the ketonisation of dianthranol, especially as dianthrone remains the sole product even when the oxidation is carried out under conditions which favour the enolic form, for example, in pyridine solution. Also dianthranol is very easily oxidised to dianthraquinone (III), for example, by mercuric acetate in cold pyridine solution, but no matter how much oxidising agent is used, dianthraquinone is never obtained by the direct oxidation of anthranol.

On the assumption that the first action of an oxidising agent on a phenol consists in the removal of the phenolic hydrogen atom, the behaviour of anthranol on oxidation appears perfectly normal, and, of course, this view also explains why anthranyl ethers are only oxidised under conditions which lead to their dealkylation.

The oxidation of a *p*-dihydric phenol to a *p*-quinone, for example, quinol to benzoquinone, anthraquinol to anthraquinone, dianthranol to dianthraquinone, etc., is probably due to a similar transient formation of a univalent oxygen radicle, although in these cases stabilisation takes place through the formation of a quinonoid structure, the reactions being exactly analogous to the formation of a quinonoid hydrocarbon by the action of metals on *ωω'*-dichloro-*ωω'*-tetraphenyl-*p*-xylene:

This explanation of the oxidation of *p*-dihydric phenols to quinones is more rational than that put forward by Ingold (*loc. cit.*) in which addition of hydroxyl groups to the "bridge" bond and subsequent loss of water is assumed to take place:

Further support of the above mechanism of the oxidation of anthranol would be furnished if evidence could be obtained of the transient existence of the anthronyl radicle and its passage into dianthrone. Certain evidence of this nature has recently been published by two of us [Barnett and Matthews (*loc. cit.*)] and this work is being extended by a general investigation of anthrone derivatives. For the present it will suffice to cite two further instances, namely, the ease with which bromoanthrone and nitroanthrone pass into dianthrone. Thus both substances, when warmed with dilute

solutions of hydriodic acid, cause an immediate liberation of iodine and pass into dianthrone, and bromoanthrone fails to react normally with either ethyl sodioacetoacetate or magnesium phenyl iodide, in both cases dianthrone being almost the sole product of the reaction. Bromoanthrone also passes very easily into dianthrone on treatment with hydrogen sulphide.

Probably substitution reactions in the aromatic series are to be regarded as addition followed by loss of halogen hydride, or of water in the case of nitration or sulphonation. In the benzene and naphthalene series, the additive compounds which are to be regarded as the primary products of the reaction are too unstable to be isolated, but in the anthracene series such compounds are much more stable and can frequently be obtained in the pure state. Thus Perkin (*Chem. News*, 1876, **34**, 144; *Bull. Soc. chim.*, 1877, [ii], **27**, 464), by treating anthracene with bromine or chlorine at a low temperature, obtained dihalides which at the ordinary temperature rapidly lost halogen hydride and passed into 9-bromo- (or chloro)anthracene. At a later date, Meisenheimer and Connerade (*Annalen*, 1904, **330**, 133; compare Dimroth, *Ber.*, 1901, **34**, 221) obtained the acetate, nitrite, and chloride of an additive compound of anthracene and nitric acid and described a convenient method of preparing 9-nitroanthracene by loss of halogen acid from the chloride.

The relative stability of these dihydroanthracene derivatives and the ease with which many of them are formed render anthracene a particularly suitable compound for the study of the mechanism of substitution reactions. Some preliminary work has already been published (Barnett, Cook, and Grainger, *T.*, 1922, **121**, 2059) and it is proposed to extend this work as soon as suitable methods for preparing substituted anthracene derivatives have been devised. The present communication deals with some preliminary work on the re-establishment of the "bridge" bond.

In the case of chloronitrodihydroanthracene (V), re-establishment of the "bridge" bond might take place either by loss of hydrogen chloride with the production of nitroanthracene, or by the loss of nitrous acid with the production of chloroanthracene. As might be expected, the former reaction is the one which takes place

exclusively. In the case of the corresponding acetate (VI), re-establishment of the "bridge" also takes place exclusively by loss

of acetic acid, and in no case has it been possible to detect any trace of anthranil acetate in the product. The ease with which this acetate parts with acetic acid in contact with suitable reagents is remarkable, as although it can be dried on the water-bath and recrystallised from boiling benzene without appreciable decomposition, it is rapidly and quantitatively converted into nitroanthracene by cold pyridine, and in this way resembles the chloride (Barnett, Cook, and Grainger, *loc. cit.*).

In the case of nitrodihydroanthranol itself (VII), the "bridge" might be re-established in three ways, namely, by loss of nitrous acid and formation of anthranol (IV), by loss of water and formation of nitroanthracene, or by loss of nitric acid and formation of anthracene itself. Unfortunately, nitrodihydroanthranol is too unstable to be isolated and its reactions could only be examined by studying the behaviour of the acetate or chloride on hydrolysis under different conditions. In both cases attempts to effect the hydrolysis by means of an alkali led only to nitroanthracene owing to loss of hydrogen chloride or acetic acid before hydrolysis could take place. If, however, the hydrolysis were effected in acid solution, the product was dianthrone (I), scarcely any nitroanthracene being produced.

The direct preparation of dianthrone by the action of nitric acid on anthracene (Dimroth, *loc. cit.*; Barnett and Matthews, this vol., p. 380) is obviously due to this reaction, and as nitrous acid oxidises anthranol very easily to dianthrone it at first seemed probable that the mechanism of the reaction consists in loss of nitrous acid and immediate oxidation by this of the anthranol formed. If this be the case, anthranol, or rather its ketonic tautomeride, anthrone, ought to be obtained by carrying out the hydrolysis under such conditions that the nitrous acid is destroyed as rapidly as formed. Hydriodic acid seemed to be a suitable reagent for this purpose, as it was found that, under the experimental conditions employed (acetic acid solutions heated on the water-bath), anthrone is not reduced by hydriodic acid and is not oxidised to any appreciable extent by iodine. The hydrolysis of the acetate or chloride by hydriodic acid takes place very readily with the instantaneous liberation of iodine, but the product is not anthrone but anthracene. It therefore follows that in the case of nitrodihydroanthranol the re-establishment of the "bridge" bond must take place by loss of nitric acid, and that the production of dianthrone must be due to the direct oxidation of anthracene by nitric acid. That dianthrone can be formed by the direct oxidation of anthracene is well known, and dianthrone is sometimes present in commercial samples of anthraquinone (D.R.-P. 340, 592). Satisfactory yields, however,

are obtained only by the decomposition of nitrodihydroanthranol, so that it would seem probable that oxidation takes place most easily when the anthracene is, so to speak, in the nascent state.

It seemed probable that in the case of the ethers of nitrodihydroanthranol re-establishment of the "bridge" bond would take place by loss of nitrous acid and the formation of an anthranyl ether. In the case of the methyl ether (VIII) this is not so, as both alkali and cold pyridine cause an immediate loss of methyl alcohol and production of nitroanthracene in quantitative yield.

K. H. Meyer and Sander (*Annalen*, 1913, 396, 150) obtained nitroanthrone (X) in 80 per cent. yield by nitrating anthrone in acetic acid suspension. The mechanism of this reaction may consist in the addition of nitric acid to the enolic anthranol (IV), and subsequent loss of water from the resulting *gem*-dihydroxy-compound (IX), although no additive compound can be isolated.

In view of the great ease with which anthranol is oxidised it is rather surprising that no dianthrone is produced by a side reaction if the above mechanism is correct. In order to test this theory of the formation of an additive compound, the nitration of anthranyl methyl and ethyl ethers was studied, as in these cases it seemed possible that the additive compounds (XI) might be isolated as such or as their acetates. In neither case could any additive compound be obtained, the reaction leading to a mixture of nitroanthrone and dianthrone in the ratio of approximately 2 : 1. The production of nitroanthrone is easily explicable on the assumption that the hypothetical additive compound (XI) at once loses alcohol. The production of dianthrone together with a little anthraquinone points strongly to a side reaction taking place in which anthranol is oxidised, and this is easily accounted for when it is remembered that the anthranyl ethers are very easily dealkylated by acids. The fact that dianthrone is formed during the nitration of the anthranyl ethers, but is not formed during the nitration of anthrone itself, renders it somewhat improbable that in the latter case nitration takes place through the enolic anthranol.

In dibromodihydroanthracene (XII) the tendency to re-establish the "bridge" bond is very great, so that 9-bromoanthracene is formed at the ordinary temperature. In spite of this, pyridine leads to a dipyridinium salt (XIII), and the same compound is

formed when anthracene is treated simultaneously with pyridine and bromine (Barnett and Cook, T., 1921, 119, 901), although this on warming with pyridine gives anthranylpyridinium bromide (XIV) with re-establishment of the "bridge" bond.

From 9-nitroanthracene, a dibromide (XV) cannot be isolated, although this probably has a transient existence, since nitro-anthranylpyridinium bromide (XVI) is readily obtained by treating solutions of nitroanthracene in pyridine with bromine, and nitro-anthracene on bromination in other solvents loses its nitro-group and passes into dibromoanthracene (XVII).

Here the tendency to re-establish the "bridge" is very great and takes place in two directions, according to the experimental conditions. Obviously the nitro-group stabilises the "bridge" bond, and this is confirmed by the fact that 9:10-dinitroanthracene will not react with bromine, and is in general harmony with the decreased reactivity of the nucleus in almost all aromatic compounds containing a nitro-group.

In the case of anthranol (IV) the hydroxyl group would be expected to increase the reactivity of the "bridge" bond, and the great ease with which anthrone is brominated may be due to addition taking place to the enolic (anthranol) form with subsequent loss of hydrogen bromide from the *gem*-halohydrin, but the possibility that the reaction is one of the direct replacement of a mobile hydrogen atom is not excluded:

When the bromination is carried out in the presence of pyridine, the reaction is more complicated owing to the possibility of simultaneous oxidation taking place, and if the calculated amount of bromine (1 gram mol.) is used the product will be an insoluble nitrogenous substance of unknown constitution. By employing

only half the calculated amount of bromine, however, it is possible to obtain anthranyl (or hydroxy-anthranyl)-pyridinium bromide, although a considerable quantity of dianthrone is always formed at the same time. This bromide is identical with the product obtained by the action of pyridine on bromoanthrone (XVIII) and there is no method of ascertaining the mechanism of its formation.

In the case of the anthranyl ethers, oxidation does not take place and hence the reaction is simpler, the calculated amount of bromine leading to alkoxypyridinium salts (XX). In these cases the reaction must consist, in the first place, in addition (XIX), as the bromoanthranyl ethers do not undergo pyridinium salt formation.

EXPERIMENTAL.

Derivatives of Nitrodihydroanthranol.

Acetate (VI).—The preparation of this compound can be considerably simplified by substituting fuming nitric acid (*d* 1.50; 18 grams for 50 grams of anthracene) for the more dilute acid recommended by Meisenheimer and Connerade (*loc. cit.*), and taking care to maintain the temperature below 30° during the reaction. The required acetate crystallised from the filtered solution after twelve hours, and, after being washed with acetic acid and water, was dried at 100°. The slightly yellow crude product separated in colourless crystals (25 grams) from a mixture of benzene and ether or of chloroform and light petroleum. Dianthrone (25 grams) was obtained by heating the acetic acid liquors from the preparation.

A solution of the acetate in alcohol or methyl ethyl ketone is yellow, but darkens on warming owing to formation of nitroanthracene. This compound was also readily obtained by dissolution of the acetate in cold pyridine, and was identified by its melting point, 146–147°, which was not depressed when the product was mixed with an authentic sample. The same result was obtained by triturating the acetate with cold dilute aqueous sodium hydroxide solution.

The hydrolysis with sulphuric acid was effected on the water-bath by slowly adding the acetate (10 grams) to 75 c.c. of glacial acetic acid containing 5 c.c. of concentrated sulphuric acid and 10 c.c. of water. Torrents of nitric oxide were evolved. After dilution, the solid was digested with a hot alkaline solution of sodium hyposulphite, and after recrystallisation from xylene was identified as

dianthrone by its conversion into dianthranol and the oxidation of this to dianthraquinone, and also by its reduction to anthrone.

The hydrolysis with hydriodic acid was carried out by slowly adding the acetate 5 grams to glacial acetic acid 50 c.c. and hydriodic acid (*d* 1.7; 10 c.c.), the whole being warmed on the water-bath and a current of carbon dioxide passed through the flask to remove oxides of nitrogen. Iodine was liberated at once and after five minutes the whole was cooled and the precipitate washed with a hot concentrated solution of potassium iodide to remove free iodine. The residue was recrystallised from pyridine and identified as anthracene by the method of mixed melting points.

Chloride (I).—This was prepared by the methods given in the literature and was recrystallised from benzene. The hydrolysis with sulphuric and hydriodic acids, and the identification of the resulting products was effected as described above.

Methyl Ether (VI).—This was obtained by boiling the nitrite with methyl alcohol (Meisenheimer and Connerade, *loc. cit.*). It was instantly converted into nitroanthracene by cold pyridine, and also by aqueous sodium hydroxide.

Derivatives of Anthranol.

Alkyl Ethers.—The preparation of the methyl and ethyl ethers is more readily effected by means of methyl and ethyl toluene-*p*-sulphonate than by the alkyl sulphate (K. H. Meyer and Schlösser, *Annalen*, 1921, 420, 128). Anthrone (50 grams) was boiled under reflux with 350 c.c. of alcohol, and the boiling solution treated alternately with small quantities of 30 per cent. aqueous sodium hydroxide (100 c.c. in all) and technical methyl toluene-*p*-sulphonate (in all, 90 grams dissolved in 50 c.c. of warm alcohol). After the whole of the ester and alkali had been added, the boiling was continued for forty minutes and the solution then cooled and poured into a large volume of water. The resulting precipitate was digested with an alkaline solution of sodium hyposulphite and recrystallised from alcohol. It then melted at 97–98°, alone or when mixed with a sample made by the methyl sulphate method (K. H. Meyer and Schlösser give the melting point as 94°). The yield of the pure product was 31 grams.

The ethyl ether was obtained in the same way, but very much better yields were obtained if potassium hydroxide was used (40 grams of anthrone, 200 c.c. of alcohol, 110 grams of technical ethyl toluene-*p*-sulphonate, and 20 c.c. of a 50 per cent. aqueous solution of potassium hydroxide diluted with 80 c.c. of alcohol). The ether separated from the hot liquor on cooling, and, after treatment with

a hot alkaline solution of sodium hyposulphite, was purified by recrystallisation from slightly aqueous acetone.

Both ethers are very easily dealkylated by acids, warming on the water-bath for two to three minutes with acetic acid containing a few drops of sulphuric acid leading to complete hydrolysis. For this reason, both ethers are readily oxidised to dianthrone by boiling with ferric chloride in acetic acid solution. They are not, however, oxidised by mercuric acetate in pyridine solution* even on prolonged boiling, although this oxidising agent at once converts anthrone into dianthrone even in the cold.

The nitration of these ethers was effected by suspending or dissolving 10 grams in 40 c.c. of glacial acetic acid and then slowly adding exactly one molecular proportion of concentrated nitric acid (*d* 1.42), diluted with five times its volume of glacial acetic acid. After keeping for two hours, the yellow solid was washed with acetic acid and water and then boiled with about 600 c.c. of a 3 per cent. solution of sodium hydroxide. The deep red solution was filtered into excess of dilute acetic acid, and the precipitated nitroanthrone washed and dried. It was found that 7.6 grams of the crude nitration product gave 4.1 grams of nitroanthrone. The nitroanthrone was purified by recrystallisation from carbon disulphide and after being washed with ether formed colourless needles which on heating decomposed with violent evolution of gas at 146°.† The identification was completed by comparison with a sample of nitroanthrone made by a different method, and by the preparation of nitroanthranyl acetate. This acetate was very easily obtained by adding acetic anhydride to a cold solution of nitroanthrone in pyridine. After a few minutes, the deep red colour of the solution turned to yellow and the acetate was then precipitated by the addition of water. After recrystallisation from a mixture of chloroform and light petroleum, it melted at 182—184°. Samples of the acetate made from nitroanthrone prepared either by the nitration of anthrone or of methyl or ethyl anthranyl ether all melted at the same temperature, either alone or when mixed with one another.

* The use of this oxidising agent does not seem to have been described previously, although it is a very convenient one for some purposes, oxidation taking place with the precipitation of metallic mercury. It at once oxidises dianthranol to dianthraquinone, but has no action on formaldehyde, benzaldehyde, tartaric acid, and most monohydric phenols.

† K. H. Meyer and Sander (*Annalen*, 1913, **396**, 150) give the m. p. as 136—137°, and Meisenheimer and Connerade (*loc. cit.*) as 148°. Several samples, prepared both by the above method and by the direct nitration of anthrone, were found to decompose sharply at 146°. The decomposition does not appear to be accompanied by melting, but the evolution of gas is so violent that the material is projected from the capillary tube.

The portion of the nitration product which was insoluble in sodium hydroxide was digested with an alkaline solution of sodium hypsulphite, and after recrystallisation from xylene was identified as dianthrone by the usual means. The yield was 2 grams from 7.6 grams of the crude nitration product.

Methoxyanthranilpyridinium Bromide.—Bromoanthranil methyl ether does not react with pyridine to give a quaternary salt, but such a salt is readily obtained by the combined action of bromine and pyridine on anthranil methyl ether. Bromine (2.5 c.c.), dissolved in pyridine (15 c.c.), was slowly added to a solution of anthranil methyl ether (10.4 grams) in pyridine (25 c.c.), the whole being stirred and cooled in a freezing mixture. After two hours, the solid was collected, washed with pyridine and with ether, and purified by recrystallisation first from very dilute hydrobromic acid and then from a mixture of alcohol and ether, but satisfactory figures could not be obtained on analysis, as the bromide is hygroscopic and retains moisture very obstinately. It was therefore converted into the *picrate* (golden-yellow needles, m.p. 183–185°) and this was recrystallised from a large volume of boiling water (Found: N = 10.9. $C_{26}H_{18}O_8N_4$ requires N = 10.9 per cent.).

The *bromide* appears to have no melting point, but commences to decompose at about 195°. It is sparingly soluble in cold, but easily soluble in hot water, and its aqueous solutions give no colour when boiled with ammonia. With sodium hydroxide, however, a red precipitate is formed at about 80°. It is easily demethylated by hydrochloric acid.

Ethoxyanthranilpyridinium Bromide.—This was prepared in the same way as the methoxy-compound, but as the bromide remained dissolved in the pyridine it was isolated by pouring the solution into dilute hydrobromic acid, and was then recrystallised first from hot water and then from a mixture of alcohol and ether. The resulting faintly yellow, crystalline powder darkened at 205° and melted rather indefinitely at 215°. Owing to its hygroscopic nature, satisfactory analytical figures could not be obtained. It was therefore converted into the *picrate* (golden-yellow needles, m. p. 187–189°) and this recrystallised from a large volume of boiling water (Found: N = 10.5. $C_{27}H_{20}O_8N_4$ requires N = 10.6 per cent.). The *bromide* behaves exactly like the corresponding methoxy-bromide, but the red precipitate with sodium hydroxide is formed somewhat more easily, namely, at about 50°. Neither compound is fluorescent in spite of the presence of the "bridge" bond, thus confirming the opinion already expressed (Barnett, Cook, and Grainger, *loc. cit.*) that the pyridinium group acts as a bathochrome.

Hydroxyanthranyl (or Anthronyl)-pyridinium Bromide.—Bromine (1.25 c.c., 0.5 gram mol.) in pyridine (10 c.c.) was slowly added to anthrone 10 grams in pyridine (25 c.c.), the whole being cooled in a freezing mixture. After keeping over-night, the solid was washed with a little pyridine and then extracted with hot dilute hydrobromic acid. The insoluble portion was recrystallised from xylene and identified as dianthrone by the usual method. The hot hydrobromic acid extract on cooling deposited orange-coloured crystals, which were recrystallised first from dilute hydrobromic acid and then from a mixture of alcohol and ether. They then melted at 187–189°, and direct comparison showed them to be identical with the bromide obtained by treating bromoanthrone with pyridine (Barnett, Cook, and Grainger, *loc. cit.*).

If in the above preparation a whole molecular proportion of bromine were used, the product was an insoluble nitrogenous substance which was very difficult to purify and was not further examined.

Dianthranyl Dimethyl Ether.

Dianthrone (10 grams) was enolised by boiling under reflux for twenty minutes with 100 c.c. of alcohol and 10 c.c. of 30 per cent. aqueous potassium hydroxide. To the boiling solution alternate additions of small quantities of technical methyl toluene-*p*-sulphonate (in all, 30 grams, dissolved in 30 c.c. of warm alcohol) and potassium hydroxide (in all, 25 c.c. of a 30 per cent. aqueous solution) were made, and the whole was finally boiled for a further period of thirty minutes. After cooling, the solid was washed with alcohol and then extracted with boiling water. The yield of the crude product was 10 grams, and by a single recrystallisation from a mixture of benzene and light petroleum it was obtained in almost colourless crystals which melted at 245°. After a further recrystallisation from acetic acid the melting point rose to 247°. This method is more convenient than that described by H. Meyer (*Monatsh.*, 1909, 30, 165) in which methyl sulphate is employed. Dianthranyl dimethyl ether is much more stable than anthranyl methyl ether and is not demethylated by boiling with hydrochloric acid in acetic acid solution. Boiling with anhydrous ferric chloride in acetic acid solution, however, effects demethylation and at the same time oxidation to dianthraquinone.

Conversion of Nitroanthrone and Bromoanthrone into Dianthrone.

(a) Nitroanthrone (1.5 grams) was suspended in 10 c.c. of glacial acetic acid, and 3 c.c. of hydriodic acid (*d* 1.7) were added. On heating, iodine was liberated at once. After boiling for two to

three minutes, the whole was cooled and the solid washed with acetic acid. After digestion with hot alkaline hyposulphite solution, the product was recrystallised from xylene and identified as dianthrone.

(b) Bromoanthrone* in acetic acid suspension was treated with hydriodic acid under conditions similar to those described above. The product was dianthrone, no anthrone or anthraquinone being formed.

(c) Bromoanthrone (5 grams) was suspended in 25 c.c. of glacial acetic acid, and hydrogen sulphide passed through the liquid while the temperature was slowly raised to the boiling point, which was maintained for ten minutes. The product was dianthrone and contained neither anthrone nor anthraquinone.

(d) Bromoanthrone (5.5 grams) was added to a solution of ethyl sodioacetoacetate (1 gram mol.) in anhydrous alcoholic solution and the whole boiled under reflux for ten minutes. The solid deposited from the cooled solution was digested with an alkaline solution of sodium hyposulphite. After recrystallisation from xylene it was identified as dianthrone.

The alcoholic liquors on dilution with water gave only a very small amount of a brown resinous substance.

(e) Bromoanthrone (1 gram mol.) was added to magnesium phenyl iodide (1 gram mol.), prepared in the usual way. After keeping for two hours, the pale yellow solid was triturated with water and then extracted with boiling alcohol to remove a little anthrone. Traces of anthraquinone having been extracted in the usual manner, the residue was found to be dianthrone.

Action of Phosphorus Pentachloride on Anthrone.

By treating anthrone with phosphorus pentachloride, Padova (*Compt. rend.*, 1909, 149, 217) obtained a product which melted at 298–300°, and as he stated that it contained neither phosphorus nor chlorine the view was expressed by one of us (Barnett, "Anthracene and Anthraquinone," 1921, p. 98) that it was probably dianthranyl. Recently, however, it has been found (Barnett and Matthews, *loc. cit.*) that dianthranyl does not melt at 360°, and therefore it was considered desirable to prepare some of Padova's product and examine it. Padova gives no experimental details and therefore the action of phosphorus pentachloride on anthrone

* In brominating anthrone it is quite unnecessary to use sufficient carbon disulphide to dissolve the whole of it, excellent results being obtained by adding bromine to 100 grams of anthrone suspended in 300 c.c. of carbon disulphide. About 25 c.c. of bromine are required, but quite a sharp end-point can be detected when sufficient has been added.

without a solvent, and also in the presence of benzene and pyridine, was examined.

(a) Anthrone (10 grams) and phosphorus pentachloride (20 grams) were heated on the water-bath for about sixteen hours until no more hydrogen chloride was evolved. The product was well washed with water and recrystallised twice from methyl ethyl ketone. It then formed long, yellow needles, which contained chlorine and melted at 209–210° alone or when mixed with dichloroanthracene. A similar result was obtained when the reaction was carried out in benzene solution.

(b) Anthrone (10 grams) was dissolved in hot pyridine (50 c.c.) and the solution cooled and treated with 4.5 grams of phosphorus pentachloride. After being heated on the water-bath for thirty minutes, the whole was poured into a large volume of cold water, and the solution acidified with hydrochloric acid. After being washed with boiling alcohol and cold ether, the solid was twice recrystallised from pyridine and then formed a slightly yellow, crystalline powder which melted and decomposed at 303°. It contained phosphorus but no chlorine, and as it gave anthrone on hydrolysis it was probably anthranyl phosphate (Found: $P = 5.10$. $C_{45}H_{27}O_4P$ requires $P = 4.96$ per cent.).

Anthrone, after being heated with phosphorus trichloride in pyridine solution, was recovered almost unchanged.

Summary.

(i) Experiments have been carried out on the re-establishment of the "bridge" bond when a dihydroanthracene derivative passes into an anthracene derivative.

(ii) Improved methods for the preparation of the alkyl ethers of anthranol have been worked out, and their behaviour towards nitric acid and towards pyridine and bromine studied.

(iii) It has been found that nitroanthrone and bromoanthrone pass very easily into dianthrone in the presence of certain reducing agents, and that bromoanthrone does not react normally with either ethyl sodioacetoacetate or magnesium phenyl iodide.

(iv) The probable mechanism of the oxidation of the phenols has been discussed and evidence collected which points to the first action consisting in the removal of the phenolic hydrogen atom.

(v) The action of phosphorus pentachloride on anthrone has been found to lead to 9 : 10-dichloroanthracene or trianthranyl phosphate according to the experimental conditions employed.

The authors desire to express their thanks to the South Metropolitan Gas Co. for gifts of anthracene and pyridine, and to the Research Fund Committee of the Chemical Society for a grant

which has defrayed some of the expenses of this research. One of them (M.A.M.) is also indebted to the Department of Scientific and Industrial Research for a grant which has enabled him to take part in this work.

CCXXI.—*The Relative Influences of Water Vapour and Hydrogen upon the Explosion of Carbon Monoxide-Air Mixtures at High Pressures.*

By WILLIAM A. BONE, DUDLEY M. NEWITT, and DONALD T. A. TOWNEND.

Introduction.

IN two papers which have recently been contributed to this Journal by H. B. Dixon and N. S. Walls (this vol., p. 1025) and W. Payman and R. V. Wheeler (*ibid.*, p. 1251), respectively, reference has been made to the results of a series of experiments carried out by one of us in conjunction with the late W. A. Haward, concerning the influence of hydrogen upon the explosion of normal carbon monoxide-air mixtures ($2\text{CO} + \text{O}_2 + 4\text{N}_2$) in our bomb apparatus at initial pressures of 50 atmospheres (*Proc. Roy. Soc.*, 1921, [A], 100, 76).

In those experiments it was shown that the replacement of even a small proportion of the carbon monoxide by its volumetric equivalent of hydrogen had a peculiar accelerating influence upon the pressure development in the explosion, which was disproportionate to its amount. Moreover, on p. 83 of Bone and Haward's paper, it was said that their experiments "seem to point to hydrogen being even more potent than its equivalent of steam as a promoter of the combustion of carbon monoxide (although this is a matter needing further investigation), and they suggest that its primary function is to resolve continuously the inert O_2 molecule into an 'active' oxidising condition (that is, into O atoms and 'activated' OH_2), itself being continuously regenerated."

In Payman and Wheeler's recent paper (*loc. cit.*), experiments are described on the relative effects of hydrogen and water vapour upon the speed of uniform movement of flame through a mixture of carbon monoxide and air ignited in an open glass tube (2.5 cm. in diameter and 4 m. long) at atmospheric pressure. Such experiments have led those authors to conclude that "moisture is more effective than hydrogen in promoting the combustion of carbon monoxide."

Although at first sight there may seem to be a contradiction between their results and those obtained in the Bone-Haward experiments, yet a closer examination of the matter will show that both sets of experimental results are correct, the seeming discrepancy between them being entirely due to the widely different conditions under which they were obtained. And here it may be pointed out how great is the difference between conditions of our high-pressure bomb experiments and those prevailing in experiments upon the propagation of flame through combustible mixtures at ordinary pressures.

It is well known that H. B. Dixon showed many years ago how the speed at which detonation is propagated through a mixture of $2\text{CO} + \text{O}_2$ at atmospheric pressure is considerably influenced by the amount of water vapour present, the optimum condition being found to correspond with a saturation of the mixture with water vapour at about 35° . Under such conditions, the speed recorded was 1738 metres per second, as compared with 1305 metres per second for the "dried" mixture, and with 1264 metres per second for the "well-dried" mixture. Payman and Wheeler have recently found that the optimum condition for the propagation of inflammation through carbon monoxide-air mixtures containing between 40 and 45 per cent. of combustible gas is reached at a similar degree of saturation. In other words, it would seem that the effect of water vapour on the speed of the flame at ordinary pressures, whether in the initial stage of inflammation or after detonation has been developed, reaches the maximum when about 6 per cent. of water vapour is present. Moreover, both Dixon and Wheeler's experiments show that in the combustion of carbon monoxide at ordinary pressures the difference between the speeds for a "dried" mixture and one containing the optimum quantity of water vapour is very considerable.

In the course of the further experiments upon the explosion of carbon monoxide-air mixtures at high pressures, which we have carried out since Haward's untimely death, we discovered a new factor which operates very powerfully under such conditions, but which is practically non-existent at ordinary pressures, namely, the energy-absorbing function and "activation" of nitrogen in the combustion of carbon monoxide (*Proc. Roy. Soc.*, 1923, [A.] 103, 205); and it is to circumstances connected with the operation of this hitherto unsuspected factor that the apparent discrepancy in question between low-pressure and high-pressure experiments is to be ascribed.

In the present paper we propose, in the first place, to describe some of the experiments which have led us to believe that water vapour has a smaller influence than hydrogen upon the rate of

pressure development in our carbon monoxide-air experiments, and then to direct attention to certain features of the Bone-Haward experiments which seem to us to be of significance in connexion with the mechanism of the combustion of carbon monoxide.

The Influence of Moisture upon the Explosion of Normal Carbon Monoxide-Air ($2\text{CO} + \text{O}_2 + 4\text{N}_2$) Mixtures at High Pressures.

In the course of our recent experiments, in which normal carbon monoxide-air ($2\text{CO} + \text{O}_2 + 4\text{N}_2$) mixtures were exploded in our bomb apparatus at initial pressures of 50 atmospheres, we endeavoured to determine for our own information what influence (if any) considerable variations in the amount of moisture initially present in the system would have upon the rate of development of pressure energy during the combustion. And as the results of these particular experiments were not included amongst those published in our recent Royal Society memoir, we think it opportune to publish them now, especially in view of those obtained with carbon monoxide-air mixtures at atmospheric pressures by the other workers referred to.

The experiments were undertaken with the idea that, inasmuch as our researches up to then had disclosed the powerful influence of nitrogen activation upon carbon-monoxide air explosions at such high pressures (which is, as we have recently found, almost negligible at ordinary pressures), water vapour might possibly be found to play a relatively subordinate part in the rate of development of pressure energy; and the experiments now to be described have shown this anticipation to be correct.

Seeing our bomb apparatus and experimental method have so recently been described in our Royal Society memoir (*q.v.*), the reader may be referred to it for details of the same. It will suffice for our present purposes to specify the particular conditions under which the experiments referred to herein were carried out, and to reproduce on a reduced scale some of the pressure-time curves obtained in them. We may say, however, that no small-scale reproductions such as are possible with a paper of this sort can convey a really adequate idea of the factors operative in our experiments; these can only be properly judged after a careful study of the actual photographic records themselves. Moreover, it should be understood that what these time-pressure records show chiefly is: (1) the rate at which the potential energy of the explosive mixture fired is transferred into kinetic (pressure or temperature) energy of the products; (2) the ratio of the maximum pressure attained on explosion to the initial pressure at which the mixture was fired, and (3) the rate of the subsequent cooling.

Also it should be borne in mind that the experiments recently

published in our Royal Society memoir have shown conclusively that the considerable time lag which is always observed in the attainment of maximum pressure when normal carbon monoxide-air mixtures are exploded in our bomb apparatus at high pressures is due in no way to any inherently slow-burning property of carbon monoxide, but rather to a peculiar power which nitrogen possesses of absorbing part of the (radiant) energy developed by the combustion of carbon monoxide under such conditions.*

Our experiments relating to the effects of moisture on the explosion of normal carbon monoxide-air mixtures at initial pressures of 50 atmospheres are divisible into four series, namely :

(A) Those in which (a) all the gases used had been previously well dried by storage for some weeks in cylinders containing freshly distilled phosphoric oxide, (b) and the bomb itself and all connexions had been thoroughly dried out in a current of hot dry air, and the explosion chamber had been kept evacuated, for at least three or four days immediately preceding each experiment, in contact with redistilled phosphoric oxide which was only removed just prior to the separate introduction of the previously well-dried ingredients of the explosive mixture. Moreover, in introducing the gases into the bomb from the separate storage cylinders they were in each case very slowly passed through a steel cylinder 8 inches long, filled with freshly distilled phosphoric oxide. By such measures it was hoped to ensure the maximum of dryness possible in experiments where an explosive mixture has to be fired in a massive steel bomb; and although complete dryness is perhaps unattainable under such

* Although the present paper is not primarily concerned with the question of the "activation" of nitrogen in carbon monoxide-air explosions at high initial pressures (and therefore we do not propose dealing with that aspect of the matter in it), yet, in order that readers may better understand the time-pressure curves published in the text, it is necessary to state that the experiments referred to (and others shortly to be published) prove beyond all reasonable doubt that at such high pressures a considerable part of the peculiar radiation emitted by the burning carbon monoxide (which otherwise would have been absorbed by the walls of the explosion chamber) was intercepted and absorbed by the nitrogen present, whereby it became chemically "activated." Any radiant energy so absorbed would not affect the maximum pressures reached in the explosions, unless the conditions of a particular experiment permitted (as they sometimes did) the secondary oxidation of part of the "activated" nitrogen to nitric oxide during the combustion period, in which case part of the kinetic energy developed by the explosion would also be absorbed, thereby lowering the maximum pressure attained. Finally, the radiant energy so absorbed by the nitrogen, *plus* part of the kinetic energy (if any) absorbed during the combustion period in forming nitric oxide from it, would be gradually liberated in a kinetic form after the attainment of the maximum pressure, as the "activated" nitrogen slowly reverted to the ordinary form (and part of any nitric oxide formed was unburnt), thus retarding the cooling period.

conditions, it is difficult to see how in the circumstances our drying arrangements, in respect of both the bomb apparatus and the gases, could have been appreciably improved. This group of our experiments will be referred to as the "dry" series.

(B) Experiments in which (a) the gases employed were directly introduced into the bomb from their respective storage cylinders without any preliminary or intermediate drying (that is, they would contain probably about 17 mm. of water vapour in 50 atmospheres), but (b) the explosion chamber had been previously dried out in a current of hot dry air. This group will be referred to as the "undried" series.

(C) Experiments in which the undried gases were slowly passed into the bomb from their respective storage cylinders through a tube packed with glass wool which had been previously wetted with water. They would thus carry forward into the explosion chamber appreciably more water vapour than was the case in the "undried" group. They will be referred to as the "moist" series.

(D) An experiment in which, not only were the gases introduced into the bomb as in (C), but also the walls of the explosion cavity had been previously thoroughly wetted with distilled water. This will be referred to as the "wet" experiment.

The results of several typical experiments in each group are tabulated as follows:—

P_i = the initial firing pressure in atmospheres.

P_m = the maximum pressure in atmospheres recorded in the explosion.

P_f = the "corrected" final pressure in atmospheres of the cooled combustion products.

t_m = the time in seconds taken for the attainment of maximum pressure.

TABLE I.

Showing the effect of varying hygroscopic conditions upon the explosion of $2\text{CO} + \text{O}_2 + 4\text{N}_2$ mixtures when fired at 50 atmospheres.

Series.	Hygroscopic state of gases and explosion chamber.	Initial temp.	Pressures.			t_m Secs.
			P_i	P_m	P_f	
A	Dry	19.0°	50	401	42.65	0.18
		18.9	50	396	42.65	0.18
		19.1	50	398	42.50	0.18
		18.0	50	400	42.50	0.18
		18.2	50	409	42.71	0.15
B	Undried	17.8	50	414	42.30	0.15
		17.0	50	411	42.20	0.13
		22.5	50	398	42.4	0.18
C	Moist	23.0	50	396	—	0.20
		22.8	50	390	42.1	0.19
D	Wet	23.1	50	380	41.5	0.17

From the above it would appear that, so far as the time taken for the attainment of the maximum pressure (t_m) is concerned, there is practically no difference between the "dry" and either the "moist" or the "wet" series; for in all these cases it amounted as nearly as may be to 0.18 second. In the "undried" series (that is, when the water vapour present would probably not much exceed 1 in 2000) the time was somewhat shorter, namely, 0.13 to 0.15 second. It therefore seems clear that the presence of a very much smaller amount of water vapour sufficed to produce the optimum combustion conditions in our said experiments than was found necessary either by H. B. Dixon for the fastest propagation of detonation through $2CO + O_2$ mixtures at ordinary pressures, or by Payman and Wheeler for the fastest inflammation of carbon monoxide-air mixtures also at atmospheric pressure.

Four typical pressure-time curves (one from each series of experiments) are reproduced in Fig. 1, and analyses of them are shown in Table II. From these analyses it will be seen that, with

% fall in 0.5 second.	{ 9	10	11.5	20

the exception of series *B*, where the conditions were the most favourable, there was little, if any, difference between the speeds at which the pressure was developed during the respective combustion periods. Also, the observed rates of cooling after the attainment of maximum pressure in series *A*, *B*, and *C* were all practically the same. In the "wet" experiment *B*, the maximum pressure attained was appreciably lower than in any of the others, a circumstance probably due to heat absorption caused by some evapora-

ation of water from the wet walls of the explosion cavity during the combustion period.

The Influence of Nitrogen.

In order that the reader may better realise the extent to which the presence of nitrogen retards both the attainment of the maximum pressure and the subsequent cooling in carbon monoxide-air explosions at such high pressures, we need only give the following comparative figures (Table III) relating to experiments in which iso-

FIG. 1.

TABLE III.

Mixture exploded.	Total energy developed. K.C.U.'s.	P_t Atms.	t_m Sec.	P_m		Actual pressure fall in 1 sec. after t_m . Atms.	% Pressure fall in 1 sec. after t_m .
				Obs. atms.	Corr.* atms.		
$2CO + O_2 + 4N_2$	10.2	50	0.19	409	440	93	23.75
$2CO + O_2 + 4O_2$	10.0	50	0.005	460	460	200	43.5
$2CO + O_2 + 4CO$	10.4	50	0.010	450	455	197	44.0

* In order to make the observed figures strictly comparable among themselves, it is necessary to apply to them a "cooling correction" because of the different time taken to reach P_m ; and it is such "corrected" values which must be considered in estimating the magnitude of any "kinetic energy" absorption during the "combustion period" in the N_2 diluent experiments.

thermic mixtures $2\text{CO} + \text{O}_2 + 4\text{R}$, where $\text{R} =$ a diatomic diluent ($\text{N}_2 + \text{O}_2$ or CO), were exploded in our bomb apparatus at an initial pressure of 50 atmospheres in each case. Apart from any specific "energy-absorbing" function of nitrogen during the combustion, the volumetric heat capacities of the three diluents would be approximately the same, and therefore both the maximum pressures attained and the subsequent ratio of cooling should be the same also. And in the two experiments in which nitrogen was excluded this is seen to be the case; in both cases the pressure falls after t_m corresponded with simple cooling curves unaccompanied by any exothermic effects. But with nitrogen as the diluent, the cooling after t_m was greatly retarded by an exothermic effect the total magnitude of which in 1.0 second was incomparably greater than that of the kinetic energy absorbed during the explosion period up to t_m , a circumstance which we attribute to an absorption of radiant energy by the nitrogen during the combustion period.

It is therefore clear that the nitrogen is the predominating factor in determining the rate of pressure development in carbon monoxide-air explosions at such high pressures as have been employed in our experiments.

The Influence of Hydrogen.

As already stated, when the publication of the Bone-Haward experiments (*loc. cit.*) directed attention to the effect which the progressive replacement of carbon monoxide by hydrogen has upon the rate of pressure development in the explosion of a normal carbon monoxide-air mixture at an initial pressure of 50 atmospheres, the predominating influence of nitrogen upon the whole course of events had not been discovered, and was at that time quite unsuspected. Hence, it is necessary now to review the former interpretation of the said phenomenon in the light of the new knowledge gained from our recent experiments.

Before doing so, however, we must deal with the claim recently made in Payman and Wheeler's paper (*loc. cit.*, 1258) that "further information is obtainable respecting the applicability of the law of speeds from the work of Bone and Haward in the combustion of mixtures of hydrogen, carbon monoxide, and air at high initial pressures," and the inference flowing therefrom. It should be understood that the paper in question was sent in (February 14th, 1923) some weeks before our new results were published (April 26th, 1923), and (as would appear) without any knowledge thereof; and therefore any statement made therein about the Bone-Haward results suffers from its authors not having known what undoubtedly

is the predominant factor in determining the rate of pressure development in a carbon monoxide-air explosion at such high initial pressures. It is to be regretted that they had never studied the original photographic pressure-time records obtained in the Bone-Haward experiments before passing judgment upon them. For these records all exhibit a characteristic feature which hardly agrees with the flame-speed law; if indeed the Bone-Haward data are at all relevant in such connexion, a point which seems to us at least open to question. Moreover, in view of what is now known concerning the relatively small influence of water vapour in the explosion of a normal carbon monoxide-air mixture at the high pressures employed by us, we cannot assign any weight to Payman and Wheeler's calculation ("from the results recorded for the two mixtures $2\text{H}_2 + \text{O}_2 + 4\text{N}_2$ and $1/12\text{H}_2 + 23/12\text{CO} + \text{O}_2 + \text{N}_2$ ") that what they term "the effective time" for the mixture $2\text{CO} + \text{O}_2 + 4\text{N}_2$ in the Bone-Haward experiments is 0.038 second, a figure which seems to us to be wholly fanciful.

Considering that what the photographic pressure-time records obtained in such high-pressure explosion experiments primarily show is the rate at which the potential energy of the explosive mixture is transferred into kinetic (that is, pressure) energy of the products, and the time taken to attain the maximum pressure (t_m), it seems to us that the data so obtained have no necessary connexion with flame-

speeds, unless indeed it is certain that in all circumstances the moment of attainment of maximum pressure exactly synchronises in our apparatus with that at which the flame point just reaches the head of the Petavel manometer, which is situated immediately opposite the ignition wire. Payman and Wheeler seem to assume that such is, or must be, the case; but we are not so sure about it. For the time being, it may be regarded as a debatable point. Besides which, even were the applicability of an empirical "flame-speed law" to the conditions of such bomb experiments conclusively proved, it would not help us much in the interpretation of the mechanism of the combustion.

The Bone-Haward principal data are shown in Table IV, and a selection of the pressure curves of the $2(\text{CO} + \text{H}_2) + \text{O}_2 + 4\text{N}_2$ series (the one under discussion) have been as faithfully as possible reproduced from the original time-pressure curves in Fig. 2, in such a manner as to show on one diagram the precise contour of the rising pressure curve up to t_m , together with a short portion of the subsequent cooling period, in each case.

Σ = the thermal equivalent of the total energy liberated in the explosion calculated from the actual composition of the mixture fired.

* This is included as being the repetition by the present authors of the experiment upon which Haward was actually engaged when he met his death.

† In this experiment the record was interrupted 0.75 sec. after t_m .

In all the experiments in which hydrogen was present, including those of a normal hydrogen-air ($2\text{H}_2 + \text{O}_2 + 4\text{N}_2$) mixture, the

explosion was marked by a distinct "click" (which is never heard in our carbon monoxide-air explosions), and the rising pressure curves exhibit a common feature in that *for the greater part of the rise the lines are all as nearly as may be parallel, irrespective of the magnitude of t_m* , which varied from 0.005 second for the normal hydrogen-air mixture up to 0.030 for the $1/12 \text{ H}_2 + 23/12 \text{ CO} + \text{O}_2 + 4\text{N}_2$ mixture. Such a general feature is capable of only two explanations, namely: *either* (a) that in all the experiments in question (which were made in two series at some months apart, namely, the first seven between May 18th and June 24th, 1920, and the remaining six between October 12th and November 3rd, 1920), and in no others during the research (either before or since), the recording manometer had been subject to some abnormal kind of mechanical lag affecting the first portion only of the rising pressure curve—a supposition which we think highly improbable; *or* (b) that the records reproduced the course of the rising pressure as faithfully as in all other experiments, and therefore that, as regards the greater part of the actual combustion period, the rate of pressure development always closely simulated that observed in a hydrogen-air explosion under like conditions—which seems to be the more reasonable view of the matter.

At the time when the Bone-Haward results were published, it was inferred, from the then known facts, that in some manner hydrogen was "capable of imposing its own character upon the whole course of the subsequent combustion at such pressures." We now know that the comparative slowness of the pressure development in the explosion of carbon monoxide-air mixtures at such high pressures is neither primarily due to any inherent slow-burning property of carbon monoxide, nor much affected by the amount of water vapour present in the system. For if, instead of progressively replacing the carbon monoxide of their carbon monoxide-air mixtures by hydrogen (as they did), Bone and Haward had wholly replaced the nitrogen by either oxygen, carbon monoxide, or argon, the time taken for the attainment of the maximum pressure would have been reduced from 0.18 second to 0.005, 0.010, or 0.025 second, respectively. And it is sad to recall that the accident which so tragically ended poor Haward's life happened in the first experiment in which he ever attempted to test the result of replacing the nitrogen in a normal carbon monoxide-air mixture by oxygen; so that whilst he died on the verge of discovering the further fact which would have opened our eyes to the important part played by nitrogen in such explosions, his results were published in ignorance of it.

Reviewing the Bone-Haward experiments in the light of the new

knowledge since gained as the result of their continuance by us, it now seems reasonable to suppose that were the nitrogen functioning merely as a diatomic diluent, and without any specific "energy-absorbing" effect, in the explosion of a normal carbon monoxide-air mixture at initial pressures of 50 atmospheres, the value of t_m , instead of actually being about 0.180 second, would lie somewhere between the 0.005 second recorded for a $2\text{CO} + \text{O}_2 + 4\text{O}_2$ mixture and the 0.025 similarly found for a $2\text{CO} + \text{O}_2 + 4\text{Ar}$ mixture under like conditions, with probably a fairly close approximation to the former value. Also, that the rate of cooling immediately after t_m would involve a pressure fall of $0.435 P_m$ in one second, instead of the $0.25 P_m$ actually observed. The difference between these actual and suppositional values is to be ascribed to the peculiar "energy-absorbing" function exerted by the nitrogen in such experiments in addition to its purely diluent action.

A careful re-examination of the pressure-time curves has shown unmistakably that the effect of the progressive replacement of carbon monoxide by hydrogen in the normal carbon monoxide-air mixture was largely to prevent or counteract the peculiar "energy absorbing" function of the nitrogen. Apparently nearly one-third of such function was prevented or counteracted by the replacement of merely one-twenty-fourth part of the carbon monoxide by its hydrogen equivalent, and the whole of it had been suppressed by the time such replacement had reached the half-way (1 : 1) stage.

We have also obtained definite evidence from experiments with mixtures corresponding to $2\text{CO} + \text{O}_2 + 6\text{Ar}$, that substitution of hydrogen for a small part of the carbon monoxide does have a specific accelerating effect upon the rising pressure curve much greater than would be produced by any addition of water vapour. It would therefore appear that, under our experimental conditions, hydrogen has a direct accelerating influence upon the combustion of carbon monoxide quite apart from any indirect effect which it also has in counteracting the influence of nitrogen when that constituent is present. Pending further investigation of the matter, which we are engaged upon, this is as much as can be said about it for the moment.

Concluding Remarks.

So far as the facts known up to the present are concerned, they seem to harmonise quite well with the view tentatively put forward on pp. 81 and 82 (*q.v.*) of the Bone-Haward memoir (*loc. cit.*) concerning the mechanism of the combustion of carbon monoxide. It may be pointed out that this view is essentially a modification in one important particular of that advanced by H. B. Dixon forty years

ago to explain his discovery of the mutual inertness of dry carbon monoxide and oxygen in flames. He supposed that the carbon monoxide is oxidised by OH_2 (but not by O_2) molecules in flames, the resulting hydrogen being immediately burnt to steam, which was thus continuously regenerated as follows: (a) $\text{CO} + \text{OH}_2 = \text{CO}_2 + \text{H}_2$ and (b) $2\text{H}_2 + \text{O}_2 = 2\text{H}_2\text{O}$.

Payman and Wheeler (*loc. cit.*, p. 1250) seem to regard such a supposition as affording a complete explanation of their results. If, however, only such interactions (and no others) occur, it is difficult to understand why the spectrum of a flame of pure (moist) carbon monoxide, whilst exhibiting the "steam lines," is in other respects so unlike that of hydrogen burning in air, or whence arises the characteristic colour of a carbon monoxide flame burning in air. The characteristic spectrum of a carbon monoxide flame, which extends far into the ultra-violet, must surely be due to the formation of molecules (or complexes) in a much more highly vibratory state than would be likely to arise merely by interactions between CO and OH_2 molecules.

In the Bone-Haward paper it was tentatively suggested that an unstable vibratory H_4O_2 complex, initially formed of the interaction of O_2 and H_2 molecules, decomposes in each of two ways, simultaneously yielding $\cdot\text{OH}_2$ molecules and $\cdot\text{O}$ atoms, both of which are capable of oxidising carbon monoxide, as follows:

$$100 \left(\begin{array}{c} \text{O} < \text{H} \\ | \\ \text{O} < \text{H} \end{array} \right) = \frac{\left\{ \begin{array}{l} \text{(i) } 2n \cdot \text{OH}_2 \\ \text{(ii) } (100-n) (2\text{O} \cdot + 2\text{H}_2) \end{array} \right.}{}$$

The ratio $n/100 - n$ would obviously depend upon both temperature and environment; the higher the temperature, and the less hydrogen in the environment, the less the magnitude of n . Collisions between CO and $\cdot\text{O}$ would give rise to highly vibratory O:C:O systems, emitting a characteristic radiation; and it may be that such radiation is of the particular kind which N_2 molecules can absorb. On the other hand, interaction between CO and $\cdot\text{OH}_2$ would presumably give rise to CO_2 in a much less highly vibratory condition; and there is conclusive evidence that the presence of hydrogen in the mixtures exploded militates against N_2 -activation. This hypothesis is not put forward as being a complete or final explanation of the case, but only as one worthy of serious consideration, and in harmony with the facts as at present known. It may have to be modified, supplemented, or even abandoned in favour of some better one, as the experimental investigation of the matter proceeds.

In Dixon and Wall's recent paper (*loc. cit.*, p. 1031), it is suggested that "pure carbon monoxide and oxygen do not combine with explosion because the product—carbon dioxide—would be above the temperature at which it would be mainly dissociated." Possibly this may apply to the propagation of the explosion wave through a $2\text{CO} + \text{O}_2$ mixture at atmospheric pressure. But when such a mixture was fired in our bomb at an initial pressure of 21.4 atmospheres, a maximum pressure of 24.5 atmospheres was developed in 0.005 second; after which the cooling period immediately set in without the slightest sign of any "after-burning." Assuming that the "chemical contraction" involved in the passage from $2\text{CO} + \text{O}_2$ to 2CO_2 was completed, at the moment of maximum pressure, the temperature at that instant would have been of the order of 5000° . It would not, therefore, seem as though "dissociation of carbon dioxide" is a limiting factor in our experiments.

There are grounds for thinking that further light upon this very complex subject may be gained from a spectroscopic investigation of hydrogen and carbon monoxide-air flames, and more particularly of the effects of gradually adding hydrogen to a carbon monoxide flame. This is an aspect of the problem which, although most fundamental, has not yet received sufficient attention. And with a view to the importance of making good the deficiency of our knowledge in such direction, experiments have already been started at the Imperial College with the kind collaboration of Professor A. Fowler. For it can scarcely be denied that a solution of the long-debated question of how carbon monoxide burns would prove to be the key to the understanding of gaseous combustion. And there is yet much to be learned.

In conclusion, our thanks are due (a) to the Government Grant Committee of the Royal Society for grants out of which the expensive apparatus employed in the research has been paid for, and (b) to the Department of Scientific and Industrial Research for maintenance grants, which have enabled two of us (D.M.N. and D.T.A.T.) to devote our whole time to the work.

CCXXII.—*The Action of Silica on Electrolytes.*

By ALFRED FRANCIS JOSEPH and JOHN STANLEY HANCOCK.

It is well known that when silica is added to a solution of a simple electrolyte such as sodium chloride, a change takes place which is shown by the solution becoming acid. Many of the explanations of such phenomena are based on rather complicated theories relating to the mechanism of adsorption, and the object of the present communication is to suggest that the observed changes can be sufficiently accounted for on the lines of straightforward chemical reactions.

I.—*The Action of Silica on Salt Solutions.*

Figures are given by Mellor ("Quantitative Analysis," 1913, p. 175) showing that silicic acid is soluble in sodium chloride solution, the cause being stated to be the formation of sodium silicate.* This solubility can be demonstrated equally well with anhydrous silica, and the following is an example of the results we have obtained by heating it with salt solution on the water-bath for four hours :

5% Sodium chloride solution alone gave...	0.0036	gram of SiO_2 per litre.
Silica and water	0.0320	" " " "
Silica and salt solution	0.0420	" " " "

There was, therefore, an appreciable amount of silica brought into solution by the sodium chloride.

The reaction taking place consists presumably in the formation of a silicate of sodium and the liberation of hydrochloric acid; the production of acid is demonstrated by measuring the hydrogen-ion concentrations (p_H) of the silica suspension and the sodium chloride before and after mixing.

The experiment was tried with washed silica which had not been dried after washing, and also with another specimen which had been ignited at a red heat. A third experiment was carried out with silica specially purified by washing ten times with hot 20 per cent. hydrochloric acid, the operations being carried out in platinum or silica vessels except for a few minutes when the suspension was being centrifuged to allow the wash liquor to be poured off; the glass centrifuge tube was well steamed immediately before use. Filter-papers were not used at all in this work. The p_H measurements were made electrometrically with a Leeds and Northrup potentiometer outfit and a Clark's calomel electrode with $N/10$.

* The solubility of silica in sodium chloride solutions is also dealt with by Lenher and Truog (*J. Amer. Chem. Soc.*, 1916, **38**, 1058).

potassium chloride; all *E.M.F.* readings were corrected for temperature.

The mixture of 1 part of silica with 50 parts of solution was kept for twenty-four hours at the temperature of the room before the p_H values were determined.

The results were as follows :

Effect of Silica on Sodium Chloride Solution.

Treatment of silica.	Washed with water.	Washed and ignited.	Ten times washed with acid and ignited.
p_H of silica suspension in water	7.12	6.97	6
p_H of 5% NaCl solution	6.52	6.52	6.69
p_H of mixture	5.33	5.55	3.96

The first two preparations were definitely alkaline, the neutral point at the temperature of the experiment being 6.8; the third sample was probably nearly pure, as the p_H of the distilled water (the determination of which is always difficult) is usually about 6.

The formation of acid is clearly shown. The other product of the reaction is probably a complex silicate of sodium containing much silica which, although only very slightly soluble in water, yields a markedly alkaline solution. This was observed by washing the residue from the experiments just described to remove most of the hydrochloric acid and sodium chloride. The presence of a sparingly soluble salt was indicated by the difficulty in raising the specific resistance of the suspension to more than about 50,000 ohms; at this stage its p_H was determined and found to be 7.92 and 8.18 in two separate experiments, thus demonstrating satisfactorily the presence of an alkaline substance.

Sparingly soluble sodium salts of this kind probably exert great influence on the properties of soil minerals and the possibility of their existence is apt to be overlooked. Thus Mukherjee (*Phil. Mag.*, 1922, [vi], 44, 343) rejects a chemical view of base exchange in soils, as it would be necessary "to postulate the existence of insoluble salts of alkali metals in a large number of cases." Bearing in mind, however, the relative meaning of the word "insoluble," many such salts actually do exist, metaphosphates and complex silicates being familiar examples, and an illustrative substance can readily be obtained by igniting 3 parts of silica with 1 part of sodium hydroxide until a clear glass is obtained. A preparation of this kind was found to have dissolved to the extent of only 0.05 gram per 100 c.c. after standing in contact with water for twenty-four hours with frequent shaking; the solution was strongly alkaline.

A detailed study of some of these complex silicates would doubt-

less throw light on many properties of soil minerals and clays which are at present very difficult to explain.

The following figures have been obtained for some other salt solutions, the silica used having been purified by three washings with acid. All suspensions were made with 1 part of silica to 50 parts of solution, the temperature was about 33°, and time of contact twenty-four hours.

Effect of Silica on Various Salt Solutions.

	5% Sodium sulphate.	0.2% Calcium sulphate.	5% Ammonium chloride.	5% Calcium chloride.
p_H of salt solution alone	6.44	6.61	4.92	6.08
p_H of silica + salt solution	4.72	6.31	3.59	4.59

II.—*The Action of Silica on Acids.*

No such simple reaction as suggested in the last paragraph would apply to the removal of an acid from solution by means of silica. This effect has been referred to by Mukherjee (*Nature*, 1922, 110, 732), who states that "silica (gel) has been found to adsorb appreciable quantities of acids, for example, acetic, citric, hydrochloric, and nitric." We have confined ourselves to experiments with hydrochloric and citric acids and ignited silica and have only obtained a positive result when the silica was incompletely purified, and in consequence slightly alkaline. The experiments were made with silica purified by a few washings with water, by prolonged washing with water, and by washing with acid as referred to in the previous section. The operations were carried out as before, those with the highly purified material being conducted entirely in platinum and silica vessels except for the short time during which it was being centrifuged to remove the wash liquor. In all cases the silica was ignited before it was added to the acid. The acid used was adjusted to a p_H of about 3.5, the actual value being determined at the same time as that of the mixture. The proportion of silica to solution and other conditions of the experiments were the same as before.

Effect of Silica on Hydrochloric Acid.

Silica treatment.	Water-washed.		Acid-washed.	
	Three Washings.	Twenty Washings.	Three Washings.	Ten Washings.
p_H of silica suspension in water	7.50	7.65	6.19	8
p_H of acid alone	3.88	3.63	3.53	3.45
p_H of silica + acid	4.96	3.78	4.08	3.46

Effect of Silica on Citric Acid.

Silica treatment.	Four times washed with water.	Ten times washed with acid.
p_H of silica suspension in water	7.50	6
p_H of acid alone	3.47	3.47
p_H of silica + acid	7.05	3.46

It is clear that the ability of the silica to remove acid from the solution disappears as the purifying treatment is pushed further, the last two numbers in the tables being the same within the limit of experimental error; it therefore seems reasonable to conclude that neither hydrochloric nor citric acid is removed from solution by pure silica.

It would be worth while repeating these experiments with silica gel, but it is very difficult to prepare such a substance in the required degree of purity. We have indications, moreover, that the reactions are not dependent on the presence of gel colloids—thus ignited purified clay was found to be as reactive towards sodium chloride solution as the fresh material which had never been heated, and as seen from the above, purified ignited silica is quite active in its behaviour towards salt solutions.

Summary.

1. The effect of silica upon a salt solution appears to be due to a chemical change resulting in the formation of free acid and of a complex silicate of low solubility but alkaline reaction.

2. Pure silica produces no effect on a solution of an acid; the reduction of acidity ordinarily observed does not take place when the silica used is well purified.

NOTE.—Since writing the above, we have seen the remarks of Dr. Mukherjee in the current number of the *Transactions of the Faraday Society* (Vol. XVIII, Part 3, p. 316), in which he states that pure precipitated silica adsorbs considerable quantities of acetic acid. We suggest, of course, that this effect would not be observed if the silica were more highly purified.

CCXXXIII.—*Dissociation of Complex Cyanides.*

By GEORGE JOSEPH BURROWS.

IN a previous communication (Burrows and Turner, T., 1919, 115, 1429), it was shown that, in aqueous solution, the nitroprussides dissociate in such a way as to indicate that nitroprussic acid has the simple formula $\text{H}_2\text{Fe}(\text{CN})_5\text{NO}$. It was decided to extend this investigation to the study of the dissociation of other complex cyanogen compounds in the hope that data would be obtained which would shed light on the molecular weight and the mode of dissociation of the ferrocyanides. The literature on the subject is by no means clear. Buchböck (*Z. physikal. Chem.*, 1897, 23, 157) found for the molecular weight of ethyl ferrocyanide by cryoscopic measurements, values about 320, in harmony with the formula $\text{Et}_4\text{Fe}(\text{CN})_6$. Berkeley, Hartley, and Stephenson, however (*Phil. Trans.*, 1909, A, 209, 319), concluded from conductivity and osmotic pressure measurements that the calcium and strontium salts are of the type $\text{M}_4[\text{Fe}(\text{CN})_6]_2$, and are capable of dissociating in each case into six ions, although the statement is made by them that equally good agreement between calculated and observed results would be obtained on the assumption that five ions are formed from each molecule. These authors also applied their method to the results of Jones and West for potassium ferrocyanide and concluded that those results also could be interpreted in accordance with the formula, $\text{K}_8[\text{Fe}(\text{CN})_6]_2$, for the molecule dissociating into ten ions.

Jones and Bassett (*Amer. Chem. J.*, 1905, 34, 313) are responsible for the view that potassium ferrocyanide dissociates into eight ions per molecule, $\text{K}_4\text{Fe}(\text{CN})_6 = 4\text{K}' + 3\text{CN}' + \text{Fe}(\text{CN})_3'$, whilst potassium ferricyanide yields six ions, $\text{K}_3\text{Fe}(\text{CN})_6 = 3\text{K}' + 2\text{CN}' + \text{Fe}(\text{CN})_4'$. Haber (*Z. Elektrochem.*, 1905, 10, 847) considers that potassium ferrocyanide dissociates in aqueous solution into four K' -ions and $\text{Fe}(\text{CN})_6''''$, the latter suffering subsequent dissociation into Fe'' and six $(\text{CN})'$ ions.

In view of this diversity of opinion, it was decided to study the cryoscopy and the conductivity of solutions, not only of potassium ferrocyanide, but also of potassium ferricyanide, and the analogous chromi- and cobalti-cyanides. The latter compounds appear to be more stable than the ferrocyanides and it was thought that their examination would perhaps lead to some definite conclusion in the case of potassium ferrocyanide.

In each case, a $M/10$ -solution of the salt was prepared and its conductivity measured at various dilutions down to 2000 litres or

more, until results were obtained from which the value of the limiting conductivity, μ_{∞} , could be found. At the same time, the freezing points of the more concentrated solutions were observed, and from these two sets of experiments the number of ions into which each molecule dissociates was calculated.

The author considers that these results furnish no evidence that the compounds examined have other than the simplest empirical formulæ. In every case the number of ions calculated for a $M/10$ -solution on the assumption that the salt is not associated and dissociates directly into positive K^+ (or Na^+)-ions and the negative complex metal-cyano-ion, for example, $[Fe(CN)_6]^{4-}$, agrees well with that required by the formula. In the case of ferro- and ferricyanides, the figures for $M/20$ - and $M/40$ -solutions are greater than those required. But the corresponding values, calculated on the assumption that the molecule is doubled, giving either (a) an associated negative ion or (b) two negative ions, show considerably greater differences. There is thus no evidence in these results to support such views.

These results are best interpreted on the assumption that the dissociation of potassium ferrocyanide is correctly represented thus,

the high values observed for the number of ions in the case of the more dilute solutions being due to the subsequent dissociation of the $Fe(CN)_6^{4-}$ -ion into Fe^{2+} and six CN^- -ions as suggested by Haber (*loc. cit.*), the amount of this dissociation increasing with dilution. That such is the case is indicated by the results obtained for potassium chromicyanide and potassium cobalticyanide. These salts are known to be stable in solution, particularly the cobalt compound, and the amount of dissociation of the complex ion has been found to be correspondingly small, as evidenced by the constancy of the values obtained for the number of ions, at the three dilutions. In the case of the iron compounds, the complex ions are not so stable and undergo secondary dissociation. At the same time, the amount of this dissociation cannot be very great under the conditions of the experiments, as otherwise the values of μ at high dilutions would show greater increases with dilution.

Furthermore, the values of μ_{∞} found for potassium ferrocyanide and potassium ferricyanide are those that would be expected on the assumption that the former dissociated into three K^+ -ions and one trivalent negative ion, and the latter into four K^+ -ions and one quadrivalent negative ion. Thus the value of μ_{∞} for $K_3[Fe(CN)_6NO]$ was found to be 258 (T., 1919, 115, 1432), and the value now found for $K_3[Fe(CN)_6]$, $\mu_{\infty} = 468$, is in good agreement with those of

$K_2[Co(CN)_6]$, $\mu_\infty = 451$, and $K_2[Cr(CN)_6]$, $\mu_\infty = 480$. The combined effect of adding one potassium-ion and increasing the valency of the negative ion by unity is thus equivalent to an increase, in the value of μ_∞ , of 210. The difference between the values for potassium ferricyanide and potassium ferrocyanide is 212. This would seem to exclude the possibility of any serious error in the values taken for the degree of dissociation of the solutions of potassium ferrocyanide, and it is considered that the conclusions stated above are supported by the experimental results.

EXPERIMENTAL.

In the following tables, v is the volume in litres containing one gram-molecule of the salt, μ is the molecular conductivity, α is the degree of dissociation and is equal to μ_v/μ_∞ , Δ is the observed depression of the freezing point of water, $M\Delta$ is the molecular depression and is equal to $v \times \Delta \times 10$, i is the van't Hoff coefficient and is equal to $M\Delta/18.7$, and k is the number of ions into which each molecule dissociates, being obtained from the equation $i = 1 + (k - 1)\alpha$. The values under k' are calculated on the assumption that the salt has twice the molecular weight indicated by the simple formula, giving an associated negative ion.

Potassium ferrocyanide, $K_4Fe(CN)_6 \cdot 3H_2O$.

CCXXIV.—Reduction Products of the Hydroxyanthraquinones. Part II.

By JOHN HALL and ARTHUR GEORGE PERKIN.

By the action of alkaline reducing agents on derivatives of anthraquinone, the corresponding anthracene compound has occasionally been obtained. The reagent mainly employed for this purpose has been zinc dust and ammonia, instances of its use being found in the work of Perger (*J. pr. Chem.*, 1881, [ii], **23**, 127), who obtained anthracene from anthraquinone, of Elbs and Eurich (*Ber.*, 1887, **20**, 136); 2:3-dimethylantracene from 2:3-dimethylantraquinone, of Liebermann (*Annalen*, 1882, **212**, 57), and of Schuler (*Ber.*, 1882, **15**, 1807), who obtained anthracenesulphonic acids from the corresponding anthraquinone compounds. On the other hand, though the action of alkaline reducing agents on the hydroxyanthraquinones has received much attention, more especially in regard to the preparation of hydroxyanthranols, there appears to be no instance on record of the subsequent conversion of hydroxyanthranol into the anthrol by the use of these reagents. For anthrol

production, as is well known, alkali fusion of the anthracenesulphonates has generally been resorted to, and in this way Liebermann (*loc. cit.*) obtained 1:2-, 1:5-, and 1:8-anthradiols, and Schuler (*loc. cit.*) flavol, which appeared to consist of the 2:6-dihydroxy-compound. Perkin and Whattam (T., 1922, 121, 289), by the prolonged action of zinc dust and ammonia on 2-hydroxyanthraquinone, obtained dihydroxydianthranyl, no anthrol apparently having been formed, and although it seemed possible that by a careful exclusion of air during the operation some 2-anthrol might be produced, more recent experiments in an atmosphere of hydrogen have failed to effect this result. It is thus evident that hydroxyanthranols are resistant to reduction by this method. This difficulty was overcome, in the case of hystazarin, by Lagodzinski (*Annalen*, 1905, 342, 104), who, employing its dimethyl ether, obtained by the aid of zinc dust and ammonia 2:3-dimethoxyanthracene, and such a method is suggestive and may prove to be of service in other cases.

By replacing zinc dust by aluminium powder and employing ammonia in the presence of dilute alcohol, Perkin and Whattam (*loc. cit.*) obtained from 2-hydroxyanthraquinone, after a two hours' digestion, an almost quantitative yield of 2-anthrol, and this appears to be the first instance of the alkaline reduction of hydroxyanthraquinone to anthrol. Attempts were accordingly made to prepare hydroxyanthracenes from other hydroxyanthraquinones by this method, and in the first instance, anthraflavic acid, containing as it does β -hydroxyls, was selected for experiment. When either this compound or its anthranol was employed, the results were disappointing, for after several hours' digestion only a small amount of the 2:6-dihydroxyanthracene appeared to be present. It seemed likely that the aluminium powder was at fault, but although other samples were obtained, these were not sufficiently active, and at the conclusion of the operation the main bulk could be recovered unchanged. The difficulty was eventually overcome by the employment of the aluminium-mercury couple first described by Cohen and Ormandy (*Brit. Assoc. Report*, 1889, 550), and with this reagent, in conjunction with dilute ammonia and with or without addition of alcohol, it has been found that anthraflavic acid, iscanthraflavic acid, 2-hydroxyanthraquinone, and alizarin, or their anthranols, rapidly yield the corresponding hydroxyanthracenes in considerable amount, whereas anthranol is converted into anthracene. Of these hydroxyanthracenes, the 2:6-compound, m. p. 297°, is evidently the flavol of Schuler, who gives m. p. 260–270° (*loc. cit.*), and the 1:2-compound, m. p. 160–162°, is the substance, described as melting at 131°, which Lagodzinski (*loc. cit.*), obtained by the reduction

of 1:2-anthraquinone,* both chemists evidently not being successful in obtaining these substances in a pure condition. Again, whereas both dihydroxyanthracenes are in reality colourless, or at most possess a faint green tint, they are described as yellow.

2:7-*Anthradiol*, which is apparently new, closely resembles the 2:6-compound, although it yields a bisazobenzene derivative of a somewhat redder shade. Preliminary experiments on the reduction of those other hydroxyanthraquinones and their anthrols which have at present been available, indicate that an anthatriol, probably the 1:2:7-compound, can in this way be obtained from anthrapurpurin. On the other hand, it has been found that those hydroxyanthraquinones, which in general do not yield anthranols when acted upon by zinc dust and ammonia, such as 1-hydroxyanthraquinone, anthrarufin, purpurin, and quinizarin, or the anthranols obtained from the former two by other methods, cannot be converted into hydroxyanthracenes by means of the aluminium-mercury couple in the presence of dilute ammonia. The difficulty may perhaps be surmounted by first methylating the hydroxyl groups, and work in this connexion, together with a more complete study of the hydroxyanthracenes here described, which are now available in quantity, is in progress.

The anthranols necessary for this investigation were obtained in almost quantitative amount from the corresponding hydroxyanthraquinones by a somewhat novel method, a description of which will be given in a subsequent communication.

We are much indebted to the British Alizarine Co., Ltd., for some quantity of the anthraflavic acid, isoanthraflavic acid, and commercial sodium anthraquinone-2:7-disulphonate employed in this investigation.

EXPERIMENTAL.

2:7-Dihydroxyanthracene.

Into a boiling solution of isoanthraflavic acid anthranol (5 grams) in alcohol (50 c.c.) and water (100 c.c.), contained in a flask provided with a reflux condenser, the washed couple † was introduced, and immediately the addition of strong ammonia was commenced, 40 c.c. being added during ten minutes. From the clear liquid a crystalline precipitate soon commenced to separate, which possibly consisted of an aluminium compound, and after digestion for about

* In a similar way, 1:4-dihydroxyanthracene, in the form of its acetyl compound, m. p. 169°, can be obtained from 1:4-anthraquinone (Dianel, *Ber.*, 1906, 39, 930).

† The aluminium-mercury couple was prepared in each case from one gram of aluminium foil in the form of pure strips. This was covered with water (75 c.c.) and a solution of 1.5 grams of mercuric chloride added.

ten minutes, the liquid was decanted hot from the unused couple* into dilute hydrochloric acid. The light brown, crystalline powder was collected, washed, and, when dry, weighed 4.85 grams.

Subsequent experiment showed that the presence of alcohol is not an essential feature in this process, good yields of the anthradiol being obtained in its absence. Again, in this and other anthrol reduction processes described in this paper, dilute alkali hydroxide may replace the ammonia, although in general the use of the latter reagent is greatly to be preferred.

The product was now digested with ten times its weight of boiling acetic anhydride containing a trace of pyridine. When cold, the mixture was diluted with alcohol and the colourless leaflets (yield 88 per cent.) were recrystallised from acetic acid. These melted at 282° (Found: C = 73.23; H = 4.79; acetic acid = 29.22. $C_{18}H_{12}O_4$ requires C = 73.49; H = 4.76; acetic acid = 29.25 per cent.). The acetyl determinations given in this paper were carried out by the acetic ester method.

2:7-Diacetoxyanthracene is very sparingly soluble in boiling alcohol, more readily soluble in acetic acid. It was hydrolysed by the gradual addition of hydrochloric acid (33 per cent.) to its solution in boiling acetic acid. By the cautious addition of boiling water, a trace of tarry matter first separated; this was at once removed from the hot liquid which, on cooling, now deposited a colourless, amorphous precipitate. By crystallisation from benzene, 2:7-dihydroxyanthracene was obtained as small, thick needles (Found: C = 79.94; H = 4.56. $C_{14}H_{10}O_2$ requires C = 80.00; H = 4.76 per cent.). When heated, it commenced to darken at 250° and melted with blackening at $280-285^{\circ}$. Its solutions in alcohol and acetic acid display violet fluorescence, whereas sulphuric acid gives a green, fluorescent, reddish-orange liquid. The latter, on heating, becomes deep bluish-green, a type of colour change which in these circumstances appears to be common to all the known hydroxy-anthracenes. Alcoholic ferric chloride forms a greenish-brown liquid, from which a dark-coloured precipitate soon separates. The disazobenzene derivative, obtained as a crimson powder insoluble in alkaline solutions, was not closely examined. It is soluble in sulphuric acid with a green coloration.

2:7-Dimethoxyanthracene was prepared by digesting 2:7-diacetoxyanthracene (1 gram) in boiling methyl alcohol (40 c.c.) and sulphuric acid (4 c.c.) for two hours. By cautious addition of hot water, a crystalline precipitate separated, and this was collected and washed with dilute sodium hydroxide solution (Yield 0.7 gram). By

* At the conclusion of this, and other experiments, recorded later, much of the couple remained unused.

recrystallisation from alcohol, and from acetic acid, it was obtained as colourless leaflets melting at $216-217^{\circ}$ (Found: C = 80.52; H = 5.91; $\text{CH}_3 = 12.4$. $\text{C}_{18}\text{H}_{14}\text{O}_2$ requires C = 80.67; H = 5.88; $\text{CH}_3 = 12.6$ per cent.). The solutions of dimethoxyanthracene in acetic acid and alcohol possess a violet fluorescence, whereas sulphuric acid gives a green, fluorescent, orange-brown liquid.

2:7-Dimethoxyanthracene, prepared from the diacetyl compound (1.5 grams), absolute alcohol (75 c.c.), and sulphuric acid (6 c.c.) by boiling for three hours, was recrystallised from acetic acid and from alcohol (Found: C = 81.31; H = 6.70; $\text{C}_2\text{H}_5 = 21.4$. $\text{C}_{18}\text{H}_{16}\text{O}_2$ requires C = 81.20; H = 6.76; $\text{C}_2\text{H}_5 = 21.8$ per cent.). It melts at $192-193^{\circ}$, and has similar properties to the dimethoxy-compound.

2:6-Dihydroxyanthracene.

In the preparation of this compound anthraflavic acid anthranol was employed, the reduction with the couple being carried out under exactly the same conditions as were serviceable in the case of the 2:7-compound. The pale brown, crystalline powder thus obtained was equivalent in amount to 90 per cent. of the theoretical. It was subsequently found, as in the former case, that the presence of alcohol during the reduction process is not essential, indeed an almost colourless preparation was obtained in its absence.

2:6-Diacetoxyanthracene, obtained by means of acetic anhydride and pyridine, separated from the boiling liquid during the acetylation process. The yield was 85 per cent. By recrystallisation from much acetic acid, it was obtained as colourless leaflets melting at $260-261^{\circ}$ (Found: C = 73.36; H = 4.77; acetic acid = 29.80. $\text{C}_{18}\text{H}_{14}\text{O}_4$ requires C = 73.47; H = 4.76; acetic acid = 29.28 per cent.). The alcoholic and acetic acid solutions are devoid of fluorescence.

For hydrolysis, the acetyl compound (2 grams), in 100 c.c. of acetic acid, was digested at the boiling point with cautious addition of hydrochloric acid. The glistening leaflets which separated were at first colourless, but subsequently developed a pale green tint (Found: C = 79.73; H = 4.77. $\text{C}_{14}\text{H}_{10}\text{O}_2$ requires C = 80.00; H = 4.76 per cent.).

When heated, 2:6-dihydroxyanthracene commences to darken at 270° , and melts with blackening at $295-300^{\circ}$. It dissolves somewhat readily in alcohol or acetic acid, the solutions possessing a blue fluorescence, whereas its pale yellow, alkaline solutions have a green fluorescence, but this rapidly disappears in presence of air, a dark-coloured precipitate separating. Sulphuric acid gives an orange liquid which, on heating, develops a bluish-violet colour, and with alcoholic ferric chloride a brown liquid is obtained.

2 : 6-Dimethoxyanthracene, obtained from the diacetyl compound by means of methyl alcohol and sulphuric acid, was digested with alcoholic potash to remove partly methylated compound, and crystallised from acetic acid. It consists of colourless leaflets melting at 255–256° (Found : C = 80.54; H = 5.36; $\text{CH}_3 = 12.3$. $\text{C}_{14}\text{H}_{14}\text{O}_2$ requires C = 80.67; H = 5.88; $\text{CH}_3 = 12.6$ per cent.). It can also readily be obtained from the dihydroxy- or diacetoxy-compound by means of alkali and methyl sulphate.

The 2 : 6-diethoxy-compound, similarly prepared, melted at 230–231° (Found : C = 81.32; H = 6.68; $\text{C}_2\text{H}_5 = 21.4$. $\text{C}_{18}\text{H}_{18}\text{O}_2$ requires C = 81.2; H = 6.96; $\text{C}_2\text{H}_5 = 21.8$ per cent.).

Although some doubt has existed as to identity of the flavol of Schuler, in that he employed as a starting point for his preparation a commercial anthraquinonedisulphonic acid, the results given above indicate that this is 2 : 6-dihydroxyanthracene. Although evidently he did not obtain this compound, which he describes as a bright yellow, crystalline powder, melting between 260° and 270°, in a pure condition, the melting point of his diacetyl compound, 254–255°, and more especially of his diethyl ether, 229°, now leave no doubt as to its identity.

Bisbenzeneazo-2 : 6-dihydroxyanthracene was obtained as a maroon-coloured powder, the solution of which, in alcohol, possessed a bluer tint than that given by the corresponding derivative of the 2 : 7-dihydroxy-compound. Sulphuric acid dissolved it with a bluish-green colour.

1 : 2-Dihydroxyanthracene.

The reduction of deoxylizarine (5 grams) was carried out as in the previous cases with the aluminium-mercury couple, a somewhat larger amount of ammonia solution (50 c.c.), however, being employed. The reaction is complete in about five minutes, and the digestion should not be extended for more than seven minutes, otherwise the product is less easy to purify. The yield averaged 96 per cent. of that required by theory. In this reduction process it is preferable to employ alcohol, as in its absence much viscid by-product is formed. The crude material, obtained in the paste form, was drained on tile, and while still moist dissolved in a minimum of boiling methyl alcohol. On cooling, a semi-solid mass of yellow leaflets was obtained and these were collected and washed with dilute alcohol, and then with benzene, which removed a tarry impurity. The yield of this almost pure preparation was 65 per cent. of the theoretical.

1 : 2-Diacetoxyanthracene, prepared in the usual manner, was crystallised from a mixture of alcohol and acetic acid. It consisted of colourless needles melting at 157–157.5° (Found : C =

73.40; H = 4.70; acetic acid = 29.04. $C_{18}H_{14}O_4$ requires C = 73.74; H = 4.76; acetic acid = 29.25 per cent.).

The diacetyl compound (1 gram) was hydrolysed in acetic acid solution (15 c.c.) with hydrochloric acid (20 c.c.), and the hot liquid, on dilution with boiling water, deposited a small amount of a dark-coloured, resinous matter. This was at once removed, the clear liquid, on cooling, now depositing colourless leaflets which ultimately developed a pale green shade (Found: C = 79.80; H = 4.89. $C_{14}H_{10}O_2$ requires C = 80.00; H = 4.76 per cent.).

Thus obtained, 1 : 2-anthradiol melted at 160–162°, and dissolved readily in alcohol or acetic acid with a yellow tint. The orange-coloured, alkaline solution quickly became blue, and finally black, on exposure to air. With alcoholic lead acetate, it yields a pale brown precipitate, and with ferric chloride a brown solution.

Attempts to prepare a dimethyl ether by means of alcohol and sulphuric acid, or methyl sulphate were, curiously enough, unsuccessful, and even with ethereal diazomethane only a small amount of a doubtfully pure substance melting from 55–60° could be obtained. Lagodzinski (*loc. cit.*) describes the 1 : 2-dihydroxyanthracene he obtained by the reduction of 1 : 2-anthraquinone as crystallising in greenish-yellow leaflets, melting at 131°, 25° lower than the m. p. given above, and thus can only have prepared his compound in an impure condition. The reactions of this, however, coincide with those given by the 1 : 2-dihydroxyanthracene described above.

2-Anthrol.

The preparation of this compound by means of the aluminium-mercury couple, according to the method given above, proceeds smoothly, with or without the employment of alcohol, and the reaction is complete in ten minutes. The pale green, almost colourless, amorphous product averaged 90 per cent. of the theoretical amount, and its identity was established by means of its acetyl compound and dimethyl ether, which melted, respectively, at 195–196° and 145–146°. The presence of alcohol during the reduction is not essential. In order to simplify the process of anthrol formation by avoiding a previous preparation of the anthranols, experiments on the reduction of the 2-, 2 : 7-, 2 : 6-, and 1 : 2-hydroxyanthraquinones by means of the aluminium couple in presence of ammonia were now carried out. As a result, it was ascertained that fair yields of the 2- (90 per cent.), 2 : 7- (72 per cent.), and 2 : 6- (80 per cent.) hydroxy-anthracenes could be obtained if the digestion was continued for a somewhat longer period than is necessary when starting with the anthranols.

In the case of alizarin, however, the method, curiously enough,

was not applicable, because reduction to the anthranol by means of the couple does not occur, the violet ammoniacal solution showing practically no change of colour. When, however, the ammonia is replaced by potassium hydroxide solution, reduction to 1:2-anthra-diol ensues,* but this method is scarcely economical owing to the rapid destruction of the couple by the action of the alkali, and the product contains much tarry impurity. There is, however, a possibility of the beneficial employment of alkali in this way, if anthrol formation is not brought about in the presence of ammonia.

Anthracene from Anthranol.

A mixture of anthranol (2.5 grams), alcohol (25 c.c.), water (25 c.c.), and the aluminium-mercury couple (0.5 gram) was digested at the boiling point, and 50 c.c. of strong ammonia were added during half an hour. The product (2.4 grams) still contained anthranol, and this was removed by two digestions with 25 per cent. sodium hydroxide solution. The residue, crystallised from benzene, melted at 213°—213° and consisted of anthracene.

isoAnthraflavic Acid.

Although it is well known (D.R.-P. 106505) that this compound can be obtained by the action of milk of lime on sodium anthraquinone-2:7-disulphonate at a high temperature, no details of the method are to be found in the literature. As a further supply of isoanthraflavic acid was required for the purposes of this investigation, this method was adopted in principle, although numerous experiments were necessary before a satisfactory process could be devised. The following was eventually adopted:

The commercial sodium anthraquinone-2:7-disulphonate, containing much sodium sulphate, requires purification and this was effected by means of its sparingly soluble aniline or β -naphthylamine salt according to the method of Perkin and Sewell (*J. Soc. Chem. Ind.*, 1923, 42, 27r). A mixture of the purified sodium disulphonate (12.5 grams), baryta (15 grams), sodium chlorate (2 grams), and water (100 c.c.) was heated in an autoclave, provided with a stirrer, for thirty-three hours at 170—180° (internal temperature). The product, diluted with 500 c.c. of boiling water, was filtered hot and the filtrate neutralised at the boiling point with hydrochloric acid. The isoanthraflavic acid thus isolated was purified by crystallisation from alcohol. The yield, which averaged 61 per cent., can possibly be slightly increased by a longer treatment in the autoclave, as some

* 2.5 Grams of deoxylizarin, 2 grams of aluminium-mercury couple, and 20 c.c. or 25 c.c. of 20 per cent. potassium hydroxide solution were employed here.

hydroxyanthraquinonesulphonic acid was still evidently present. The time of reaction cannot be satisfactorily shortened by increasing the temperature above 180°, for in this case the resulting product is dark coloured and of a very impure character.

[Received, June 19th, 1923.]

CCXXV.—*Cryoscopic Measurements with Nitrobenzene.*

By HUGH MEDWYN ROBERTS and CHARLES R. BURY.

IN the course of an investigation of the picrylamines, for which benzene proved to be an unsuitable solvent, nitrobenzene was used for cryoscopic purposes. This was found to absorb water from the air so readily that a constant freezing point could not be obtained for the pure solvent: the results were not entirely satisfactory even when the usual precautions against moisture were taken. A study of the influence of water on the freezing point of nitrobenzene has therefore been undertaken, with the ultimate object of obtaining satisfactory conditions for molecular-weight determinations.

In the first place, the freezing point was determined in the presence of salt hydrate pairs, or other substances in the presence of which the vapour pressure of water is constant and is known. Sidgwick (T., 1920, 117, 1340) has measured the freezing point of benzene in the presence of dehydrating agents, and assumed that this is lowered by an amount proportional to the aqueous vapour pressure of the substance with which it is in contact, provided that the substance itself is insoluble. Owing to the larger molecular depression of the freezing point of nitrobenzene, and to the greater solubility of water in this solvent, the effect is much more marked than with benzene, and more capable of accurate measurement. Determinations in the presence of water, phosphoric oxide, and the three salt hydrate pairs $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$, $\text{SrCl}_2 \cdot 6\text{H}_2\text{O}$, and $\text{H}_2\text{C}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ show that the freezing point is only approximately a linear function of the vapour pressure.

When once the relation between the freezing point and the aqueous vapour pressure has been established, the vapour pressure of any salt hydrate pair can easily and accurately be determined by measuring the freezing point of nitrobenzene in contact with it. The method is as accurate as any other except the gas current saturation method, and is specially suitable for the low vapour pressures of hydrates at this temperature, which render the direct method unsuitable. On the other hand, it has the disadvantage

of only giving the vapour pressure at one temperature, although the same method could be employed with other suitable solvents freezing at other temperatures. To illustrate the method, the vapour pressures of several salt hydrate pairs have been determined.

In the presence of these substances the freezing point of nitrobenzene is perfectly constant, any water absorbed being automatically taken up by the lower hydrate. On one occasion, a sample of nitrobenzene was left in contact with $\text{CuSO}_4 \cdot 3-5\text{H}_2\text{O}$ in a Beckmann freezing-point apparatus for two months, no precautions being taken to prevent access of moisture; at the end of that period the freezing point was unchanged. Advantage was taken of this to determine molecular weights in the presence of some suitable salt hydrate pair. When using hygroscopic solvents, this method is much more convenient than the usual one of passing a current of dry air through the apparatus; any error which might be caused by the introduction of moisture during the addition of solute is avoided. The results are as accurate as those obtained when using non-hygroscopic solvents. There is no reason why this method should be restricted to nitrobenzene; it should be equally applicable to any other solvent.

According to Nernst's law of the lowering of solubility, the water content of a solvent in contact with a salt hydrate pair is lowered by the addition of a solvent. The effect, however, is negligible, and in any case is automatically corrected for if the molecular depression constant be determined empirically.

EXPERIMENTAL.

Purification of Materials.—A pure sample of nitrobenzene from Robinson, Nelson & Co. was used, the bulk of which distilled over within a range of 0.3° . The middle portion was fractionally crystallised five times, and allowed to stand over phosphoric oxide until required. Immediately before use it was distilled over phosphoric oxide under reduced pressure (10–15 mm.) directly into the freezing-point tube, the middle portion only being collected. The distillation apparatus was carefully dried before introducing the nitrobenzene, and was filled with dry air at the close of the experiment. Precautions were taken to prevent the nitrobenzene coming in contact with rubber or lubricated glass joints.

The action of phosphoric oxide on nitrobenzene has been much exaggerated (Wood, *Proc. Roy. Soc.*, 1921, [A], 99, 371); impure nitrobenzene is rapidly discoloured, but when pure a slight colour is only developed on standing for several months. The nitrobenzene obtained on distilling these coloured samples gave identical freezing points with those obtained from fresh, uncoloured samples. The

fact that the freezing point of nitrobenzene in contact with phosphoric oxide has a constant reproducible value shows that the action is negligible over short intervals of time.

On several occasions nitrobenzene was kept over phosphoric oxide in the distillation apparatus for more than a week; the behaviour on distillation recalls Baker's observations on the influence of thorough drying on the boiling points of liquids (T., 1922, 121, 568). The flask containing nitrobenzene stood in a boiling saturated solution of sodium chloride; nevertheless it could only be made to boil with difficulty by reducing the pressure to a minimum. The bath could sometimes be evaporated to dryness without distillation beginning; once boiling started, however, it proceeded regularly and quietly, and a thermometer suspended in the vapour registered a temperature of about 90°. When nitrobenzene was distilled immediately, without long drying, boiling started without difficulty as soon as the bath became hot, the temperature registered being the same as before.

Sodium sulphate, strontium chloride, and oxalic acid were recrystallised three times, other salts twice. Three samples of phosphoric oxide from different sources were used. Pure samples of naphthalene, *o*-chloronitrobenzene, and α -nitronaphthalene were used for the molecular-weight determinations.

Two specimens of benzene from different sources were carefully purified in order to standardise the thermometer, the first from a pure sample from Messrs. Harrington, the second from a crude commercial product. These were shaken up with concentrated sulphuric acid until free from thiophen as tested by the isatin reaction, then with alkali, and lastly with water. After drying over calcium chloride, they were fractionally distilled, the middle portion being fractionated by crystallising five times. The product was again distilled over phosphoric oxide immediately before use.

Measurement of Temperature.—A Beckmann thermometer was used throughout, temperatures being confirmed, as far as possible, by a standard thermometer graduated in tenths of a degree. The Beckmann thermometer was graduated in hundredths of a degree and read to 0.002° with a lens; it was frequently standardised by means of the freezing point of benzene, for which Richards, Carver, and Schumb's value of 5.493° was taken (*J. Amer. Chem. Soc.*, 1919, 41, 2024). The freezing point of benzene was determined in the presence of phosphoric oxide, and in a current of dry air, the procedure being the same as that used in the case of nitrobenzene (*vide infra*). The two samples of benzene the preparation of which has been described gave results agreeing to 0.002°, the temperature being independent of the amount frozen.

All readings were corrected for emergent stem; this is of little importance, since actually very small differences of temperature were being measured.

Freezing Point of Nitrobenzene.—The nitrobenzene was contained in a Beckmann inner tube, fitted with a glass stirrer. The liquid was half frozen, then placed in a Beckmann outer tube, which was held in a Dewar flask containing water at 5.5°. When the freezing point was being determined in the presence of phosphoric oxide, this was added to the tube before nitrobenzene was distilled into it, and a current of dry air was passed through the apparatus throughout the experiment. After the mixture had been stirred gently for about five minutes, the temperature became constant and remained so for an hour or more, until all the nitrobenzene had melted.

On other occasions a drop of water was added to the nitrobenzene, the freezing point determined as before, then the lower hydrate of a pair was added, and the freezing point again determined.

The results are shown in Table I, where the first column gives the substance in the presence of which the freezing point was determined; under *N* is shown the number of independent experiments, and under *T* the mean value of the freezing point, with the greatest deviation from the mean.

TABLE I.

	<i>P</i> (mm.).	<i>N</i> .	<i>T</i> (obs.).	<i>T</i> (calc.).	Diff.
Phosphoric oxide ...	nil.	3	5.669°	—0.002°	5.669° 0
H ₂ C ₂ O ₄ .0—2H ₂ O ...	0.60	3	5.627	—0.002	5.627 0
SrCl ₂ .2—6H ₂ O	1.92	3	5.534	+0.002	5.532 —0.002°
Na ₂ SO ₄ .0—10H ₂ O ...	4.31	3	5.346	—0.002	5.348 +0.002
Water saturated with nitrobenzene	6.60	6	5.158	+0.003	5.158 0

Under *P* are given the aqueous vapour pressures: phosphoric oxide is assumed to absorb water completely. An estimate of the solubility of nitrobenzene in water at 5° can be made from the measurements at higher temperatures by Davis (*J. Amer. Chem. Soc.*, 1916, 38, 1166); the amount present is insufficient to lower the vapour pressure of water appreciably. The vapour pressures of the salt hydrates have been determined by Baxter and Lansing (*ibid.*, 1920, 42, 419), and are the only accurate data available at this temperature.

If the freezing points are plotted against the vapour pressures, the resulting line is approximately straight, but the deviations are outside the limits of experimental error. The ratio of the vapour pressure of water to its concentration in the solvent depends on the temperature, but if allowance is made for the fact that deter-

minations have been made over a range of half a degree, the improvement is negligible. The experimental figures can only be represented adequately by some such formula as

$$T = 5.669^\circ - 0.0689 P - 0.0013P^2,$$

which, as can be seen from the last two columns of Table I, agrees within the limits of experimental error. The formula has no theoretical significance, except that it implies that the osmotic pressure of water in nitrobenzene solution does not obey the simple gas laws; it would be explained if water were about 15–20 per cent. associated in the saturated solution. There are other indications that this is the case; from the difference between the freezing point of the wet and the dry solvent (0.511°), and the molecular depression of the freezing point (69), the solubility of water can be calculated. This is 0.133 gram per 100 grams of nitrobenzene if the water is assumed to be undissociated; if it is 20 per cent. associated, the solubility would be 0.148. This latter value, although still low, is more consistent with the results of Davis (*loc. cit.*) for the solubility at higher temperatures.

After experience had been gained in the handling of dry nitrobenzene, it was found possible to determine the freezing point of the dry solvent without having any phosphoric oxide or other dehydrating agent in the freezing-point tube. Three independent experiments gave the value $5.666^\circ \pm 0.001^\circ$, which only differs by 0.003° from that obtained in the presence of phosphoric oxide. The fact that it is lower is probably due to traces of moisture, and shows that phosphoric oxide introduces no appreciable impurity into nitrobenzene. Taking into account possible errors in the standardisation of the thermometer, it is safe to assert that the freezing point of pure dry nitrobenzene is $5.668^\circ \pm 0.010^\circ$. This is important in view of the discordant values quoted in literature for this constant.*

Vapour Pressures of Salt Hydrates.—Exactly the same experimental procedure was adopted in measuring the freezing point of nitrobenzene in the presence of other salt hydrates. The results, which are shown in Table II, have been used to calculate the vapour pressures of these hydrates by means of the equation given

* Mitscherlich (*Berz. Jahresber.*, 15, 429), 3° ; Raoult (*Ann. Chim. Phys.*, 1884, [vi], 2, 66), 5.3° ; Ampola and Carlinfanti (*Gazzetta*, 1896, 26, ii, 76), 3.9° ; Linebarger (*Amer. Chem. J.*, 1896, 18, 437), 3.6° ; Friswell (*T.*, 1897, 71, 1011), 5° ; Auwers (*Z. physikal. Chem.*, 1899, 30, 300), 6.0° ; Tammann ("Kristallisieren und Schmelzen," Leipzig, 1903, 227), 5.62 – 5.72° ; Meyer (*Z. physikal. Chem.*, 1910, 72, 245), 5.82° ; Tsakalotos and Guye (*J. Chim. Phys.*, 1910, 8, 340), 8.8° ; Timmermanns (*Proc. K. Akad. Wetensch. Amsterdam*, 12, 507), 8.70° ; Böseken and van der Eerden (*Rec. trav. chim.*, 1914, 33, 300), 5.7° .

above. The values obtained can be considered accurate to about 0.03 mm.

TABLE II.

	<i>T</i> .	<i>P</i> (calc.).	<i>P</i> (Frowein).
CuSO ₄ .1—3H ₂ O	5.624°	0.65 mm.	0.72 mm.
BaCl ₂ .0—2H ₂ O	5.583	1.22 "	1.15 "
CuSO ₄ .3—5H ₂ O	5.531	1.93 "	2.00 "
ZnSO ₄ .6—7H ₂ O	5.444	3.09 "	3.16 "
Na ₂ HPO ₄ .7—12H ₂ O	5.335	4.47 "	4.35 "

There are no accurate data with which these can be compared; in the last column, however, are shown the vapour pressures at 5.5° extrapolated from Frowein's determinations at higher temperatures (*Z. physikal. Chem.*, 1887, 1, 1, 362). The method employed in extrapolation has been to plot the logarithms of the vapour pressures against the temperatures.

The method has been found unsuitable for salt hydrate pairs, such as ZnSO₄.1—6H₂O, where equilibrium is only attained very slowly.

Molecular-weight Determinations.—One to two grams of anhydrous sodium sulphate and a drop of water were added to a weighed quantity of nitrobenzene in a freezing-point tube. The ordinary Beckmann freezing-point apparatus was used, and the usual procedure followed; no current of dry air or other precautions were taken against moisture. Some of the results obtained are shown in Table III, where *W* is the weight of solute per 100 grams of nitrobenzene, *D* is the observed depression, and *K* is the molecular depression of the freezing point calculated from these two values. The constancy of *K* shows that the method can yield as good results as can be obtained with the most favourable solvents.

TABLE III.

Naphthalene (128).			o-Chloronitrobenzene (157).			α-Nitronaphthalene (173).		
<i>W</i> .	<i>D</i> .	<i>K</i> .	<i>W</i> .	<i>D</i> .	<i>K</i> .	<i>W</i> .	<i>D</i> .	<i>K</i> .
0.663	0.359	69.3	0.582	0.261	69.3	0.471	0.187	68.7
1.073	0.574	68.4	0.792	0.352	69.9	0.717	0.282	68.0
1.354	0.723	68.3	1.261	0.560	69.9	0.981	0.390	68.7
1.588	0.854	68.8	1.579	0.698	69.5	1.392	0.550	68.3
Mean		68.7	Mean		69.6	Mean		68.4

The mean value of *K* (68.9) is in excellent agreement with the value (68.7) calculated from Meyer's determination of the latent heat of fusion as 22.46 cal.

Sodium sulphate was chosen rather than any other salt because it can be easily purified, is not liable to react with organic substances, and can absorb more water than most other salts.

Summary.

- (1) The freezing point of pure dry nitrobenzene is $5.668^{\circ} \pm 0.010^{\circ}$.
- (2) The influence of water on the freezing point of nitrobenzene has been studied, and is discussed.
- (3) The vapour pressures of a number of salt hydrates have been determined by an indirect method, which consists in measuring the freezing point of nitrobenzene in their presence.
- (4) A means of eliminating the errors involved in the use of a hygroscopic solvent for molecular-weight determinations by the freezing-point method, has been devised.

CCXXVI.—*The X-Ray Investigation of Fatty Acids.*

By ALEX MÜLLER.

It is well known that ordinary paraffin wax gives an extremely strong powder-reflection of X-rays. The first experiment which showed this was described by Friedrich (*Physikal. Z.*, 1913, **14**, 317). He sent a pencil of X-rays through a layer of paraffin wax and obtained on a photographic plate a very well-marked reflection ring round the incident beam. The theory of the phenomenon was not known at the time when the experiment was made. Ordinary paraffin wax is known to contain molecules which possess long CH_2 -chains. De Broglie (*Compt. rend.*, 1923, **176**, 738) and Friedel pointed out recently that these long chains could be detected by means of X-rays and described an experiment in which they measured a large spacing (43.5 Å.U.) in a film of sodium oleate. A series of systematic measurements have been undertaken and have been described by Piper.* He found the interesting fact that the length of the spacings increases with an increasing number of CH_2 -groups. This confirms the theory which chemists gave long ago.

The author has made independent investigations along the same line. The substances used were a series of fatty acids belonging to one class. Here again it is found that large spacings exist in these substances, and the size of the spacings increases with the number of CH_2 -groups present in the acid.

The following was the method of procedure. A small amount

* The paper is to appear shortly in the *Proceedings of the Physical Society of London*.

of the substance was melted on a glass plate and spread out so as to form a strip 2—3 mm. wide, 1 cm. long, and 0.1—0.2 mm. thick. Those fatty acids which were used were found to crystallise in flakes which oriented themselves parallel to the glass surface. They gave extremely good reflections. This is clearly shown by the good definition of the lines which are near the centre line (see Plate I). It is obviously necessary in these circumstances, to oscillate the crystal-holder; the crystal flakes, being oriented parallel to the plane surface of the glass, act as a single crystal. The glass plate, on which the substance was deposited, was fixed on the table of a small X-ray spectrometer. Following the method usually adopted, reflections were obtained on each side of the primary beam. This avoids errors which would be involved by using the image of the primary beam as a zero line. The substance was oscillated through 10° on either side of the direct beam. The X-ray bulb, fitted with an iron anticathode, was run at approximately 40 K.V. and 5 M.A. The time of exposure was approximately three-quarters of an hour for each side. The distance between the axis of the spectrometer and the plate was 6.94 cm.

The photographs, the reproduction of which is given on Plate I, show a group of well-defined lines lying symmetrically on each side of the central beam. The distances between corresponding lines are different for the different substances investigated. They decrease as the number of CH_2 -groups increases, that is, the spacing increases with the number of CH_2 -groups. These sharp lines were all found to be the various orders of reflection by the main set of planes, having a spacing which may be called d_1 . Besides the sharp lines, there are two rather broad lines outside. These lines, which show on all the plates except that of capric acid, are in the same position for all the substances. The spacings corresponding to these lines may be called d_2 and d_3 . The values of the three spacings are given in Table I, where "M. p." denotes the melting point, and N

the total number of carbon atoms in the chemical formula. The table shows that there is a distinct increase in the spacing d_1 which corresponds to the increase in the number of carbon atoms or

PLATE I.

[From *Trans.*, p. 241.]

CH_2 -groups in the substance. The increase of d_1 per CH_2 -group in the chemical formula is constant within the limits of error; its value is

$$\delta d_1 / \delta N = 2.0.$$

The approximate constancy of this increase is shown in Fig. 1.

The existence of the two small spacings, d_2 and d_3 , which have the same value for all the substances investigated, suggests that the unit cell is a long prism which has the same cross-section for all the substances in question. The length of the prism increases proportionally to the number of CH_2 -groups in the substance. It is obviously impossible to give the exact structure if the angles between the planes which constitute the cell are not known. If the angles

FIG. 1.

are supposed to be right angles it is possible to calculate the number n of molecules in the unit cell. We have

$$(1) \quad \text{Density} = n \times \frac{\text{Mol. wt.} \times \text{Weight of H-Atom}}{\text{Volume of unit cell.}}$$

For stearic acid, n is found to be very nearly 1.0. But if we calculate the length of the chain which is obtained by piling all the carbons and oxygens one on top of the other in a straight line, we find for that length something like 30 Å.U. The observed spacing is 38.7 Å.U. The difference is far too large to be accounted for by experimental errors. We have therefore to suppose that there is more than one molecule in the unit cell and that the assumed form of the cell is only an approximation. The right length of d_1 could be obtained by putting two or more molecules together in a

spiral or zigzag arrangement. How this can be done, and what assumptions are necessary to satisfy equation (1) must be the subject of a more detailed investigation.

Photographs have also been taken with margaric and undecic acid. These acids have odd numbers of carbon atoms, namely, 17 and 11. Margaric acid shows a series of lines which are arranged similarly to those shown in Plate I. In this case, however, each line is double and the distances correspond very nearly with those of stearic acid. Between the d_2 and d_3 lines which give the same spacing as the substances with an even number of carbon atoms there is another fairly broad line. Undecic acid shows no peculiarities. It is impossible to decide from the two photographs whether the different behaviour of margaric acid is due to impurities in the substance or to a different arrangement of the molecules.

An experiment was also made with elaidic acid. A different phenomenon was found. Elaidic acid is, according to chemical analysis, stereoisomeric with oleic acid and belongs to the unsaturated type. The d_1 spacing, in spite of the fact that the substance contains the same number (18) of carbon atoms as stearic acid, is much larger than the corresponding d_1 of stearic acid. Its value is nearly 48 Å.U., that is to say, about 9 Å.U. longer than the d_1 for stearic acid. The spacings d_2 and d_3 of elaidic acid are the same, within the limits of error, as the previous ones. From the differences in the d_1 spacing it would appear that the linking between the carbon atoms is of a different type in the unsaturated and saturated chains.

It is interesting to note that the first and third orders of the d_1 spacing are very strong on all the photographs, the second and fifth moderately strong, and the fourth in most of the cases very weak. In the case of elaidic acid the 14th order of the d_1 spacing has been measured.

Adam (*Proc. Roy. Soc.*, 1922, **101**, 452) has measured the length of these long chains in fatty acids by an entirely different method. He calculated them from the area and the density of unimolecular surface films. His figures are: myristic acid, 21.1; pentadecic acid, 22.4; stearic acid, 26.2; behenic acid, 31.4 Å.U.

Considering the fact that Adam investigated the substances in a different state, it is obviously impossible that his figures should be in close agreement with the ones given in Table 1. The order of magnitude, however, is the same, and his figures, too, show distinctly the increase of size of the chain with the increase of the number of CH_2 -groups in the molecule.

Becker and Jahnke (*Z. physikal. Chem.*, 1923, **99**, 242) made an investigation on fatty acids and analogous substances. From the dimensions which they attribute to the unit cell they appear to have

found in the case of lithium salts of acids with odd numbers of carbon atoms a typical increase of the largest spacing with increasing number of CH_2 -groups. Their results with the acids which have been investigated in the present paper are in almost complete disagreement with those given above (except for lauric acid, where the authors give approximately the same value for d_1). It seems to the author that the method which they used was not very suitable for finding these large spacings. The reason why has been pointed out at the beginning of this paper.

In conclusion, the author wishes to take this opportunity of thanking Professor Sir W. Bragg for his very kind interest in the work. It is well known that the substances used in this investigation are very difficult to prepare in a pure state, and the author gratefully acknowledges the help received from Mr. N. K. Adam, of Sheffield University, from whom most of the specimens were obtained, and from Mr. W. E. Garner, of University College, London, for his preparation of the capric and the undecic acids. He also wishes to express his indebtedness to the Department of Scientific and Industrial Research, whose support made this work possible.

[Received, July 4th, 1923.]

CCXXVII.—*The Isomerism of the Dinitrobenzidines.*

By OSCAR LISLE BRADY and GERALD PATRICK MCHUGH.

STRAKOSCH (*Ber.*, 1872, 5, 236), by the nitration of diacetylbenzidine and subsequent hydrolysis of the acetyl compound, obtained a dinitrobenzidine (I) in which the nitro-groups were in the ortho-position to the amino-groups. This was shown by Brunner and Witt (*Ber.*, 1887, 20, 1024) by reduction to the tetra-amine (II), which with nitrous acid gave an azoimide (III) and with benzil a diquinoxaline (IV).

Later, Bandrowski (*Monatsh.*, 1887, 8, 471) prepared a dinitrobenzidine by the nitration of diphthalylbenzidine.

Cain, Coulthard, and Micklethwait (*T.*, 1912, 101, 2298; 1913, 103, 586, 2074; 1914, 105, 1437) pointed out that the identity of the dinitrobenzidines obtained by Strakosch and Bandrowski had been assumed without warrant in the literature and they re-investigated the problem. They showed that the two dinitrobenzidines were distinct, that obtained by Strakosch's method melting at 275° and that by Bandrowski's at 233°. On removal of the amino-groups by diazotising and boiling with alcohol, two dinitrodiphenyls were obtained melting at 197–198° and 110°, respectively. Both dinitrobenzidines on reduction gave tetraamines which, on condensation with benzil, gave the same diquinoxaline, and further when the acetyl derivatives of both were oxidised 3-nitro-4-acetylaminobenzoic acid was obtained. In both cases, therefore, at least one nitro-group was in the ortho-position to the amino-group and the condensation of the tetraamines with two molecular proportions of benzil suggested that both nitro-groups were also in that position.

Cain and his co-workers finally adopted the Kausler formula for diphenyl (V) (*Annalen*, 1907, 351, 151) and represented Strakosch's compound as 3:5'-dinitrobenzidine (VI) and Bandrowski's as 3:3'-dinitrobenzidine (VII).

At that time this type of isomerism was a novelty, but recently the work of Kenner and his collaborators (*T.*, 1921, 119, 593; 1922, 121, 614; this vol., p. 779) has clearly shown that isomerism of a special type exists among diphenyl compounds.

A few points remain, however, to be cleared up in connexion with the dinitrobenzidines, and the present work was undertaken with the view of confirming and completing as far as possible the earlier investigations. The determination of the position of the nitro-groups in the case of 3:3'-dinitrobenzidine depends on the isolation of a small quantity of 3-nitro-4-acetylaminobenzoic acid on oxidation and the production of a diquinoxaline on reduction to

the tetra-amine and condensation with benzil; no description is given of any attempt to obtain an azoimide from the tetra-amine as in the case of that derived from 3:5'-dinitrobenzidine. Cain claimed that the same diquinoxaline was obtained from both tetra-amines, but the only evidence that was given was a mixed melting-point determination, which, with compounds of this type melting at 299–300°, is not completely convincing. It has, moreover, not been made clear whether the two tetra-amines are identical or otherwise, an interesting point in view of the fact that, so far, this type of isomerism has been observed only with nitro-derivatives of diphenyl.

Some of these points have now been decided. First, it has been shown conclusively that Strakosch's dinitrobenzidine is a di-ortho-substituted diamine by its synthesis in such a way as to leave no doubt of its constitution. This has been carried out as follows:

The dinitrodiethoxydiphenyl obtained in the course of this synthesis was found to be identical with that obtained by the nitration of diethoxydiphenyl, although it was hoped that isomerism analogous to that of the dinitrobenzidines would be observed. Cain and his collaborators assumed that Strakosch's compound was the 3:5'-derivative on account of its higher melting point. This view is supported by the above synthesis, as Kenner and others (*loc. cit.*) have shown that the dinitrodiphenic acid obtained by a similar method has an analogous constitution.

Secondly, it has been found that the tetra-aminodiphenyls obtained by reduction of the two nitro-compounds are distinct, although they apparently give the same diquinoxaline with benzil, as stated by Cain. This is analogous to the behaviour of the acid chlorides of the two dinitrodiphenic acids described by Kenner and Stubbings, which gave the same compound on treatment with hydrazine. Bandrowski (*loc. cit.*) apparently thought that the

tetra-aminodiphenyl obtained by the reduction of his dinitrobenzidine was the same as that prepared from Strakosch's compound, but he produces little evidence in support. We have found that the hydrochlorides of the two tetra-amines differ greatly in solubility and are of distinct crystalline form; moreover, their solutions in dilute hydrochloric acid behave quite differently towards nitrous acid. The oxidation of both dinitrobenzidines to 3-nitro-4-acetylaminobenzoic acid, as described by Cain and others, has been repeated and confirmed, and in view of this and the quinoxaline condensation there seems no doubt that the orientation of the two compounds has been correctly inferred. On the other hand, although the formation of an azoimide from the tetra-amine obtained from Strakosch's dinitrobenzidine has been confirmed (compare Brunner and Witt, *loc. cit.*), an acid solution of the tetra-amine from the other dinitrobenzidine, on treatment with nitrous acid, gave a dark brownish-red, amorphous compound which was undoubtedly not an azoimide; it could not, however, be satisfactorily purified and it has not been fully investigated.

It is remarkable that the isomeric dinitrobenzidines and their derivatives are not interconvertible, except in the case of quinoxaline formation, and attempts have been made to bring this about; 3:5'-dinitrobenzidine was phthalylated and the product hydrolysed, and 3:3'-dinitrobenzidine was acetylated and the product hydrolysed; acid, in place of alkali, hydrolysis was employed in the usual preparation of the former and *vice versa*, but no evidence of interconversion was obtained.

EXPERIMENTAL.

4-Iodo-2-nitrophenetole (X).—Ten grams of nitrophenacetin (VIII), prepared according to the method described in D.R.-P. 101778, were warmed with 250 c.c. of 20 per cent. sulphuric acid until dissolved and then treated on the water-bath for an hour. The solution was rapidly cooled with thorough shaking, when the pink sulphate of 3-nitro-*p*-phenetidine (IX) separated in a finely divided crystalline condition. The suspension was cooled to 0°, 3.5 grams of sodium nitrite in water were added, and the mixture was kept at 0° for an hour, when a solution of 18 grams of potassium iodide was run in. The mixture was left for some hours to attain room temperature and finally heated on the water-bath. The oily iodo-compound was extracted with ether, the ethereal solution washed thoroughly with sodium thiosulphate solution in order to remove iodine, dried over anhydrous sodium sulphate, and the solvent removed. The mass of red crystals left was crystallised first from alcohol and then from light petroleum, when *4-iodo-2-nitrophenetole*

was obtained in large, orange-red, irregular crystals melting at 80° (Found: I = 43.2. $C_8H_8O_3NI$ requires I = 43.3 per cent.).

3:5'-Dinitro-4:4'-diethoxydiphenyl (XI).—4-Iodo-2-nitrophenetole was mixed with its own weight of copper powder (freshly prepared by precipitation from copper sulphate with zinc, washed with alcohol and ether, and dried), and the mixture heated in an oil-bath first for forty minutes at $185-195^{\circ}$ and then for twenty minutes at $215-220^{\circ}$. After cooling, the melt was extracted with boiling glacial acetic acid, the solution cautiously diluted with water, and the precipitated compound crystallised from acetic anhydride, when the 3:5'-dinitro-4:4'-diethoxydiphenyl obtained melted at $192-193^{\circ}$. This compound was also prepared by the nitration of 4:4'-diethoxydiphenyl according to the method of Hirsch (*Ber.*, 1889, 22, 336), but it was found better to stir mechanically during the nitration and to crystallise from acetic anhydride instead of from glacial acetic acid. The 4:4'-diethoxydiphenyl is best prepared by Hirsch's method by the ethylation with ethyl iodide of 4:4'-diphenol prepared from benzidine; we have also prepared it by the action of copper powder on *p*-iodophenetole.

3:5'-Dinitrobenzidine (XII).—The 3:5'-dinitro-4:4'-diethoxydiphenyl was heated in a sealed tube for five hours with alcoholic ammonia at $160-170^{\circ}$. The liquid in the tube, when cool, contained brilliant red crystals, which were separated and crystallised by dissolving in boiling alcohol, in which they were sparingly soluble, and, after cooling carefully diluting the solution with water. In this way a compound was obtained resembling in appearance and solubility the 3:5'-dinitrobenzidine obtained by Strakosch (Found: N = 20.0. Calc., N = 20.4 per cent.). It melted at 268° , and at $266-268^{\circ}$ when mixed with a sample of dinitrobenzidine prepared by Strakosch's method.

The alcoholic filtrate from the tube was diluted with water and gave a red, pasty material which resisted all attempts at purification; owing to the small amount available, it was not further investigated.

Diacetylbenzidine.—Strakosch acetylated benzidine by boiling with glacial acetic acid, but a better result was obtained by boiling 20 grams of benzidine under reflux for two hours with a mixture of 22 c.c. of acetic anhydride and 50 c.c. of glacial acetic acid, diluting, and purifying the precipitated diacetylbenzidine by repeated extraction with boiling alcohol, in which it is almost insoluble.

3:3'- and 3:5'-Dinitrodiphenyl.—The following method for preparation of these compounds was found to be an improvement on that described by Brunner and Witt. To 125 c.c. of absolute alcohol, 50 c.c. of fuming sulphuric acid (20 per cent. SO_3) were

were produced by each modification, and, furthermore, reversible phenomena of the following kind were sometimes observed: the yellow form of 2-nitro-4'-methoxystilbene-4-carboxylic acid gave an orange pyridine salt, whilst the orange acid gave a yellow pyridine salt, the acids being regenerated by treatment with hydrochloric acid. It was found possible to go by a series of reactions from the yellow acid to the orange acid and vice versa in this way:

Yellow acid \rightarrow orange salt \rightarrow (with excess of pyridine)
yellow salt \rightarrow orange acid \rightarrow (on heating) yellow acid.

In Pfeiffer's view, these nitromethoxystilbenes exist in two forms only when the methoxyl group is in the para-position; when it is in the ortho- or the meta-position, there is only one form. The other benzene nucleus contains a nitro-group in the ortho- or the para-position. The substitution of hydrogen, or an alkyl or acyloxy-group for methoxyl causes the phenomenon to disappear, but replacement of methoxyl by hydroxyl is without this effect. This led Pfeiffer to the conclusion that the nitrostilbenes occur in forms of different colour only when, in addition to the chromophoric groups (nitro-group and ethylene linking), an auxochromic group is also present. Of the two varieties, the paler one is similar in colour to the corresponding compound lacking the auxochrome, whilst in the more deeply coloured substance the typical effect of the auxochromic radicle is made manifest.

In the present work, several nitrohydroxystilbenes were examined, compounds containing the hydroxyl group in the para-position being first studied. 4-Nitro-4'-hydroxystilbene, like 4-nitro-4'-methoxystilbene (Pfeiffer, *Ber.*, 1915, 48, 1794), was found to exist in two forms, one golden-yellow, the other greenish-yellow. The latter form was unstable and was readily converted into the former on being rubbed or heated. Both modifications melted at the same temperature, and the colours of each in solution were identical. The compound produced by acetylating the hydroxyl group was obtained, as expected, in one form only—yellow.

Two forms were also obtained in the case of 2:4-dinitro-4'-hydroxystilbene, one red (the stable modification) the other yellow. The latter, on being heated, turned red, and melted at the same temperature as the red form (2:4-dinitro-4'-methoxystilbene was found by Pfeiffer, *Ber.*, 1915, 48, 1780, to exist in one form only). 2:4-Dinitro-4'-acetoxystilbene could not be obtained in more than one form.

o-Hydroxystilbene derivatives were also investigated, and in every case one form only of each substance was found to exist; for example, 2:4:6-trinitro-2'-hydroxystilbene was isolated as a

yellow substance. The product from the interaction of *p*-nitrophenylacetic acid and salicylic acid, in the presence of a little piperidine, consisted almost entirely of 3-*p*-nitrophenylcoumarin :

In addition, there was a small amount of oil which, on treatment with acetic anhydride, gave a compound which analysis indicated to be 4-nitro-2'-acetoxystilbene.

Derivatives of *m*-hydroxystilbene also showed no tendency to crystallise in more than one form, the 4-nitro-, 2:4-dinitro-, and 2:4:6-trinitro-derivatives of 3'-hydroxystilbene all being obtained as yellow substances only.

Stilbene compounds containing a nitro-group in the meta-position had not been previously examined for the purpose of determining if they yielded forms of different colour. *m*-Nitrophenylacetic acid was therefore condensed, by the usual method, with *p*-hydroxybenzaldehyde. The product, 3-nitro-4'-hydroxystilbene, was found to exist only in one form, which was colourless. As 4-nitro-4'-hydroxystilbene is yellow, the nitro-radicle in derivatives of stilbene is therefore, as regards deepening of colour, less effective in the meta- than in the para-position. The sole product obtained by condensing *m*-nitrophenylacetic acid and salicylaldehyde was 3-*m*-nitrophenylcoumarin.

4:4'- and 4:3'-Dinitrostilbenes each crystallised in one form only.

The colours of the above compounds in solution were observed to vary considerably with the nature of the solvent (about 0.01 gram of the substance in 2 c.c. of the solvent was taken) :

Derivative of stilbene.	Benzene.	Glacial acetic acid.	Trichloroacetic acid.
4-Nitro-4'-hydroxy.	*Greenish-yellow.	Deep yellow.	Orange-red.
4-Nitro-4'-acetoxy.	Pale yellowish-green.	Greenish-yellow.	Deep greenish-yellow.
2:4-Dinitro-4'-hydroxy.	*Greenish-yellow.	Orange-yellow.	Orange-red.
2:4-Dinitro-4'-acetoxy.	*Yellow—with green tint.	Deep yellow.	Orange-yellow.
2:4:6-Trinitro-2'-hydroxy.	*Deep yellow.	Orange-yellow.	Orange-red.
4-Nitro-2'-acetoxy.	Greenish-yellow.	Orange-yellow.	Orange-yellow.
4-Nitro-3'-hydroxy.	*Greenish-yellow.	Deep yellow.	Orange-yellow.
2:4-Dinitro-3'-hydroxy.	*Yellow.	Orange.	Orange-red.
2:4:6-Trinitro-3'-hydroxy.	*Yellow.	Wine-red.	Deep red.
3-Nitro-4'-hydroxy.	*Pale yellow.	Orange-yellow.	Orange-red.
4:4'-Dinitro.	*Faint yellow.	Deep yellow.	Deep yellow.
4:3'-Dinitro.	Greenish-yellow.	Deep yellow.	Deep yellow.

* In these cases 0.01 gram did not dissolve completely in benzene.

The wide divergency of colour in different solvents exhibited by these compounds is evidently due to the formation of additive compounds with the solvents, since in certain cases such products have been isolated. For example, from a moderately concentrated solution—deep red in colour—of 4-nitro-4'-hydroxystilbene in alcohol two additive compounds, $C_{14}H_{11}O_3N, 2C_2H_5 \cdot OH$ (black) and $C_{14}H_{11}O_3N, C_6H_5 \cdot OH$ (red), have been obtained.

In certain cases, attempted condensations under the usual conditions were unsuccessful. Thus *o*-nitro-*p*-toluic acid or its ethyl ester did not react with *p*-hydroxybenzaldehyde in the presence of piperidine. Also *m*-nitrophenylacetic acid did not appear to condense with benzaldehyde or with anisaldehyde. 2:4-Dinitrophenylacetic acid was found to be incapable of reacting to give condensation products in the presence of piperidine, as the latter decomposed it even at a low temperature, giving in quantitative amount 2:4-dinitrotoluene.

EXPERIMENTAL.

The general method employed for the preparation of the stilbene compounds described in this paper was the condensation, in the presence of piperidine, of nitrotoluenes and aromatic aldehydes. Mononitrotoluenes did not react, however, under the usual conditions of these experiments, and mononitrophenylacetic acids were accordingly used for the preparation of mononitrostilbene derivatives. The employment of piperidine in such reactions is due to Pfeiffer and Sergiewskaja (*Ber.*, 1911, 44, 1107), and it is found to effect the elimination of both water and carbon dioxide:

When piperidine is not present, higher temperatures are required, and water only is removed, the products being substituted phenylcinnamic acids, the elimination of carbon dioxide from which is usually very difficult (compare Walther and Wetzlich, *J. pr. Chem.*, 1900, [ii], 61, 181; Ogialoro, *Jahresber.*, 1897, 731). Stilbene-carboxylic acids have also been prepared by Pschorr (*Ber.*, 1886, 29, 497), who employed the Perkin reaction.

4-Nitro-4'-hydroxystilbene.—This compound, described by Hewitt, Lewcock, and Pope (*T.*, 1912, 101, 606), is obtained in good yield by the following method: A mixture of 2 grams of *p*-nitrophenylacetic acid (best got by Borsche's method, *Ber.*, 1909, 42, 3596) and 1 gram of *p*-hydroxybenzaldehyde was heated with ten drops of piperidine for one hour at 140°, at which temperature vigorous evolution of gas was observed. The dark, solid product was washed

with cold alcohol, and after crystallisation from glacial acetic acid, or better from dilute alcohol, a pure product resulted, consisting of bright yellow leaves, melting at 204° (the previous investigators gave the melting point as 193°).

Two additive compounds with alcohol were isolated. On allowing a fairly concentrated solution in that solvent to evaporate slowly at the room temperature, black needles, melting at 158° , separated (Found: $C_2H_6O = 25.4$. $C_{14}H_{11}O_3N, 2C_2H_6O$ requires $C_2H_6O = 27.6$ per cent.). On pouring a hot concentrated alcoholic solution into a little water, a red powder was precipitated (Found: $C_2H_6O = 15.9$. $C_{14}H_{11}O_3N, C_2H_6O$ requires $C_2H_6O = 16.0$ per cent.). Both these additive compounds on long standing, or on heating or rubbing were observed to lose alcohol, giving a canary-yellow powder. The red substance, on being heated, changed to yellow at about 100° and melted at the same temperature as the alcohol-free substance.

The yellow modification was found to be the stable one, but a second form was also isolated. On addition of light petroleum to a cold dilute benzene solution, and very rapid evaporation of the solvents, greenish-yellow, microcrystalline leaflets were obtained. This variety readily changed to yellow on being rubbed or heated.

4-Nitro-4'-hydroxystilbene is soluble in most organic solvents, but not very soluble in benzene or ligroin. On boiling it with acetic anhydride, the *acetyl* derivative was obtained as yellow plates, melting at $182-184^{\circ}$. It was only slightly soluble in ether or alcohol, somewhat more soluble in benzene, and readily soluble in chloroform, glacial acetic acid, or acetone (Found: $N = 5.07$. $C_{16}H_{13}O_4N$ requires $N = 4.95$ per cent.). The solution in concentrated sulphuric acid is intense violet in colour.

2:4-Dinitro-4'-hydroxystilbene.—This compound was produced in 90 per cent. yield by condensing, in presence of piperidine, equivalent proportions of 2:4-dinitrotoluene and *p*-hydroxybenzaldehyde at 150° for one hour. One crystallisation from glacial acetic acid was sufficient to give the pure compound, m. p. 158° (compare Pfeiffer and others, *Annalen*, 1916, 411, 72), who also obtained it by hydrolysing the acetyl derivative with methyl-alcoholic potash). The above compound also resulted in small yield from the condensation of 2:4-dinitrobenzaldehyde and *p*-cresol. The aldehyde was prepared by decomposing the *p*-diethylaminoanil (formed by condensing *p*-nitrosodiethylaniline and 2:4-dinitrotoluene; Sachs and Kempf, *Ber.*, 1902, 35, 1227) with dilute nitric acid. Five grams of dinitrobenzaldehyde and 2.5 grams of *p*-cresol were heated with 10 drops of piperidine under an air condenser at 140° for one and a half hours. The oily product, after being washed with

alcohol and crystallised several times from glacial acetic acid, was obtained in a pure condition.

Two modifications were isolated. From a moderately concentrated, hot solution in glacial acetic acid, large, deep-red prisms were deposited on cooling. On pouring a fairly dilute, cold solution in the same solvent into water, with shaking, a deep yellow product separated, consisting of fine needles. The latter is the unstable modification. At about 100° its colour changed to red, and it melted at the same temperature as the stable form. The colours given by both forms in solution were found to be identical. Yellow, fern-like crystals were obtained by recrystallisation from acetone. The solution in concentrated sulphuric acid or in alcoholic caustic soda is violet in colour.

3-p-Nitrophenylcoumarin.—When salicylaldehyde reacts with phenylacetic acid or its nitro-derivatives, the main products are 3-phenylcoumarins, and stilbene compounds are formed only in very small amount (compare Walther and Wetzlich, *loc. cit.*, p. 186; Borsche, *loc. cit.*, p. 3598). In the case of *p*-nitrophenylacetic acid, the following was the method employed :

Two grams of *p*-nitrophenylacetic acid and an equivalent amount of salicylaldehyde were heated under an air condenser with ten drops of piperidine at 130° for one hour, the reaction mixture being well shaken from time to time. The brown, oily product was washed several times with alcohol, the residue consisting of yellowish-white, crystalline scales, melting at 262°. It was almost insoluble in chloroform, acetone, or alcohol, slightly soluble in boiling glacial acetic acid, and readily soluble in nitrobenzene or tetrachloroethane. It may be recrystallised from nitrobenzene.

4-Nitro-2'-acetoxystilbene.—On evaporation of the solvent from the alcohol solution obtained in the above reaction, a dark oil remained, and this was dried and heated with excess of acetic anhydride. After boiling under reflux for four hours, a small quantity of bright yellow prisms separated on cooling and melted at 135°. The compound was soluble to some extent in alcohol or benzene, and dissolved very readily in glacial acetic acid, chloroform, or acetone (Found : N = 5.12. $C_{16}H_{13}O_4N$ requires N = 4.95 per cent.).

2:4:6-Trinitro-2'-hydroxystilbene.—A mixture of 4.5 grams of salicylaldehyde and 2.4 grams of 2:4:6-trinitrotoluene together with fifteen drops of piperidine was heated at 160° for three hours. The product, after washing with alcohol, and repeated crystallisation from glacial acetic acid, was deposited as yellow needles, which melted at 148°. The yield was fair (Found : N = 12.86. $C_{14}H_5O_7N_3$ requires N = 12.69 per cent.).

4-Nitro-3'-hydroxystilbene.—*p*-Nitrophenylacetic acid (3.6 grams) and *m*-hydroxybenzaldehyde (2.4 grams) were heated with ten drops of piperidine to 110°, at which temperature vigorous effervescence was observed. The temperature was kept constant at 110° for one hour, when the oily product, after being washed with a little alcohol and crystallised from the same solvent, was obtained pure, in bright yellow clusters of needles melting with decomposition at 188°. It dissolved readily in acetone or glacial acetic acid, but was only slightly soluble in ether, chloroform, or carbon tetrachloride. The yield was good (Found: N = 6.01. $C_{14}H_{11}O_3N$ requires N = 5.81 per cent.).

2:4-Dinitro-3'-hydroxystilbene.—A mixture of 3 grams of 2:4-dinitrotoluene and an equivalent amount of *m*-hydroxybenzaldehyde together with ten drops of piperidine was heated at 140° for an hour. The dark-coloured product was washed with alcohol and taken up with glacial acetic acid, from which it crystallised in yellow prisms melting at 194°. The yield was good (Found: N = 9.77. $C_{14}H_9O_5N_2$ requires N = 9.79 per cent.). The compound was slightly soluble in alcohol or chloroform, but dissolved readily in acetone.

2:4:6-Trinitro-3'-hydroxystilbene was obtained in a similar manner to the above from 2:4:6-trinitrotoluene and *m*-hydroxybenzaldehyde. The product, after crystallisation from glacial acetic acid, formed yellow leaflets, melting with decomposition at 205°. The yield was small (Found: N = 12.66. $C_{14}H_6O_7N_3$ requires N = 12.69 per cent.). The crystals were slightly soluble in chloroform or alcohol, readily soluble in acetone or glacial acetic acid.

3-Nitro-4'-hydroxystilbene.—A mixture of *m*-nitrophenylacetic acid (2 grams), *p*-hydroxybenzaldehyde (1.4 grams), and ten drops of piperidine was heated at 160–170° until all evolution of gas had ceased (about one hour). The brown, oily product was washed with a little cold alcohol, and then crystallised a few times from hot alcohol. A small yield was obtained of 3-nitro-4'-hydroxystilbene, consisting of fine, white needles which melted at 210°. It may be crystallised from acetone (Found: N = 5.81. $C_{14}H_{11}O_3N$ requires N = 5.81 per cent.).

3-*m*-Nitrophenylcoumarin.—Three grams of *m*-nitrophenylacetic acid and 2.1 grams of salicylaldehyde were heated under an air condenser with ten drops of piperidine to 160–170°. In a few minutes the reaction mixture solidified to a cake and was maintained at the same temperature for an hour longer. The product was washed thoroughly with boiling alcohol, the residue consisting of a white solid. The latter was almost pure 3-*m*-nitrophenylcoumarin. It may be recrystallised from glacial acetic acid, when it forms colourless, feathery needles melting at 254°. It is slightly

soluble in most organic solvents, but dissolves readily in hot nitrobenzene or tetrachloroethane (Found: $N = 5.31$. $C_{15}H_9O_4N$ requires $N = 5.24$ per cent.). The yield is almost quantitative.

4: 4'-Dinitrostilbene.—*p*-Nitrobenzaldehyde (3 grams) and *p*-nitrophenylacetic acid (3.6 grams) were heated at 120° with ten drops of piperidine for an hour. The resulting solid was washed with hot alcohol and extracted with boiling glacial acetic acid, from which pale yellow needles, melting at $234-235^\circ$, separated out. The yield was fair (Found: $N = 10.53$. Calc., $N = 10.37$ per cent.). The product may be recrystallised from nitrobenzene. Walden and Kernbaum (*Ber.*, 1890, 23, 1959) give the m. p. as $210-216^\circ$.

4: 3'-Dinitrostilbene.—This compound was readily prepared in a similar manner to that described above, *m*-nitrobenzaldehyde being substituted for *p*-nitrobenzaldehyde. On warming, vigorous effervescence ensued, and the temperature was maintained at 100° for one hour, the mixture being shaken from time to time. The nitrostilbene, after being washed with alcohol and crystallised from glacial acetic acid, was obtained as yellow needles melting at 155° . It is slightly soluble in alcohol, giving a green solution, soluble in chloroform, benzene, or acetone. In the latter solvent, a deep green colour is produced (Found: $N = 10.38$. $C_{24}H_{10}O_4N_2$ requires $N = 10.37$ per cent.).

In conclusion, the author desires to express his thanks to Professor T. Campbell James for giving him facilities for carrying out the work, and also for his kindly interest.

CCXXIX.—*Surface Phenomena in Sucrose Solutions.*

By RAYMOND RENARD BUTLER.

THE purpose of this preliminary investigation was to discover a relation between surface tension, osmotic pressure, and adsorption at the surface of solutions of sucrose of various concentrations, with special reference to the exosmosis phenomena which have been shown by Czapek to occur in plant-cells when immersed in solutions having surface tensions 0.65 to 0.68 times that of water. It seemed possible that an explanation might be found in adsorption, and prior to the investigation of solutions the surface tensions of which were lower than that of water, examination was made of solutions of higher surface tension, in order to obtain some idea of the magnitude of the Gibbs adsorption constant.

Morse and his collaborators (*Amer. Chem. J.*, 1912, 48, 29) found that the osmotic pressures of sucrose solutions of concentrations up to (weight) normal follow the van't Hoff gas laws. The values recorded by other investigators, however, are not concordant (Castell-Evans, *Physico-chemical Tables*, Vol. II), and therefore the surface tensions of such solutions under varying conditions of temperature and concentration have been determined, and, in addition, the relation between the density and the temperature of the various solutions.

The paper therefore divides naturally into three parts, namely, the relation between density and temperature, the determination of surface tension, and the relationship between surface tension and osmotic pressure.

Density-Temperature Curves.

These were obtained in the usual way. The pycnometer was filled with air-free, distilled water and standardised at a series of temperatures in a thermally-regulated bath. In this way, the exact volume of liquid contained by the instrument at known temperatures was ascertained, and the procedure was then repeated with sugar solutions of known strengths.

Pure white crystal sugar was used. The strengths of the solutions were determined polarimetrically, and checked against the density-concentration figures at 15° recorded by Plato (*Z. Ver. Deut. Zuckerind.*, 1900, 50, 982).

Densities of Sugar Solutions.

The following series of sugar solutions was made up:

Per cent. by volume.	Per cent. by weight.	Normality.	d_{15}^{20} .	Polarimeter reading.
6.48	6.32	0.19	1.02511	8° 39'
13.39	12.73	0.39	1.05174	17° 49'
20.52	19.00	0.60	1.07900	27° 15'
27.67	25.01	0.81	1.10656	36° 50'
32.62	29.00	0.95	1.12491	—

The densities of these solutions were then determined.

Normality of solution.	(Water).	0.19N.	0.39N.	0.60N.	0.81N.
Temperature.	Density of solution.				
0°	0.9999	1.027	1.054	1.082	1.110
10	0.9997	1.026	1.053	1.081	1.108
20	0.9982	1.024	1.051	1.078	1.105
30	0.9956	1.0215	1.048	1.075	1.1015
40	0.9923	1.018	1.044	1.071	1.097
50	0.9882	1.014	1.040	1.066	1.093
60	0.9834	1.009	1.035	1.061	1.087
70	0.9779	1.003	1.029	1.055	1.081

Determination of Surface Tension.

The capillary tube method was employed, the tube, attached to a finely divided scale, which was read by the aid of a pocket lens, being contained in an outer tube immersed in a constant-temperature bath. Four different strengths of sugar solutions were used, and temperature-surface tension readings taken over the range 14° to 70° ($\sigma = \frac{1}{2}rhdg$).

Normality.	$d_4^{15^\circ}$.	Percentage of sugar.		r (mean value in cm.).
		By vol.	By wt.	
(water)	0.9995	—	—	0.0319
0.20	1.0267	6.90	6.72	0.0362
0.40	1.0528	13.64	12.96	"
0.61	1.0805	20.91	19.36	"
0.82	1.1071	27.93	25.23	"

The following values of the surface tension at intervals of 10° were obtained. The table contains also the calculated values of u (see below).

Normality.	(Water).	0.20		0.40		0.61		0.82	
		N.		N.		N.		N.	
Temp.	σ .	σ .	$u \times 10^3$.	σ .	$u \times 10^3$.	σ .	$u \times 10^3$.	σ .	$u \times 10^3$.
10°	74.0	74.5	6.1	75.0	12.0	75.5	18.5	76.1	24.8
20	72.2	72.8	5.9	73.2	11.6	73.7	17.9	74.2	23.9
30	70.6	71.1	5.7	71.5	11.2	71.9	17.3	72.4	23.1
40	69.1	69.5	5.5	69.9	10.9	70.3	16.7	70.8	22.4
50	67.5	67.9	5.4	68.3	10.6	68.7	16.2	69.2	21.7
60	66.0	66.4	5.2	66.8	10.2	67.2	15.7	67.7	21.0
70	64.6	65.0	5.0	65.4	9.9	65.8	15.3	66.3	20.4

These values of σ (dynes/cm.) agree very well with those calculated from the formula, suggested by Knipp (*Physical Rev.*, 1900, 11, 129), connecting surface tension and temperature over a limited range:

$$\sigma_t = \sigma_0(1 - At + Bt^2),$$

where t is the temperature and A and B are constants.

For the curves shown, the average values of these constants are $A = 0.00247$ and $B = 0.00000469$.

The accuracy with which surface tension can be determined depends on the accuracy of measurement of the height of the liquid in the capillary tube. The viscous nature of these sucrose solutions necessitated the use of a tube of somewhat wider dimensions than usual. A tube of radius 0.0362 cm. gave satisfactory results in the case of the more viscous solutions, but it should be noted that the value found for water at 25° is lower by 0.8 per cent. than that recorded by Richards and Carver (*J. Amer. Chem. Soc.*, 1921, 43, 827).

The degree of accuracy claimed for the above figures is 0.75 per cent. The chief error arises in the determination of the position of the surface of the liquid at the place where the capillary tube enters it. The level of the bottom of the meniscus was taken in each case, probably correctly to 0.1 mm. The minimum rise measured was 3.42 cm., so that the error introduced from this source may be about 0.3 per cent.; and since the diameter of the tube and the densities are correct to three significant figures, the possible error in the final surface tension figures is as stated.

FIG. 1.

Relation between surface tension and temperature.

Quincke's attempt to connect the surface tension σ_s of a solution with the surface tension of water σ_w by the equation $\sigma_s = \sigma_w + ky$, where k is a constant, and y the number of equivalents per 100 molecules of water, was modified by Dorsey (*Phil. Mag.*, 1897, [v], 44, 369), who put y = the number of gram-equivalents per litre of solution. In the case of dilute solutions of sucrose, if y = the number of gram-molecules dissolved per litre of solution, k appears, from the experiments here recorded, to have the approximate value 2.23. It has, however, been shown by Quincke that the equation breaks down for sugar solutions of higher concentration than normal.

The change in surface tension ($d\sigma$) can now be read directly from the curves together with the corresponding change in concentration (dc); and given the values of $d\sigma/dc$, it is possible to calculate the deficiency of solute in the surface, by the Willard Gibbs equation

$$u = -c/RT \cdot d\sigma/dc,$$

where u is the deficiency in grams per sq. cm., c is the concentration in grams per c.c., R is the gas constant, and T is the absolute temperature. For $dc = 0.21$, the values of $d\sigma$ at 30°, 40°, 50°, 60°, and 70° are 1.25, 1.25, 1.3, 1.3, and 1.25, respectively, giving a mean value of $d\sigma/dc = 6.1$. If the gram is taken as the unit of mass, $R = 8.315 \times 10^7/M$ ergs. Inserting this value in the above equation, u can be calculated in grams per square centimetre of surface. The values are given in the preceding table.

Osmotic Pressures of Sucrose Solutions.

The following values of the osmotic pressures of the sugar solutions used in the surface-tension experiments are obtained by interpolation from the data given by Morse (*J. Amer. Chem. Soc.*, 1912, 48, 29).

Concentration. Volume normal.	Concentration. Wt. normal.	Mean osmotic pressure at :						
		10°.	20°.	30°.	40°.	50°.	60°.	70°.
0.20	0.208	5.09	5.27	5.24	5.37	5.49	5.66	—
0.40	0.434	10.63	11.00	11.17	11.50	11.64	11.79	—
0.61	0.70	17.50	18.13	18.50	18.93	19.20	19.40	19.57
0.82	1.0	25.69	26.64	27.22	27.70	28.21	28.37	28.62

There is a definite relation between osmotic pressure and the Gibbs adsorption constant u , and the slope of the curve plotted between P and u shows a nearly constant value of dP/du .

The product Pu is obviously a function of the concentration over a limited temperature range (in this case, 283° to 333° absolute). This was to be expected in the case of dilute non-dissociated solutions, since P is proportional to the concentration c , and the adsorption constant u is also proportional to c , if $d\sigma/dc$ is a constant. At a definite temperature T , or over a very small range of temperature dT , the product Pu should therefore be proportional to c^2 . The relationship will therefore take the form

$$Pu = K \times c^2,$$

from which x can be calculated in the usual way.

If $\log Pu$ is plotted against $\log c$, all the points will be on a straight line (Fig. 2).

Concentration.		Log Pu .		α .
Volume normal.	Grams per 100 c.c.	Mean value.	Log c .	
0.20	6.9	— 7.52286	0.83885	2.08
0.40	13.6	— 6.90367	1.13481	2.08
0.61	20.9	— 6.50295	1.32035	2.09
0.82	27.9	— 6.21034	1.44607	2.12

It would appear, therefore, that the relationship $Pu = Kc^2$ holds for concentrations up to approximately 20 per cent. of sucrose (grams per 100 c.c.), for a limited range of temperatures. Above that concentration, the value of α begins apparently to increase.

FIG. 2.

Whether this is due to an alteration in the value of $d\sigma/dc$ at high concentrations, or to the effect of decreasing hydration of the solute molecules, is not clear, and will be made the subject of a further paper.

If P is expressed in atmospheres, u in grams per square centimetre of surface, and c in grams of sucrose per 100 c.c. of solution, the constant K has a value lying between 5.3×10^{-10} and 5.5×10^{-10} . In view of the degree of accuracy obtainable in these experiments, it is not possible to fix the value more closely.

CCXXX.—*The Structure of the Benzene Nucleus. Part III. Synthesis of a Naphthalene Derivative involving a Bridged Phase of the Nucleus. The Constitution of Naphthalene and Anthracene.*

By WILLIAM ARTHUR PERCIVAL CHALLENGOR and CHRISTOPHER KELK INGOLD.

IN Part I of this series, attention was directed to the fact that the properties of aromatic substances could be brought into correspondence with those of aliphatic compounds, and especially with the intermediate class of compounds showing intra-annular tautomerism, by ascribing to the benzene nucleus a bridged phase (I), intimately related to and in dynamic equilibrium with the conventional Kekulé phase (II):

A verifiable consequence of this view was that, if a bridged cyclohexadiene derivative of type (I) could be synthesised by the methods which have been employed in producing other types of bridged homocyclic rings, it should be found to be not isomeric but identical with the corresponding aromatic substance. In Part II (p. 23), the synthesis of a dicyclohexanedione (III) from the cyclobutanone derivative (IV) was described: the product was found to be identical with ordinary orcinol (V).

The purpose of this paper is to extend the above considerations to the more complex cases of naphthalene and anthracene.

Bamberger (*Annalen*, 1890, 257, 1) has laid stress on the remarkable difference of properties between many derivatives of naphthalene and the corresponding derivatives of benzene, contrasting this with the close similarity between derivatives of tetrahydronaphthalene and those of benzene. Since there is no valid evidence of asymmetry in the naphthalene nucleus, Bamberger concluded that it contains two identical carbon systems, neither of which, however, exists as a true benzene ring, although either becomes converted into one

when the other takes up four atoms of hydrogen. Adopting Bam-
berger's nomenclature :

Bamberger's interpretation of his data is limited entirely by static ideas. On the dynamic conception of cyclic nuclei, the notable differences between benzene and naphthalene must be interpreted as arising from the influence of each nucleus on the tautomeric change taking place within the others; only thus can the remarkable effect of the hydrogenation of one ring in restoring the full benzenoid character of the other be explained. Moreover, it is to be inferred from the variety of quinonoid structures to which naphthalene can give rise that the intra-nuclear tautomerism of naphthalene must be of a more complex character than is the case with benzene, and must involve several individual phases. Further, it is evident that in naphthalene the disturbing effect of each nucleus on the other must be exerted from one side, that is, asymmetrically about the dotted line in formula (VI).

In anthracene, new conditions arise. It is evident, in the first place, that the tautomeric change within the two end rings of the anthracene nucleus will be asymmetrically affected by the rest of the molecule, just as is the case in naphthalene. Actually, as is well known, there is a remarkable similarity between the chemistry of the terminal rings of anthracene and the chemistry of naphthalene; the laws regulating substitution, the properties of corresponding derivatives, and the relationships with derived quinonoid structures, are extremely similar in the two series.

On the other hand, the condition of the central ring of anthracene has no parallel either in naphthalene or benzene. It is plain that the terminal rings must affect the tautomerism of the central ring equally and in opposite directions, the result being to promote the formation and increase the permanence of any phase which is symmetrical about the dotted line in formula (VII). Thus the bridged phase of the central ring (in which the bridge connects the "meso" carbon atoms) is the permanent, indeed, almost the only phase; and around this circumstance, in the authors' view,

the chemistry of the central ring of anthracene revolves. Additions to the 9:10-positions, eliminations from these positions, the mobility of tautomeric structures in which the mobile hydrogen atom passes across the *meso*-ring, all may be seen to result from the practical elimination of all phases other than the bridged phase.

Thus, without making too specific a hypothesis as to the condition of the phases in naphthalene and anthracene, considerations of symmetry and of the general lines on which any such hypothesis must be developed lead of themselves to certain broad deductions in good agreement with the main chemical facts.

They are also in agreement with the crystallographic facts. Whilst no confusion must be allowed to arise between the "crystal molecule" and the molecule in solution, it must be recognised that there is a close connexion between them; namely, that the former, in all cases, is necessarily a *possible* phase or modification of the latter; otherwise, crystallisation could not occur. The connexion may be limited to this inclusion of one amongst the phases of the other, and it is safer in the meantime to assume that it is. But it is sufficient for the purpose to recognise that if the atom-centres in a crystal molecule can be shown by X-ray analysis to be orientated in a particular way with respect to one another, then the chemical molecule must be held together by valencies in such a way that, even in solution, the atoms *can* take up that particular relative configuration on which the possibility of crystallisation depends. We may go further and assume that near the crystallising point there must be a certain, and possibly considerable, proportion of molecules in or very nearly in the configuration of the crystal molecule.

As regards benzene, it is evident that the bridged formula,* hitherto proposed only as a representation of a single phase in the liquid state, is stereochemically identical with the disposition of atoms (VIII) suggested by Sir W. Bragg (T., 1922, 121, 2766) for the molecule of crystalline benzene, the carbon atoms being

* The non-existence of optically active modifications of the simpler derivatives of benzene imposes another stereochemical condition which must be satisfied by any suggested benzene structure; namely, that in any static formula the carbon and hydrogen atoms must lie in one plane, and that in any dynamic formula they must pass through a uniplanar configuration. Since the "crystal-molecule" is not uniplanar, a dynamic formula is the alternative indicated, and since the Kekulé formula is the only one which has a uniplanar space model, this must be one phase. Combining this result with the crystallographical evidence (above) that the bridged formula also represents one phase, we see that the main thesis underlying this series of investigations might have been derived from spatial considerations alone.

arranged in two planes (1—2—3—4 and 1—6—5—4) in such a way as to give rise to four-fold symmetry (IX) :

In fact, since *X*-ray analysis deals only with the relative positions of atoms and not with their mode of union, one might have derived the chemical formula from the spatial arrangement. The natural interpretation of this result is that, whereas liquid benzene contains a certain proportion each of the bridged and the Kekulé phases, the former variety is the first to crystallise, and that hence, owing to the disturbing effect of crystallisation on the mobile equilibrium, the solid consists entirely of this form.

Shearer (*Proc. Physical Soc.*, 1923, 35, ii, 81) has also assumed the para-bridged structure in order to account for the symmetry possessed by the unit lattice of a benzene crystal. He has, moreover, extended his considerations to the *X*-ray analyses of naphthalene and anthracene, and has arrived at the following structural formulæ (X and XI) :

Whilst the bridged-bonds in the naphthalene rings and in the two outer rings of anthracene must be regarded only as illustrative of a certain asymmetry (compare p. 2067) in the dynamic constitution of these rings, rather than as a picture of their actual condition, it is interesting to observe the appearance of the symmetrical bridge-bond in the central ring of anthracene, and to note that both formulæ conform in their more general features to the lines laid down on the basis of chemical considerations at the commencement of this section.

Thus there is both chemical and crystallographic evidence that naphthalene (and the outer rings of anthracene also) differ in some fundamental respect from the benzene ring itself, and for this reason it seems desirable that all experimental work carried out on the constitution of the benzene nucleus should as far as possible be paralleled in the naphthalene series.

In this paper experiments are described the object of which is to produce by synthesis a bridged modification of the naphthalene

nucleus, in a manner similar to that in which the synthesis of the bridged phase of orcinol was accomplished.

A convenient starting point appeared to be provided in *o*-phenylene diacetic acid (XII), the dibromo-ester (XIII) of which might be expected to give the unsaturated ester (XIV) on treatment with sodium ethoxide. This substance might then condense with ethyl sodiomalonate to give the ester (XV), which on treatment with molecular sodium should yield the bridged-ring structure (XVI) (or XVII or XVIII).

A synthesis very similar to this has now been accomplished, but it has not been possible to carry out the above series of reactions in the manner originally intended owing to the instability of the unsaturated product (XIV), which, apparently, at the moment of its formation, or very shortly afterwards, becomes converted into a polymeride of high molecular weight. Thus, when the dibromo-ester (XIII) is treated with organic bases or concentrated alkalis, the main product is always an amorphous polymeride, probably of the compound (XIV). Certain specimens of the amorphous product on distillation with a little aluminium chloride gave a small amount of a nearly colourless oil, b. p. about $230^\circ/20$ mm., which on analysis gave figures indicating the constitution represented by formula (XIV), but this substance, on keeping for a few hours, first darkened and finally set to a brittle resin, and it was not found possible to stabilise it sufficiently to carry out the next step of the synthesis.

The action of water or dilute sodium hydroxide solution on the dibromo-acid chloride (XIX) led to a different result. Two products were obtained; one was an amorphous acid of high molecular weight, probably a polymeride of the unsaturated acid (XX); the other consisted of $\alpha\alpha'$ -dihydroxy-*o*-phenylenediacetic acid (XXI).

This substance, on heating to 110° , yielded a lactone (XXII), which was sufficiently stable to be crystallised from water without conversion into the original dihydroxy-acid. On treatment with acetyl chloride, the lactone apparently underwent further dehydration, giving a dilactone (XXIII), which very easily passed into a mono-lactone (XXIV), isomeric with and easily convertible into the original mono-lactone. These relationships suggest that the two lactones are stereoisomeric, as the following formulæ show :

Another attempt which was made to overcome the instability of the ester (XIV) consisted in causing it to be formed in the presence of sodiomalonate ester, which might be expected to condense with it before polymerisation set in. The products of these experiments, however, were ethyl ethanetetra-carboxylate, a substance which could not be distilled and gave an amorphous acid on hydrolysis, and the ester (XXV), which on treatment with alcoholic potassium hydroxide gave the hexacarboxylic acid (XXVI) or the pentacarboxylic acid (XXVII) according to the conditions.

The formation of these substances seems the more remarkable when it is recalled that Perkin (T., 1888, 53, 1) did not encounter the ester (XXVIII) as a product of the action of *o*-xylylene bromide on ethyl sodiomalonate; the condensation product consisted exclusively of the hydrindene derivative (XXIX).

Equally remarkable as an example of the complete change in the direction of the condensation caused by a slight modification in the constitution of one of the reacting substances, is the interaction of ethyl sodiomalonate and the dibromo-derivative of *o*-phenylenediacetonitrile. The dibromo-nitrile (XXX) very readily loses hydrogen bromide, giving an amorphous product which appears to be a polymeride of the unsaturated nitrile (XXXI); but when treated under carefully regulated conditions with ethyl sodiomalonate, the product, in addition to this polymeride, is a bridged-ring derivative (XXXII), analogous in constitution to the ketonic ester (XVI) which experiments on the dibromo-ester had failed to produce. As often happens in sodium ethoxide condensations, this substance became partly hydrolysed during isolation, giving an acid amide (XXXIII):

An examination of this substance clearly showed that it was strongly enolic, and, in fact, that it had the characteristic properties of a naphthol (XXXIV). On hydrolysis by acids, it yielded the amide (XXXV), which on further hydrolysis with concentrated aqueous sodium hydroxide yielded β -naphthol (XXXVI).

The identity of the amide was confirmed by converting it into its *p*-toluenesulphonyl derivative (XXXVII) and treating this with bromine and alkali, which gave a mixture of the sulphonyloxy-base (XXXVIII) and the hydroxy-base (XXXIX):

The next step was to identify the sulphonyloxy-base and hydroxy-base by synthesis from a naphthalene derivative of known constitution. For this purpose, 2:4-dinitro- α -naphthylamine (XL) was selected as the starting point, and was converted by way of the diazo-oxide (XLI) into 4-nitro- β -naphthol (XLII) in the manner described by Morgan and Evens (T., 1919, 115, 1126). Attempts to reduce the nitronaphthol with aluminium amalgam in moist ether led to the complete elimination of the amino-group, naphthalene being amongst the products formed. The nitronaphthol was therefore converted into the *p*-toluenesulphonyl derivative and the product (XLIV) reduced by means of aluminium amalgam in moist ether (Morgan and Burgess, T., 1921, 119, 697) to the amino-*p*-toluenesulphonate (XLV), with which the substance (XXXVIII) was found to be identical in every respect. The amino-*p*-toluenesulphonate was converted, by hydrolysis with alcoholic sodium hydroxide, into 4-amino- β -naphthol (XLIII), with which the compound (XXXIX) was identified by direct comparison.

EXPERIMENTAL.

(A) Syntheses from *o*-Phenylenediacetic Acid and its Nitrile.

Preparation of o-Phenylenediacetonitrile and *o*-Phenylenediacetic Acid.—*o*-Xylene dibromide was prepared by brominating *o*-xylene at 125–130° (Perkin, T., 1885, 53, 5) and converted by treatment with alcoholic sodium or potassium cyanide into *o*-phenylenediacetonitrile (Moore and Thorpe, T., 1908, 93, 165). The dinitrile was then hydrolysed to the diamide by treatment with strong sulphuric acid, and the aqueous acid solution of the amide, obtained on dilution with water, made alkaline with sodium hydroxide and boiled until the evolution of ammonia had ceased (compare Moore and Thorpe, *loc. cit.*). The amide was only precipitated in a few instances when the aqueous acid solution was made alkaline with ammonia (compare Moore and Thorpe, *loc. cit.*), and this was the

reason for following the above method. The diacetic acid was isolated by extraction with ether and crystallised from the concentrated solution, from which it separated in an almost pure condition, m. p. 149—150°.

Dibromination of o-Phenylenediacetic Acid. Preparation of Ethyl $\alpha\alpha'$ -Dibromo-o-phenylenediacetate.—*o*-Phenylenediacetic acid (20 grams) was mixed in a Geissler flask with phosphorus pentachloride (45 grams). A vigorous reaction set in, clouds of hydrogen chloride being evolved, and the mixture liquefied. It was then heated on the steam-bath and, when the reaction had ceased, treated with dry bromine (10.6 c.c.) in small quantities timed by the rate of absorption. When all the bromine had disappeared, the mixture was allowed to cool and poured into 150 c.c. of absolute alcohol, and the solution boiled for a few minutes after the vigorous reaction had ceased. It was then allowed to cool and poured into a large excess of water and extracted with ether. The ethereal solution was washed with water, sodium hydrogen carbonate solution, and finally with water. A deep red colour was produced during the washing with sodium hydrogen carbonate. After drying over calcium chloride and removal of the ether, a red oil was left, which decomposed on distillation at 10 mm., and hence could not be purified. On distillation at atmospheric pressure, it decomposed with evolution of hydrogen bromide (Found: Br = 39.2. $C_{10}H_8O_4Br_2$ requires Br = 44.1 per cent.). The red colour could be removed by treatment with animal charcoal in alcoholic solution.

Attempted Monobromination of o-Phenylenediacetic Acid.—The monobromination of *o*-phenylenediacetic acid has been described by Schad (*Ber.*, 1893, 26, 223), but attempts to repeat his work were unsuccessful. Monobromination was attempted under a variety of conditions, but always with the result that about half of the material remained unchanged, whilst most of the remainder underwent dibromination.*

Action of Concentrated Aqueous and Alcoholic Potassium Hydroxide and Pyridine, Quinoline, and Diethylaniline on the Dibromo-ester and Dibromo-acid Chloride.—An outline of these experiments has already been given (p. 2070), and it is unnecessary to add further details here, since the use of drastic reagents such as organic bases and concentrated alkalis had to be abandoned owing to the intractable character of the products.

* A specimen of monobromo-ester on keeping for fifteen months deposited crystalline matter consisting mainly of *o*-phenylenediacetic acid, but containing also a small proportion of the lactone described by Shad (*loc. cit.*). Hence mono-bromination must have occurred to a small extent.

Action of Water on $\alpha\alpha'$ -Dibromo-o-phenylenediacyl Chloride; Formation of $\alpha\alpha'$ -Dihydroxy-o-phenylenediacyl Acid.—o-Phenylenediacyl acid (40 grams) was dibrominated as previously described (p. 2074), using 100 grams of phosphorus pentachloride and 22 c.c. of bromine. The product was then slowly poured into hot water (400 c.c.) with rapid stirring. A rather vigorous reaction occurred, and the oily acid chloride rapidly went into solution. After heating on the steam-bath for some time, the liquid, filtered from a little resinous substance, was treated with animal charcoal, again filtered, and allowed to cool, when a white solid separated. This was collected and the mother-liquors were extracted with ether. A further quantity was obtained in this way, the total yield being 80 per cent. of the theoretical. The product was recrystallised from water, in which it is readily soluble near the boiling point, but only slightly soluble in the cold. M. p. 205° (Found: C = 52.94; H = 4.5. $C_{10}H_{10}O_6$ requires C = 53.08; H = 4.46 per cent.). The acid readily loses water at 110° , giving the lactone (A) (*v. infra*) (1.1480 grams, on being heated at 110° for three and a half hours, lost 0.0938 gram, that is, 8.17 per cent. H_2O ; 1.0147 grams, at 110° for one hour, lost 0.0816 gram, that is, 8.04 per cent. H_2O ; 0.3840 gram, at 110° for one hour, lost 0.0307 gram, that is, 7.99 per cent. H_2O . $C_{10}H_{10}O_6 \rightarrow C_{10}H_8O_5$ requires loss = 7.97 per cent.).

The lactone (A) obtained by heating the dihydroxy-acid at 110° could be readily crystallised from water without reconversion into the dihydroxy-acid. Its melting point is $211-212^{\circ}$ (Found: C = 57.85; H = 4.18. $C_{10}H_8O_5$ requires C = 57.68; H = 3.83 per cent.). Both the lactone (A) and the dihydroxy-acid are almost insoluble in dry ether.

The silver salt of the dihydroxy-acid was formed as a white precipitate from silver nitrate and the sodium salt in aqueous solution (Found: Ag = 49.06. $C_{10}H_8O_6Ag_2$ requires Ag = 49.06 per cent.).

The dianilide was prepared by heating the free dihydroxy-acid or its lactone with excess of aniline for four and a half hours at about $150-170^{\circ}$. The mixture was extracted with hot dilute hydrochloric acid and finally with water. The solution of the residual dark oil in alcohol was kept for several days, during which it slowly deposited crystals of the dianilide. These were collected and crystallised from absolute alcohol. The dianilide is almost insoluble in cold alcohol and only moderately soluble in hot; it separates in elongated rhomboids, m. p. $208-209^{\circ}$ (Found: N = 7.69. $C_{22}H_{20}O_4N_2$ requires N = 7.45 per cent.).

Conversion of Lactone (A) into Lactone (B).—The lactone (A) dissolved when heated under reflux with about five to ten times

its weight of acetyl chloride for four to five hours. The solution was evaporated on the steam-bath, and the last traces of the acetyl chloride were removed by potassium hydroxide in a desiccator. During the purification, crystals gradually appeared and the whole mass ultimately solidified. The solid was crystallised from water, which yielded thin plates, m. p. 179–180° (Found: C = 57.51; H = 4.19. $C_{10}H_8O_5$ requires C = 57.68; H = 3.88 per cent.). The lactone (B) was readily changed back to the (A)-form by keeping it in sodium hydroxide solution for a few hours. On acidifying, the (A)-form crystallised. The change was not instantaneous, however, as, on dissolving the (B)-form in sodium bicarbonate solution and immediately acidifying with hydrochloric acid, an oily product was obtained which slowly solidified and melted at 172–174°. The change can also be brought about by boiling with water, and it is even difficult to avoid a certain amount of reconversion when the B-lactone is crystallised from water.

Action of Hot Dilute Sodium Hydroxide on $\alpha\alpha'$ -Dibromo-o-phenylenediacetyl Chloride.—o-Phenylenediacetic acid (10 grams) was dibrominated as previously described (p. 2074) and the acid chloride poured into a hot solution of 40 grams of sodium hydroxide in 200 c.c. of water. A very violent reaction ensued. When all the bromo-acid chloride had been added, the solution was heated on the steam-bath for about one hour, filtered when cold, and acidified with hydrochloric acid; the large precipitate of amorphous acid was collected, and the clear filtrate extracted several times with ether. The ether extracts on evaporation yielded a small amount of a semi-solid substance, which, on mixing with a little dry ether, gave a solid, m. p. 200°. On crystallisation from water, it melted at 205° and was identical with $\alpha\alpha'$ -dihydroxy-o-phenylenediacetic acid. The yield was 11–12 per cent. of the theoretical.

The amorphous acid underwent some further change on keeping, but the freshly prepared substance, on analysis and titration, gave figures approximating to those required for a dibasic acid of the composition $C_{10}H_6O_4$. Its insolubility and general properties pointed to a very high molecular weight and hence it may be regarded as a polymeride of an acid of type (XIV). It rapidly absorbed permanganate in alkaline solution.

Action of Ethyl Sodiomalonate on Dibromo-o-phenylenediacetic Ester.—Sodium (4.6 grams) was dissolved in absolute alcohol (75 c.c.), malonic ester (32 c.c.) added, and the solution, cooled to 35–40°, treated with 40 grams of the dibromo-ester, the temperature being maintained below 40°. After about one hour, the solution was heated on the steam-bath for three to four hours, cooled, poured into water, and shaken with ether after addition

of a little sodium carbonate solution. The red oily residue from the dried ethereal extracts decomposed when distilled under reduced pressure, and therefore could not be purified. On keeping for some time, it deposited crystals of ethyl ethanetetrcarboxylate, which were removed and the residual oil hydrolysed.

For this purpose, 10 grams were boiled with a solution of 15 grams of potassium hydroxide in 75 c.c. of alcohol for about two hours. The alcohol was evaporated with the addition of water, and the solution then evaporated nearly to dryness. It was acidified with hydrochloric acid, and the amorphous acid (p. 2076) thereby precipitated was removed and the solution extracted several times with ether. The ethereal extracts were dried over calcium chloride and evaporated. The residual oil, which partly solidified, was rubbed with a little acetone and a large volume of dry ether was added, and the crystalline material thus obtained was collected and washed with ether. It melted at 192° with decomposition, and was further purified by dissolving it in acetone, adding chloroform, and evaporating the solution until crystals began to separate. These, washed with chloroform, melted at 187° with decomposition. Analysis showed them to consist of the hexacarboxylic acid (Found : C = 48.32; H = 4.08. $C_{16}H_{14}O_{12}$ requires C = 48.22; H = 3.54 per cent.).

Action of Ethyl Sodiomalonate on "Monobromo-o-phenylenediacetic Ester."—Sodium (1.5 grams) was dissolved in absolute alcohol (60 c.c.) and malonic ester (12 c.c.) added. The solution was cooled carefully to $35-40^{\circ}$ and 20 grams of the "monobromo-ester" were added slowly, the temperature being kept below 40° . After about one hour, the mixture was boiled for two hours, poured into water, and extracted with ether. The ethereal solution was dried over calcium chloride and distilled, and the red oil, which decomposed on attempted distillation under reduced pressure, hydrolysed with excess of alcoholic potassium hydroxide. The alcohol was evaporated with the addition of water, and the aqueous solution acidified with hydrochloric acid. A certain amount of an amorphous acid product was precipitated. The filtrate from this was extracted several times with ether, the ethereal solution dried over calcium chloride, and evaporated. The oil thus obtained, on keeping for a short time, partly solidified, and was rubbed with ether and filtered. The resulting solid was then extracted several times with boiling benzene, which on evaporation yielded a solid, m. p. 150° , identical with o-phenylenediacetic acid. The solid which was insoluble in benzene was dissolved in a little acetone, and, after the addition of some chloroform, the solution evaporated until crystals began to separate. This was repeated several times

until ultimately a white, crystalline solid, m. p. 187° (decomp.) was obtained. This substance consisted of the pentacarboxylic acid (Found: C = 50.45; H = 4.31. $C_{15}H_{14}O_{10}$ requires C = 50.83; H = 3.98 per cent.).

Dibromo-o-phenylenediacetonitrile.—A chloroform solution containing 156 grams of the nitrile was treated with a solution of 320 grams of bromine in the same solvent and the mixture kept in a warm place until a considerable quantity of oil had collected and the evolution of hydrogen bromide had greatly slackened. The oil was then separated, washed repeatedly with small quantities of chloroform, and the chloroform pumped off at a low temperature with the addition of ether. The dinitrile was thus obtained as a yellowish-red oil which lost hydrogen bromide on heating and hence could not be purified by distillation (Found: Br = 50.5. $C_{10}H_6N_2Br_2$ requires Br = 50.9 per cent.).

On heating the dinitrile until no more hydrogen bromide was evolved, a brittle, amorphous substance was obtained which was free from bromine, and seemed from its composition to be a polymeride of the unsaturated nitrile (XXXIII) [Found: C = 78.2; H = 2.4; N = 18.8. $(C_{10}H_4N_2)_2$ requires C = 78.9; H = 2.6; N = 18.4 per cent.].

Action of Dibromo-o-phenylenediacetonitrile on Cold Ethyl Sodiomalonate; Formation of 4-Cyano-1-carboxylamido- β -naphthol-3-carboxylic Acid.—Ethyl malonate (160 grams) was added to a solution of sodium ethoxide prepared from 23 grams of sodium and 300 grams of ethyl alcohol. After the precipitation of the sodio-ester, 1000 grams of ether and 76 grams of the dibromodinitrile were added. The mixture was kept at 0° for ten days, or until the dark grey solid which separated ceased to appear, and was then poured into dilute hydrochloric acid, and the ethereal layer separated. The ethereal solution was washed with sodium hydrogen carbonate solution, which caused the separation of a dark, amorphous solid, and then with dilute sodium hydroxide. The sodium hydroxide solution was acidified and extracted with much ether. The substance which was deposited when the extract was concentrated, separated very slowly from its solution in benzene as a cinnamon-coloured powder. It was soluble in sodium hydroxide, gave an olive-brown colour with ferric chloride, and on distillation with soda-lime yielded β -naphthol (Found: N = 11.08. $C_{13}H_8O_4N_2$ requires N = 10.92 per cent.).

β -Naphthol-4-carboxylamide.—The above amide was boiled with hydrochloric acid until ethyl alcohol ceased to be evolved, and then under a reflux condenser for twenty hours. The solution was cooled and the brittle, resinous product crushed and extracted

with dilute sodium hydroxide. The precipitate which was obtained when solid sodium hydrogen carbonate was stirred into this solution was washed, dried, and crystallised from xylene. M. p. about 220° with decomposition (Found: C = 70.3; H = 4.98. $C_{11}H_9O_2N$ requires C = 70.7; H = 4.81 per cent.). The residual aqueous solutions, when acidified and extracted with ether, yielded a small quantity of the acid (below).

The amide gives a brown colour with ferric chloride and is soluble in sodium hydroxide, but not in sodium hydrogen carbonate solution. It also gives a *p*-toluenesulphonyl derivative (below). It is remarkably stable towards hydrochloric acid and moderately concentrated sodium hydroxide, but hot, very concentrated sodium hydroxide, fused potassium hydroxide, and soda-lime cause the complete elimination of the carboxylamido-group and the formation of β -naphthol. Nitrous acid gives an amorphous, intensely coloured precipitate.

The *p*-toluenesulphonyl derivative, prepared with the help of *p*-toluenesulphonyl chloride, separated from xylene as a fine, pearly-grey powder, m. p. about 210° (decomp.).

Action of Bromine and Sodium Methoxide on the p-Toluenesulphonyl Derivative of β -Naphthol-4-carboxylamide.—The amide (3.2 grams) was mixed with bromine (1.6 grams), and an aqueous solution containing about 0.5 gram of potassium hydroxide was added until the colour of the bromine was just discharged. The solid was washed with water and dried on porous porcelain. It was then added to a mixture of sodium hydroxide and sodium methoxide made by dissolving 0.7 gram of sodium in 10 c.c. of absolute methyl alcohol and adding 0.1 gram of water. The solution was boiled for a few minutes and then evaporated with addition of water. The aqueous suspension was acidified with dilute hydrochloric acid and then filtered. The dark-coloured filtrate was boiled repeatedly with successive quantities of animal charcoal until it was only a pale greenish-yellow, and then treated with an excess of warm saturated sodium hydrogen carbonate. The precipitate was collected by filtration in an atmosphere of carbon dioxide, washed with water and then with cold moderately concentrated sodium hydroxide, and then again with water. The residue was crystallised from benzene, from which it separated as pale yellow prisms, m. p. 137° , which were identified as the *O*-*p*-toluenesulphonyl derivative of 4-amino- β -naphthol by direct comparison and a mixed melting-point determination with a specimen prepared by a conventional synthetic method (below).

The sodium hydroxide solution was saturated with carbon dioxide and the pale yellow precipitate collected, dissolved in dilute hydro-

chloric acid, and, after repeated treatment with charcoal, reprecipitated by sodium hydrogen carbonate. It was collected by filtering in carbon dioxide, dried in an evacuated carbon dioxide-filled desiccator, and then recrystallised from alcohol from which it separated in needles which melted and decomposed at 198° with previous sintering. It was identified as 4-amino- β -naphthol by analysis (Found: C = 74.92; H = 6.06; Calc., for $C_{10}H_7ON$, C = 75.44; H = 5.70 per cent.), and by direct comparison with a specimen synthesised for the purpose by the method described below.

(B) *Syntheses from 4-Nitro- β -naphthol.*

2:4-Dinitroaceto- α -naphthalide.—Aceto- α -naphthalide was nitrated according to the method described by Morgan and Evens (*loc. cit.*). The yield of the pure dinitro-derivative was only 30 per cent. of the theoretical, that is considerably less than Morgan and Evens were able to obtain.

4-Nitro- β -naphthol.—The above dinitro-compound was diazotised and the diazo-oxide boiled with alcohol in the presence of aluminium powder, just as described by Morgan and Evens, excepting that as it was found that the reaction was completed in six to eight hours, the prolonged heating they recommend was not resorted to. The crude 4-nitro- β -naphthol was crystallised until its m. p. rose to above 110° , and was then used for the experiments described below.

4-Nitro- β -naphthyl-*p*-toluenesulphonate.—This substance was prepared by grinding 4-nitro- β -naphthol (21 grams) together with anhydrous sodium acetate (9 grams) and *p*-toluenesulphonyl chloride (23 grams) in a hot mortar. The mixture gradually became pasty and the reaction was completed by heating on the steam-bath. When cold the product was triturated with warm aqueous sodium carbonate, and after three hours the mixture was acidified with hydrochloric acid and filtered. The residue was crystallised from alcohol, from which the toluenesulphonate separated in long, pale yellow needles, m. p. 122° . The alcoholic mother-liquors contained a little unchanged nitronaphthol, which was recovered on evaporation.

The nitronaphthyltoluenesulphonate is almost insoluble in cold alcohol and ether, slightly soluble in boiling ether, and fairly readily soluble in boiling alcohol (Found: N = 4.34. $C_{11}H_{13}O_5NS$ requires N = 4.08 per cent.).

4-Amino- β -naphthyl-*p*-Toluenesulphonate.—The preceding toluenesulphonic ester (10 grams) was dissolved in 500 c.c. of moist ether and the warm solution treated with three to four times the theoretical quantity (5–6 grams) of amalgamated aluminium foil.

The reduction was complete after three or four hours, and the mixture was then filtered, the aluminium hydroxide being extracted several times with ether. When the combined ethereal extracts were evaporated to a small bulk, 4-amino- β -naphthyl toluenesulphonate separated. It was purified by crystallisation from alcohol, from which it separated in pale yellow prisms, m. p. 137° . It is moderately easily soluble in boiling alcohol, but nearly insoluble in the cold (Found: N = 4.81. $C_{17}H_{15}O_3NS$ requires N = 4.47 per cent.).

4-Amino- β -naphthol.—This substance was prepared by hydrolysing 4-amino- β -naphthyl *p*-toluenesulphonate with alcoholic sodium hydroxide, and isolated by precipitation from the faintly acid solution by means of sodium hydrogen carbonate as described above. It crystallised from ethyl alcohol in needles and agreed in its properties with the description given in the literature, although the m. p. (198° with decomposition) was somewhat higher than the recorded value (185°) (Found: C = 74.92; H = 5.83. Calc., for $C_{10}H_7ON$, C = 75.44; H = 5.70 per cent.).

We are greatly indebted to Professor G. T. Morgan for a number of valuable suggestions, including that of the synthesis from 2:4-dinitro- α -naphthylamine; and to the Royal Society for a grant which has defrayed a considerable part of the cost of this investigation. The work was carried out during the tenure by one of us (W.A.P.C.) of a British Scientific Research Fellowship, to the trustees of which we desire to express our indebtedness.

CCXXXI.—*The Structure of the Benzene Nucleus.* *Part IV. The Reactivity of Bridged Linkings.*

By CHRISTOPHER KELK INGOLD.

THE evidence which has been offered hitherto in support of the dynamic conception of the benzene nucleus proposed in the first part of this series (T., 1922, **121**, 1633) is of four kinds: (a) evidence derived from the properties of aromatic compounds themselves (*loc. cit.*); (b) the experimental study of five-carbon ring compounds which display an analogous kind of intra-annular tautomerism, and in many respects simulate the properties aromatic substances (*loc. cit.* and this vol., p. 853); (c) proof that the para-bonded structure, when produced by synthesis, cannot be distinguished from

an ordinary aromatic structure (T., 1922, 121, 1144; this vol., p. 2067); (d) the evidence of crystalline form (this vol., p. 2070).

The properties of aromatic compounds themselves bear on the question in two ways. In the first place, these are what may be termed the "positive" properties of the aromatic nucleus, that is, the definite and often unique transformations which it is known to undergo; secondly, there are the "negative" properties, general insensitivity to mild reagents, the lack of olefinic character, and so forth. In Part I, attention was directed exclusively to the "positive" properties of the nucleus, because it was felt that the best guidance could be obtained by examining such transformations, especially those in which the internal structure of the nucleus becomes disarranged, and that in such cases close attention to the first discernible steps of the process might yield a clue to the nature of the structure undergoing disarrangement. Thus it was shown that the characteristically "aromatic" varieties of mobile-hydrogen tautomerism (for example, of nitrosophenol with quinonememoxine, or of anthranol with anthrone) rest upon known types, that the numerous ways in which ortho- and para-quinonoid structures can be formed receives a face-value interpretation, and that the alkylation on carbon of phenols and numerous other transformations undergo unification with aliphatic reactions, only as consequences of the dynamic view put forward in that paper.

Whilst, however, the "positive" properties are vastly more important * in the sense that they alone can give positive indications

* It is remarkable that the older special formulae for benzene

and

appear to have been proposed mainly in relation to what have been termed the "negative" properties of aromatic compounds, surely a less logical procedure than that now advocated. However, certain authors, notably Hollemann, have employed Thiele's hypothesis in relation to positive properties, and have applied it in a more reasonable and less uncompromising manner than that for which Thiele himself is responsible. In this way a *partial* unification with the aliphatic series can be secured, but it is not possible to cover the whole ground (compare Part I), excepting by the assumption of a definite 1:4-linking, the introduction of which, although quite foreign to Thiele's ideas regarding either butadiene or benzene, obliterates one of the main distinctions with the view now under discussion. There is, however, a more fundamental matter which those who would build upon the Thiele theory must needs consider; and that is that the theory itself rests on experimental foundations which are extremely slight and to a large extent self-contradictory, and therefore quite inadequate to carry the superstructure of the theories of aromatic chemistry which Hollemann and others have based upon them.

for our guidance, "negative" properties must be accounted for. Thus it may be inquired whether the low general reactivity of many aromatic compounds can be interpreted naturally on the grounds of the two-phase system proposed for benzene.

In the first place, it should be understood that the whole course of the work carried out in this laboratory on bridged five-carbon rings has shown that a bridge bond of the type postulated is remarkably similar in its susceptibility to attack by oxidising and additive agents to the "labile constituent" of an ordinary double bond; so much so is this the case, that it is frequently impossible to distinguish between an unsaturated compound and its bridged-ring isomeride by any experiment designed to estimate its susceptibility to oxidation, reduction, or addition reactions. It follows that formula (II), with a bridge and two double bonds, and formula (I), with three double bonds, are in exactly the same position as regards the reactivity which they would indicate if no other structural factor had to be considered.

It is generally conceded, however, that addition to unsaturated substances must always take place as a result of the occurrence of "stray" affinity around the unsaturated residue. In cyclic compounds, only that stray affinity which is outside the ring avails for the purpose of initiating addition, and in conjugated cyclic compounds there is very little external stray affinity owing to the formation of internal subsidiary linkings. In this way, the low reactivity of the Kekulé structure has been accounted for, and the underlying idea has been pictorially expressed by symbols such as (III) (below). But, as has been remarked, the position in this matter of the para-bonded and Kekulé formulæ is the same. In the bridged structure the three elements of unsaturation are conjugated just as much as in the Kekulé formula, if by "conjugated" we imply that the complete, or almost complete, elimination of external stray affinity can be brought about by the formation of internal subsidiary linkings. A corresponding symbol would be (IV).

Connected with the same matter is the question as to how far the bridge-bond is to be regarded as a "partial" affinity. There is no doubt that the bridge linking in five-carbon rings, and particularly in aromatic compounds, is a weak or attenuated bond, prone to disruption, and similar to or even surpassing in reactivity a double bond in like situation; indeed, this comparison forms

perhaps the most exact definition of its actual character. It would be possible to express this consideration by writing a dotted line for the bridged linking (formula V), but there are serious and obvious objections to this device.

The disadvantages attaching to the use of all such complicated formulæ as (III), (IV), and (V) in place of the elementary formulæ (I) and (II) are, first, that the more complex formulæ "lose in obviousness what they gain in definition" (Walker, this vol., p. 944) and, secondly, that the "gain in definition" is a gain of very doubtful value; for the formulæ imply that we know, whereas actually we do not know, the exact manner in which the residual affinity satisfies itself within the ring. Therefore, in the author's view, it is better to regard as *implied* by the simpler formulæ the fact that there must be *some* way of using up within the ring the affinity which would otherwise pass out into surrounding space and thus initiate addition, rather than to employ formulæ containing embellishments the introduction of which cannot be justified in detail by reference to definite chemical reactions. Thus the significance of the bridge-bond is experimental rather than speculative (as, in the author's opinion, all features of organic formulæ should be), in that it connotes a bond of affinity, not of any defined strength (for that could not be ascertained by experiment), but one responsible for a large and important group of reactions.

The only other "negative" line of evidence to which reference need be made is the degradation of benzene derivatives to aliphatic substances. On the dynamic benzene structure, either phase (I or II) may be concerned in the attack of a particular oxidising or other reagent, and the very full list of degradations given in Richter's "Organische Chemie" (11^{te} Aufl., Bd. 2, 46) reveals the remarkable fact that almost all of them proceed by way of an ortho- or para-quinone or the ortho- or para-ketonic modification of a phenol. The significance of this will at once be seen in view of what has been written in Part I of this series and in the recent paper (*loc. cit.*) on the oxidation of bridged five-membered rings: in each case, oxidation almost invariably commences at the (comparatively) very reactive bridge bond. It may be that by careful attention to conditions the great difficulties attending the degradation of aromatic compounds to substances in which the para-carbon atoms are found to be directly connected will ultimately be overcome, but, to judge by the behaviour of the five-carbon ring compounds in which the

ridge linking is on the whole more stable than in the aromatic series, the task is not likely to prove an easy one.

One of the most noteworthy examples of the fission of the bridge linking is provided by the formation of quinones by the oxidation of benzene, phenol, quinol, and other mono-substituted and di-*p*-substitution products of benzene :

The hypothesis that the bridged phase is responsible for these reactions opens the possibility of establishing a common mechanism for them all, and therefore any evidence as to the mechanism of such changes is of interest. The number of possibilities which must be kept in view is maximal in the case of quinol, for which the two following appear to be the most plausible on general grounds * :

(a) Direct removal of hydrogen to give Graebe's structure (VI) and the subsequent reversion of this to Fittig's :

(b) The addition of two hydroxyl groups at the bridge, and the subsequent dehydration of the quinone dihydrate (VII) :

Since mechanism (B) differs from (A) in that its initial stage involves combination with water, it might be supposed that its admissibility could be decided by a consideration of well-known experiments in which dihydroxy-benzenes have been converted into quinones by oxidation with anhydrous oxidising agents, such as silver oxide in dry ether or benzene. This is not the case, how-

* Others, for instance, certain obviously possible transformations involving para-ketonic modifications, must not be lost sight of, however.

ever, for, since for every molecule of water which enters into the reaction two are liberated in the free state, a very small initial concentration of water would at once commence to "grow" with a rapidity and in a manner suggestive of bacterial multiplication. Only if the initial concentration of water were *extremely* low would an appreciable period of induction be expected, and this was far from case in Willstätter, Pfannenstiel, and Müller's experiments (*Ber.*, 1904, **37**, 4744; 1908, **41**, 2580), since precipitated silver oxide contains upwards of 3-4 molecular per cent. of absorbed or loosely combined water, even after drying over phosphoric oxide; and the investigators referred to did not take this precaution.

In order to ascertain, if possible, whether any evidence on the point could be obtained, the author carried out the oxidation of quinol and 1:4-dihydroxynaphthalene under more strictly anhydrous conditions than those employed by Willstätter and his collaborators, and in each case observed a marked period of induction. Thus mechanism (B) is indicated.*

Corresponding experiments with pyrocatechol and 1:2-dihydroxynaphthalene yielded no undeniable evidence of a period of induction, and thus, for the formation of ortho-quinones, a mechanism analogous to (A) is suggested:

This contrast, and the implied difference of mechanism between the formation of ortho-quinones and of para-quinones by the oxidation of dihydric phenols, appear singular at first sight, but the difference is in agreement with certain well-known facts. For instance, it is in keeping with the contrast between the extreme difficulty which attends the formation of rings connected to the para-positions of a benzene ring and the remarkable ease with which ortho-positions can become involved in ring-formation. The intermediate products (VI) and (VIII) in schemes (A) and (C) are dieyclic structures, and it may well be that whilst the series of reactions represented by scheme (C) provides an easy path for the formation of ortho-quinones, the corresponding path to the para-quinone (scheme A) is unavailable on account of the difficulty attending the formation of the para-ring in (VIII). Hence mechan-

* This conclusion is stated with reserve, in view of the fact that to prove that water intervenes is by no means the same as showing that it operates as scheme (B) indicates. An illustration of the caution that should be exercised in such matters will be given in a paper on "The Mutarotation of the Sugars," shortly to be published.

ism (*B*) is that which the reaction actually follows. In confirmation of this there is the fact that Willstätter and Müller have isolated the unstable form (VIII) of *o*-benzoquinone by arresting the oxidation of pyrocatechol at an early stage, an experiment which has no parallel in the *para*-series.

The points examined above have for the most part been raised by Robinson in a criticism incorporated in the *Annual Reports* for 1922 (pp. 86—87), and in view of this fact it has been thought desirable to publish this paper without further delay. The author feels, however, that more crucial tests ought to be devised and applied before the indications given above can be replaced by positive conclusions, and that until this be done positive conclusions and criticism alike are premature.

EXPERIMENTAL.

General.—The oxidation of pyrocatechol to *o*-benzoquinone by silver oxide, suspended in ether at the ordinary temperature, has been described by Willstätter and Pfannenstiel, and by Willstätter and Müller (*loc. cit.*).

1:2-Dihydroxynaphthalene is easily and quantitatively oxidised to β -naphthaquinone by either silver oxide, or lead peroxide, suspended in boiling benzene.

The oxidation of quinol to *p*-benzoquinone by metallic oxides in dry solvents does not appear to have been described. The action of silver oxide is slow, but lead peroxide in boiling benzene effected rapid and quantitative oxidation.

1:4-Dihydroxynaphthalene may be converted in a similar manner into α -naphthaquinone.

Method.—Each dihydroxy-compound was purified with the utmost care and then sealed up in a bulb communicating with a phosphoric oxide chamber. Internal bulbs, specially shaped so that they could be broken by a simple mechanical device, contained the dry solvent and the dry oxide.

The oxide was chemically pure (in the case of silver oxide the purity was that of material used for atomic weight determinations), and was dried at about 150° in a completely evacuated tube having a phosphoric oxide chamber.

The solvents were specially purified and had been stored over sodium for about three and a half years. They were distilled over sodium in an apparatus the internal surfaces of which had been dried at 500—600° by air dried by phosphoric oxide.

After allowing two months in which to dry the dihydroxy-compounds, the external surfaces of the inner bulbs, and the internal surface of the outer bulb, the substances were caused to mix and

the oxidation was carried out side by side with a reference experiment similar in every respect to the first excepting that no special care had been taken to diminish the concentration of water.

Results.—(i). Pyrocatechol with silver oxide (five times the theoretical quantity) in ether at 18° (compare Willstätter and Pfannenstiel, *loc. cit.*). So far as qualitative observation went, there was no difference in the rate of oxidation in the two cases.

(ii). 1 : 2-Dihydroxynaphthalene with lead peroxide (five times the theoretical quantity) in benzene at 100°. No appreciable difference of velocity was observed, the reaction being practically complete in ten to twenty minutes.

(iii). Quinol with lead peroxide (ten times the theoretical quantity) in benzene at 100°. In the reference experiment, oxidation was complete in two to three hours, whilst under anhydrous conditions no reaction appeared to take place during the first six hours' heating, although after ten hours it was practically complete.

(iv.) 1 : 4-Dihydroxynaphthalene with lead peroxide (ten times the theoretical quantity) in benzene at 100°. This experiment proceeded similarly to the last, the "period of induction" observed in the oxidation with dry materials being about four hours.

In carrying out these few experiments, the author had the benefit of much detailed and valuable advice from Professor H. B. Baker, to whom, and to Mr. A. L. Riley, he is indebted for gifts of material.

CCXXXII.—*Sintering : Its Nature and Cause.*

By ROBERT CHRISTIE SMITH.

IN a previous communication (Wright and Smith, T., 1921, 119, 1683), attention was directed to the sintering of platinum black and other finely divided metals. The following work was undertaken to determine, if possible, the nature and cause of sintering.

There are two possible theories of sintering.

(1) The sintering may be due to the lowered melting point of the small particle, and connected with the phenomenon of its increased vapour pressure.

(2) It may be due to a change in structure (*a*) from amorphous

o crystalline, (b) from one crystalline form to another, (c) from one size of crystal to another.

In the previous paper it was suggested that the sintering might be due to (1), but subsequent investigation has shown that this theory will not wholly account for it. Pavlov (*Z. physikal. Chem.*, 1908, 65, 1) has determined theoretically the lowered melting point of a small particle due to its increased vapour pressure, and gives results obtained with commercial salol. Meissner (*Z. anorg. Chem.*, 1920, 110, 169) denied these results. The author, however, found that small particles of diphenylamine had a lowered melting point, but that the lowering amounted to only a fraction of a degree. In the above cases, it is most probable that the small particles were obtained by grinding (at least it was the case with the author), and it is quite possible that the smallest particles were, not crystalline, but wholly vitreous; moreover, it is possible that a vitreous substance should melt at a lower temperature than the crystalline form, as energy is considered to be stored when a substance passes from the crystalline to the vitreous state. The lowered melting points obtained, however, under this head are not sufficient to explain sintering occurring hundreds of degrees below the melting point of the substance. If sintering were a melting-point phenomenon, the introduction of a second substance should affect the sintering temperature. Platinum black was mixed with excess of precipitated gold and the mixture heated; the gold in the mixture did not sinter as readily as the pure variety, and seemed to gather itself into isolated lumps, as if a coating of platinum were surrounding it and preventing sintering (the sintering point of platinum is 250° higher than that of gold), and where particles of platinum were observed they did not sinter until the usual temperature was reached. Hence the mixing of the powders has no effect on the sintering temperature.

(2) (a) Bennett (*J. Physical Chem.*, 1912, 16, 294), investigating the tensile strengths of copper electrolytically precipitated under different conditions, states that the precipitation of the metal in the crystalline state is not at all probable, and that it is likely that the metal comes down first of all in a condition analogous to a "melt" and then crystallises from this. It seems probable that with metals precipitated with rotating cathode (or anode) the atoms are kept in a state of vibration until they can take up their correct crystallographic position, and hence the metal is precipitated in the crystalline state, whereas with high current densities and no motion the atoms do not have the opportunity to orient themselves and are precipitated in the amorphous state (burnt). It seems therefore probable that platinum black, gold, etc., obtained by

electrolytic deposition are in the amorphous state. This assumption is supported by the fact that the precipitated metals, gold and silver, have a lower density than the annealed or crystalline varieties, and this is now generally accepted as indicating that they are at least partly amorphous (Lowry and Parker, T., 1915, 107, 1005). In all the determinations of the sintering temperatures, the most definite results were obtained with the substances in the amorphous state. The results are given in tabulated form.

It was shown by Beilby ("The Aggregation and Flow of Solids," 1921) that when metals are cold-worked or hardened, they are rendered vitreous or amorphous, and that annealing is simply heating the metal to the point at which the atoms or molecules have sufficient mobility to orient themselves in crystal formation, and that this temperature may be far below the melting point of the solid. The vitreous state is brought about either by crushing and causing a flow of the crystals or by a sudden chilling preventing the molecules taking their correct orientation to form a crystal. Hence it was to be expected that in the case of powders obtained by grinding or filing the sintering would not be nearly so definite as in the case with amorphous (precipitated) particles. This was found to be the case with copper, nickel, and cobalt, the reason being that the powders obtained by grinding were vitreous on the outside only, and that the sintering which took place was due to the recrystallising of this amorphous layer. In the cases of the determinations of the sintering temperatures of the samples of aluminium, cobalt, copper, lead, nickel, and molybdenum, not obtained by precipitation, evidences of sintering were very slight and this in most cases was due to the fact that all these samples had been obtained by grinding.

The theory that sintering is due to change of state is further supported by the fact that prolonged heating at a low temperature does not produce sintering; for example, platinum black, heated for six hours at 400°, and also at 500°, showed no more sintering than if it had been heated at these two temperatures respectively for half an hour. Further evidence is also obtained from the fact that if a crystalline nucleus is introduced, sintering will be observed at a lower temperature. The lowest temperature given for the commencement of the sintering of platinum black in the previous paper is 300°, whereas in this, where the platinum black was supported not by platinum but by pipeclay, it is given as 500°. This observation was confirmed by placing platinum black in intimate contact with crystalline platinum, and part of the same sample of black on pipeclay. At 500°, the sample supported by the metal showed a higher degree of sintering than the other. It should

be noticed that the intimacy of the contact of the crystalline with the amorphous substance has a great deal to do with the result obtained. This phenomenon has also been noted by Beilby (*loc. cit.*) and Hanriot (*Compt. rend.*, 1911, 152, 704). A powder produced by grinding should therefore show a lower sintering temperature than that obtained by precipitation; this was observed in the case of nickel. It has been emphasised that sintering is dependent on the nature of the particle, and it should be noted that the size does not affect sintering. For instance, the effect of heating four blocks of silver, two with polished (or amorphous) surfaces and two with crystalline surfaces in contact, was investigated, and, as far as the evidence went, the uniting force between the two surfaces was very much greater in the case of the polished than in the case of the crystalline surfaces. Various factors had to be considered in drawing this conclusion, such as the area in contact and the fact that the polished surfaces would give better contact. The crystalline surface was obtained by first polishing the blocks smooth and then annealing in order to eliminate the latter factor as much as possible.

(2) (b) It is found also that sintering takes place when a substance changes from one crystalline form to another. For instance, iron (reduced) was found to sinter at 750–760° and at 850–900°; the latter of these temperature ranges corresponds to a change in the crystalline state of the iron. This might be classed as an allotropic change—if solids which are polymorphous are admitted to be allotropes—but there is so much uncertainty as to an exact definition of allotropy that the author prefers to class these changes as being due to a transition from one crystalline form to another. With regard to the temperature of the change at 750–760°, this is said to be purely a magnetic transition point, X-ray analysis showing no change in the space lattice. For the development of magnetism, however, there must be some change in the internal strain, and this would quite conceivably give rise to the type of change to be considered next under (2) (c).

(2) (c) It is known that silver black cannot be preserved and that it speedily changes into grey or white, crystalline silver (Kohlschütter and Toropoff, *Z. Elektrochem.*, 1913, 19, 161). It therefore seems probable that its sintering temperature is below ordinary room temperature, and that it would be possible to prepare and preserve silver black at low temperatures. However, if the grey silver obtained by precipitation is heated, it gives evidence of sintering from 180°. It seems probable, therefore, that sintering is due in this case to a change in the size of the crystals of the silver. It is now well known that certain crystals change their size

on heating and the explanation has been suggested that adjacent crystals are only in equilibrium when the crystallographically equivalent lattice planes of both crystals lie in one plane (compare Tammann, T., 1919, **116**, 273; Carpenter and Elam, *J. Inst. Met.*, 1920, **24**, 83). This would explain why the sintering temperature of cobalt in the amorphous state is lower than that of the filings; in the latter case, there is so little of the amorphous form present that its change is undetectable, and sintering will be observable only when the particles begin to change in size. In the case of copper, confirmation of this view was obtained in the increased sintering observed when the amorphous sample reached the sintering temperature of the reduced sample. It should be noticed that the reason that the sintering temperature of the reduced copper is higher than that of the amorphous copper and was due to change of size of crystals. This was due to the fact that the temperature at which the copper oxide was reduced was probably higher than the sintering temperature of amorphous copper.

Kohlschütter and Eydmann (*Annalen*, 1913, **398**, 1), in a series of experiments with finely divided silver, drew the conclusion that sintering did not occur in the case of crystalline substances, but Day and Allen (*Carnegie Inst. Pub.* No. 31, 1905) pointed out that sintering took place even with the purest crystals of feldspar obtainable, and in view of the facts stated above it seems that sintering takes place even in crystalline substances.

Evidence of sintering was found in the case of several inorganic substances. The powders used were obtained by grinding, and therefore the particles would be covered by an amorphous or a vitreous layer. In the case of soluble salts, it is difficult to draw any definite conclusions, as the cohesion may be due to expulsion of absorbed water. Bunsen (*Wied. Ann.*, 1885, **24**, 327) showed that absorbed water in certain cases was driven off only at 600–800°. Therefore, although a substance may be subjected to a preliminary drying at low temperature, some moisture may still remain.

Conclusions.

It has been shown that:

- (1) Sintering may take place in crystalline and in amorphous substances.
- (2) The sintering of a crystalline substance is due to a change in the size of the crystals or to the formation of an allotrope.
- (3) The sintering of an amorphous substance is due to the formation and growth of crystals (Beilby's pulsation cell theory).

(not heated above 800°.)

* The caking observed here was due to reduction of the film of oxide with which the iron was coated.

EXPERIMENTAL.

The powder was passed through a sieve of 150 mesh and placed either in a porcelain boat or on a strip of pipeclay. In the case of the oxidisable metals, the loaded carrier was placed in a silica test-tube, fitted so that a continuous stream of hydrogen gas could be passed through it. In other cases, the boat was inserted directly in the furnace, which was electrically heated. The hydrogen gas was purified by passing it through potassium permanganate and concentrated sulphuric acid. The palladium was heated in an atmosphere of carbon dioxide. The samples were heated at increasing temperatures, 150°, 200°, 250° . . . up to the sintering temperature or to 1000°, the heating being maintained at each temperature for a period of half an hour. Some of the samples, observed microscopically, were seen quite plainly to be oxidised and the reduction was followed with increasing temperature. Sintering was detected by the lightening of the colour of the powder, by the appearance of metallic lustre, and by prodding the particles with a light wire to determine when they were clinging to each other. Some powders showed a tendency to cling together before heating, but sintering was quite plainly evidenced by a definite caking.

The melting point of the diphenylamine was determined by placing some of the powder in a melting-point tube, and immersing it along with a thermometer in a bath of 7 litres capacity, the temperature of which was raised at the rate of one degree in ten minutes. The particles were observed by means of a short-focus telescope. The

melting points of the particles were seen and observed quite definitely.

In the case of the powders that were to be heated in a vacuum the silica test-tube was fitted with a rubber stopper and carried a water jacket round the mouth of the tube. The vacuum was obtained by means of a Töpler pump.

In the experiments on the heating of polished and of crystalline surfaces in contact, one face of each of several small blocks of silver was polished. Two of the blocks were then heated until the polished surfaces became crystalline. They were then placed together with the crystalline surfaces in contact and were heated, along with two other blocks with polished surfaces in contact, in a furnace at 500°. On cooling, the union in both cases sustained a weight of 56 lb., but broke when subjected to a side thrust—the crystalline sample breaking first.

CCXXXIII.—*Derivatives of Phthalonic Acid, 4:5-Dimethoxyphthalonic Acid, and 4:5-Dimethoxy-*o*-tolylglyoxylic Acid.*

By (Miss) CHIKA KURODA and WILLIAM HENRY PERKIN, jun.

IN a previous communication (T., 1921, 119, 1724) dealing with the synthesis of *m*-opianic acid, it was shown that this acid may be obtained from 4:5-dimethoxyphthalonic acid either (i) by heating with sodium hydrogen sulphite or (ii) with the aid of aniline:

During the course of that investigation a number of interesting changes were observed which could not, at the time, be followed up, and the study of these has now been undertaken and forms the subject of the present communication. It is characteristic of 4:5-dimethoxyphthalonic acid (I) that it separates from water in prisms having the composition $\text{C}_{11}\text{H}_{10}\text{O}_7 \cdot 2\text{H}_2\text{O}$, and that, when heated at 100°, one only of these molecules of water is given off, whereas

the second molecule cannot be removed by heat without, at the same time, decomposing the acid. If, however, the ethereal solution of the hydrated acid is dried over anhydrous sodium sulphate and concentrated, the anhydrous acid, $C_{11}H_{10}O_7$, separates in prisms melting at about 187° . While the hydrated acid is very readily soluble in cold water, the anhydrous acid dissolves with difficulty, and it is stated in the earlier communication (p. 1726) that the latter separates from water in anhydrous prisms. This result was certainly achieved on one occasion, but we have not been able to repeat the conditions, for in every subsequent experiment the solution of the anhydrous acid in water always deposited, on cooling, prisms of the composition $C_{11}H_{10}O_7 \cdot 2H_2O$. The remarkable difference in solubility in cold water indicated that the hydrated and anhydrous acids are differently constituted and it was suggested at the time that the former is the hydrated form of normal 4 : 5-dimethoxyphthalonic acid (IV), whereas the latter is the tautomeric modification (V) and this we propose to call 4 : 5-dimethoxy- ψ -phthalonic acid.

The study of the action of acetyl chloride has furnished direct evidence of the existence of these two modifications. The hydrated acid (IV), on treatment with acetyl chloride, is converted almost exclusively into 4 : 5-dimethoxyphthalonic anhydride (VI), which is bright yellow and melts at 216° , whereas the anhydrous acid (V) yields, under the same conditions, *acetyl*-4 : 5-dimethoxy- ψ -phthalonic acid (VII) as well as the yellow anhydride of melting point 216° .

This interesting acetyl derivative of the ψ -acid is colourless and, when heated, is decomposed into acetic acid and the yellow anhydride of m. p. 216° , a curious rearrangement of the molecule. It may be dissolved in cold water without decomposition and titrates as a monobasic acid, but, on boiling with water, it decomposes quantitatively into acetic and dimethoxyphthalonic acids. The tendency to combine with water is not only a characteristic of dimethoxyphthalonic acid itself, but also extends to the *hydrogen methyl* and *hydrogen ethyl* salts. These crystalline substances are obtained when dimethoxyphthalonic anhydride is boiled with methyl or ethyl alcohol and, as they occur in the hydrated form,

it is probable that the group $>\text{CO}\cdot\text{CO}_2\text{H}$ is intact in these esters, which may therefore be assumed to have the formulae

When the silver salts of these acid esters are treated with methyl iodide, they yield the *dimethyl* and *methyl ethyl* esters

and it is interesting that these substances exhibit no tendency to combine with water.

An unsuccessful experiment is described on p. 2102 which had for its object the preparation of the methyl ester of 4:5-dimethoxy- ψ -phthalonic acid (V). On the other hand, the interesting *methyl ester of acetyl-4:5-dimethoxy- ψ -phthalonic acid*,

has been obtained from the acetyl ψ -acid by treatment with silver oxide and methyl iodide in the presence of ether. It melts at 127° and is not immediately hydrolysed on boiling with water.

4:5-Dimethoxyphthalonic acid and its anhydride exhibit a marked tendency to react with aniline and its derivatives, and a careful study of the behaviour of the acid and its anhydride with aniline and also with phenylhydrazine has led to interesting results. In the previous communication (*loc. cit.*, p. 1726) it was shown that a hot aqueous solution of the acid reacts with aniline to yield the aniline salt of anilino-4:5-dimethoxyphthalonic acid and that this substance, on heating, yields anilino-*m*-opianic acid with elimination of aniline and carbon dioxide:

The anhydride of 4:5-dimethoxyphthalonic acid reacts still more readily with aniline and the following substances have been obtained during the study of this change.

(i) A substance, $\text{C}_{26}\text{H}_{20}\text{O}_6\text{N}_3$, formed when the anhydride, suspended in benzene, is mixed with aniline. It melts at 151° , dissolves in sodium carbonate solution, and is probably *aniline α -anilino- α -hydroxy-4:5-dimethoxyhomophthalanilate*,

(ii) A substance, $C_{17}H_{15}O_6N$, produced from (i) by heating with solvents. This substance melts at 208° , is soluble in sodium carbonate solution, and is probably 4 : 5-dimethoxyphthalon-2-anilic acid, $C_6H_2(OMe)_2(CO_2H) \cdot CO \cdot CO \cdot NHPh$, but it may also have the isomeric formula containing the aniline residue attached to the other carboxyl group. On treatment with aniline, this anilic acid is converted into the aniline salt (i).

(iii) The substance (ii) is decomposed at its melting point yielding 4 : 5-dimethoxyphthalonanil (m. p. 238°) and *m*-hemipinanilic acid (m. p. 160°),

The latter substance, which may also be obtained from *m*-hemipinic anhydride by the action of aniline, does not appear to have been described.

(iv) 4 : 5-Dimethoxyphthalondianilide,

which melts at 238° and is produced when dimethoxyphthalonic anhydride and aniline are heated on the steam-bath without a solvent.

Action of Phenylhydrazine.—The boiling aqueous solution of 4 : 5-dimethoxyphthalonic acid reacts readily with phenylhydrazine to yield 1-keto-6 : 7-dimethoxy-2-phenyl-1 : 2-dihydrophthalazine-4-carboxylic acid, $C_{17}H_{14}O_6N_2$, which is evidently formed from the normal hydrazone by internal condensation according to the scheme

This substance melts at 244° and is soluble in dilute ammonia.

The interesting observation was made that, if *p*-bromophenylhydrazine is substituted for phenylhydrazine and the experiment conducted under the same conditions, the substance produced has the composition $C_{17}H_{15}O_6N_2Br$ (m. p. 222°) and is therefore the normal *p*-bromophenylhydrazone of 4 : 5-dimethoxyphthalonic acid.

The anhydride of dimethoxyphthalonic acid also reacts readily with phenylhydrazine, and the substance produced, $C_{23}H_{22}O_5N_4$ m. p. 260° , appears to be 4 : 5-dimethoxyphthalonic acid-1-phenylhydrazide-2-phenylhydrazide (VIII), $C_6H_2(OMe)_2 \begin{matrix} \diagup CO \cdot NH \cdot NHPh \\ \diagdown C(N \cdot NHPh) \cdot CO_2H \end{matrix}$.

The results of the careful investigation of the properties of 4 : 5-dimethoxyphthalonic acid, which have just been summarised, seemed to make it desirable that the behaviour of the parent acid-phthalonic acid, under similar conditions, should be more carefully investigated than had so far been done and the results of this investi-

gation fall in line with those observed in the case of the dimethoxy-acid. Like the latter acid, phthalonic acid exists in the hydrated form, $C_6H_4(CO_2H) \cdot CO \cdot CO_2H \cdot 2H_2O$, and as the anhydrous acid. We investigated, in the first place, the action of acetyl chloride on anhydrous phthalonic acid and obtained the normal yellow anhydride

$C_6H_4 \begin{array}{l} \diagup CO \cdot CO \\ \diagdown CO \cdot O \end{array}$, which melts at 186° and had already been described

by Tcherniac (*Ber.*, 1898, **31**, 139; *T.*, 1916, **109**, 1238), who obtained it from phthalonic acid by the action of acetic anhydride. From the acetyl chloride mother-liquors of the anhydride, we were able to isolate small quantities of *acetyl-ψ-phthalonic acid*,

$C_6H_4 \begin{array}{l} \diagup C(OAc) \cdot CO_2H \\ \diagdown CO \cdot O \end{array}$, which is colourless and, on heating, is converted into acetic acid and normal phthalonic anhydride (compare p. 2106).

It is evident therefore that phthalonic acid, like the dimethoxy-derivative, is capable of existing in two modifications, the hydrated acid being represented by formula (IX), whilst the anhydrous acid is the ψ -modification (X).

The behaviour of the anhydride of phthalonic acid with aniline, described on p. 2107, is so exactly analogous to that observed in the case of the dimethoxy-derivative that a detailed discussion of the constitutions of the substances obtained is unnecessary.

The third section of this communication deals with the properties of 4:5-dimethoxy-*o*-tolylglyoxylic acid and especially with its behaviour with aniline and with the conditions required for its conversion into 4:5-dimethoxy-*o*-tolualdehyde, $(MeO)_2C_6H_2Me \cdot CHO$.

4:5-Dimethoxy-*o*-tolylglyoxylic acid is readily obtained (together with 4:5-dimethoxyphthalonic acid) by the oxidation of 4:5-dimethoxy-*o*-tolyl methyl ketone with permanganate,

(*T.*, 1921, **119**, 1735), but has been little investigated. A number of new and interesting derivatives are described in the experimental section. Unexpected difficulties were met with in attempting to convert the acid into 4:5-dimethoxy-*o*-tolualdehyde. Unlike many glyoxylic acids, this acid is not decomposed by boiling with sodium hydrogen sulphite with elimination of carbon dioxide

and formation of the aldehyde. It combines, however, readily with aniline yielding the aniline salt and this, on boiling with xylene, is decomposed in the normal manner with elimination of carbon dioxide and formation of 4:5-dimethoxy-o-tolylideneaniline, $(\text{MeO})_2\text{C}_6\text{H}_3\text{Me}\cdot\text{CH}\cdot\text{NPh}$.

Attempts to obtain the free aldehyde from this derivative by hydrolysis with hydrochloric acid were, for a long time, unsuccessful. When the tolylidene derivative is boiled with hydrochloric acid, it is not decomposed, with the separation of the rather sparingly soluble aldehyde, but merely combines with the acid, and a hydrochloride of the composition $[(\text{MeO})_2\text{C}_6\text{H}_3\text{Me}\cdot\text{CH}\cdot\text{NPh}\cdot\text{HCl}]_2\cdot\text{H}_2\text{O}$ crystallises from the solution. Some hydrolysis must, however, take place, because aldehyde may be removed from the solution by extraction with ether.

This process evidently upsets the equilibrium and ultimately the whole of the aldehyde may be recovered by repeated extraction with ether.

The addition of hydroxylamine hydrochloride or semicarbazide hydrochloride and sodium acetate to the solution of the hydrochloride of the tolylidene derivative in dilute hydrochloric acid causes the oxime or semicarbazone of the aldehyde to separate, but the same difficulty is again met with in attempting to obtain the aldehyde from these derivatives by hydrolysis with acids.

EXPERIMENTAL.

Derivatives of 4:5-Dimethoxyphthalonic Acid.

4:5-Dimethoxyphthalonic Anhydride (Formula VI).—In order to prepare this substance, the anhydrous acid (2 grams: T., 1921, 119, 1736) is heated with acetyl chloride (6 c.c.) in a reflux apparatus on the steam-bath for two hours and allowed to remain over-night. The bright yellow crystals (1 gram) which will have separated are collected by the aid of the pump, washed with ether, and dried in a vacuum desiccator. The anhydride may also be conveniently prepared by boiling dimethoxyphthalonic acid with acetic anhydride, when, on cooling, brilliant yellow crystals separate. It may also be obtained by boiling the hydrated acid with acetyl chloride (compare p. 2095) (Found: C = 55.8; H = 3.4. $\text{C}_{11}\text{H}_8\text{O}_6$ requires C = 55.9; H = 3.4 per cent.). Dimethoxyphthalonic anhydride melts at 216° and dissolves with some difficulty in most of the usual solvents in the cold; it may be recrystallised from boiling benzene or xylene, but the best solvent for this purpose is acetic anhydride. Exposure to the air does not appear to convert the anhydride into the acid, but boiling with solvents which are not anhydrous, such as 80 per cent. acetic acid, soon brings about hydrolysis. This

change takes place rapidly when the anhydride is boiled with water and, on concentrating, hydrated dimethoxyphthalonic acid, $C_{11}H_{10}O_7 \cdot 2H_2O$, separates. The anhydride is coloured red by concentrated sulphuric acid, but, on warming, the liquid rapidly becomes colourless, carbon monoxide is liberated, and the solution contains *m*-hemipinic acid.

Acetyl-4:5-dimethoxy-ψ-phthalonic Acid (Formula VII).—When the acetyl chloride mother-liquors, from which the yellow crystals of dimethoxyphthalonic anhydride have been removed by filtration, as explained above, are allowed to concentrate over solid potassium hydroxide in a vacuum desiccator, small, colourless crystals of the acetyl-ψ-acid gradually separate. The yield of the washed (ether) product is 0.8 gram, and the substance may be recrystallised by adding ether to the solution in glacial acetic acid, when it separates in colourless prisms (Found: C = 52.7; H = 4.0. $C_{13}H_{12}O_8$ requires C = 52.7; H = 4.0 per cent.). If the hydrated crystals of dimethoxyphthalonic acid, $C_{11}H_{10}O_7 \cdot 2H_2O$, (5 grams) are boiled with a large excess of acetyl chloride (30 c.c.), a vigorous action takes place and, after heating on the water-bath to complete the decomposition, almost the whole product (3.6 grams) separates as the yellow anhydride and only a very small quantity of the colourless acetyl derivative of the ψ-acid is produced. This interesting observation was confirmed by several experiments.

Acetyl-4:5-dimethoxy-ψ-phthalonic acid exhibits an interesting behaviour when heated in a capillary tube. The colourless substance shrinks at about 150° and gradually changes to yellow crystals which melt at 215–216° and consist of dimethoxyphthalonic anhydride. On repeating the experiment in a test-tube with somewhat larger quantities, a liquid distilled which had a strongly acid reaction, and the odour of acetic acid, containing a little acetic anhydride, became apparent. A similar change takes place when the acetyl-ψ-acid is boiled with xylene, and yellow crystals of the anhydride separate on cooling. The action of water on the acetyl-ψ-acid has been investigated in some detail.

It is somewhat remarkable that this substance dissolves in cold water and is so slowly hydrolysed that it may be accurately estimated by titration with sodium carbonate if the operation is rapidly carried out. The substance (0.1010 gram) was dissolved in cold water and titrated with *N*/10-sodium carbonate, using methyl-orange as indicator, when it neutralised 3.45 c.c., whereas this amount of a monobasic acid, $C_{13}H_{12}O_8$, should neutralise 3.4 c.c. When, however, the acetyl-ψ-acid is boiled with water, it is rapidly hydrolysed and, on evaporation, crystals of hydrated dimethoxyphthalonic acid, $C_{11}H_{10}O_7 \cdot 2H_2O$, separate. The change is quantita-

tive, as the following experiment shows. The acetyl- γ -acid (0.1770 gram) was distilled in steam and the acetic acid in the distillate estimated by titration with $N/10$ -sodium hydroxide, phenolphthalein being used as indicator. The amount required for neutralisation was 6.02 c.c., whereas that calculated is 5.98 c.c. The solution of dimethoxyphthalonic acid in the distillation flask neutralised 11.85 c.c. of $N/10$ -sodium hydroxide instead of 11.96 c.c., which is the amount theoretically required.

Methyl Hydrogen Dimethoxyphthalonate,

—When the anhydride of dimethoxyphthalonic acid (3 grams) is boiled with alcohol (6 c.c.) for a few minutes, a colourless solution is obtained and, on addition of water, the *methyl hydrogen* ester separates as a mass of needles, which is purified by recrystallisation from water. The needles soften at 112° , melt at 120 – 122° , and contain water (Found: C = 50.1; H = 4.9. $\text{C}_{12}\text{H}_{12}\text{O}_7\cdot\text{H}_2\text{O}$ requires C = 50.3; H = 4.9 per cent.).

The corresponding *ethyl hydrogen* ester, obtained in a similar manner, also separates from water in needles containing $1\text{H}_2\text{O}$; it softens at 85° and melts at 92° (Found: C = 51.9; H = 5.2. $\text{C}_{13}\text{H}_{14}\text{O}_7\cdot\text{H}_2\text{O}$ requires C = 52.0; H = 5.3 per cent.).

Dimethyl Dimethoxyphthalonate,

—In order to obtain this ester, the silver salt of methyl hydrogen dimethoxyphthalonate was prepared by adding silver nitrate to the neutral solution of the ammonium salt, when it separated in needles. The silver salt was collected, dried, suspended in ether, boiled with excess of methyl iodide for three hours, the product filtered, and the ether evaporated. The solid residue crystallised from ether in prisms and melted at 105 – 106° (Found: C = 55.2; H = 5.1. $\text{C}_{13}\text{H}_{14}\text{O}_7$ requires C = 55.3; H = 4.9 per cent.).

Methyl Ethyl Dimethoxyphthalonate,

—The *silver* salt of ethyl hydrogen dimethoxyphthalonate, obtained by adding silver nitrate to the neutral solution of the ammonium salt, crystallises in needles (Found: Ag = 28.0. $\text{C}_{13}\text{H}_{13}\text{O}_7\cdot\text{Ag}$ requires Ag = 27.7 per cent.). This substance was digested, in ether suspension, with methyl iodide for three hours, and the filtered ethereal solution evaporated, when a solid remained which separated from alcohol in prisms and melted at 100° (Found: C = 56.8; H = 5.4. $\text{C}_{14}\text{H}_{16}\text{O}_7$ requires C = 56.8; H = 5.4 per cent.).

The Semicarbazone of Dimethoxyphthalonic Acid,

—When semicarbazide hydrochloride (4 grams), dissolved in a

little water, is added to the hot aqueous solution of dimethoxy-phthalonic acid (2 grams), and the whole heated on the steam-bath, colourless crystals soon commence to separate. After being washed successively with water, alcohol, and ether, the substance melted at 275° (Found: C = 44.4; H = 4.8; N = 12.7. $C_{12}H_{15}O_8N_3$ requires C = 43.8; H = 4.6; N = 12.9 per cent.). On titration, 0.1500 neutralised 9.2 c.c. of *N*/10-sodium hydroxide, whereas this amount of the dibasic acid should neutralise 9.16 c.c. The semicarbazone dissolves to a red solution in concentrated sulphuric acid and, on diluting, a yellow precipitate separates.

The analysis given above indicated that the composition of the semicarbazone is unusual, since it contains $1H_2O$. When it is heated in the steam-oven, it does not change, but at 105° it gradually loses weight (0.2220 gram lost 0.0230 after being heated at 105° for twelve hours, the loss corresponding to 10.4 per cent., whereas $C_{12}H_{13}O_7N_3 \cdot H_2O$, losing $2H_2O$, requires loss = 10.97 per cent.).

Dehydration is, however, most conveniently brought about by boiling with glacial acetic acid, when, on cooling, a colourless substance, $C_{12}H_{11}O_6N_3$, separates which probably has the constitution $C_6H_2(OMe)_2 < \begin{matrix} CO \\ \diagup \end{matrix} N \cdot CO \cdot NH_2$ (Found: C = 49.6; H = 3.9. $C_{12}H_{11}O_6N_3$ requires C = 49.1; H = 3.7 per cent.).

This anhydrosemicarbazone melts at 280° and is soluble in dilute ammonia. It dissolves in sulphuric acid to a yellow solution and, on diluting with water, a white precipitate separates.

It has been suggested (p. 2095) that anhydrous 4 : 5-dimethoxy-phthalonic acid is, in reality, the ψ -modification of this acid, and accordingly an attempt was made to obtain the methyl ester of this ψ -modification by adding dilute ammonia to the suspension of the anhydrous acid in water until most had dissolved, filtering immediately, and then adding silver nitrate, when needles of a silver salt rapidly separated. This salt was collected, dried in a vacuum desiccator, suspended in ether, and warmed with excess of methyl iodide for two hours; on concentrating, a substance separated in needles, melted at 105–106°, and was recognised as the dimethyl ester of ordinary 4 : 5-dimethoxyphthalonic acid. A similar result was obtained in an experiment carried out under the same conditions with acetyl 4 : 5-dimethoxy- ψ -phthalonic acid; the ethereal solution of the product of the action of methyl iodide on the silver salt deposited, on concentration, needles which melted at 105–106° and consisted of the dimethyl ester of 4 : 5-dimethoxy-phthalonic acid. Ultimately, however, we succeeded in obtaining the methyl ester of acetyldimethoxy- ψ -phthalonic acid under the following unusual conditions. The acetyl acid (0.2 gram) was

mixed with silver oxide (0.5 gram), anhydrous sodium sulphate (2 grams), and dry ether, and the whole heated for two hours on the steam-bath with frequent shaking. Excess of methyl iodide was then added and the heating continued for a further three hours. The ethereal solution was then concentrated and yielded small, colourless crystals, which were recrystallised by adding ether to the concentrated solution in benzene (Found: C = 54.3; H = 4.7. $C_{14}H_{14}O_8$ requires C = 54.2; H = 4.5 per cent.).

The methyl ester of acetyl-4:5-dimethoxy- ψ -phthalonic acid melts at 127–128° and is insoluble in cold dilute sodium carbonate solution. It may be recrystallised from water if the operation is rapidly conducted, the crystals which separate melting at 127°, but long boiling with water hydrolyses the ester and the solution becomes strongly acid.

Action of Phenylhydrazine on 4:5-Dimethoxyphthalonic Acid.

1-Keto-6:7-dimethoxy-2-phenyl-1:2-dihydrophthalazine-4-carboxylic Acid. (Formula, p. 2097).—When phenylhydrazine (2 grams) is added to the boiling aqueous solution of dimethoxyphthalonic acid (1 gram), a syrup separates which soon crystallises. The substance was collected, washed first with water, then with alcohol and ether, and recrystallised from acetic acid from which it separated in very pale yellow crystals (Found: C = 62.6; H = 4.7; N = 8.7. $C_{17}H_{14}O_5N_2$ requires C = 62.6; H = 4.3; N = 8.6 per cent.). This substance melts at 244°, and is very sparingly soluble in alcohol, acetic ester, benzene, or light petroleum; it dissolves with difficulty in dilute sodium carbonate solution, but is readily soluble in aqueous ammonia. It undergoes change on boiling with nitrobenzene and, on cooling, yellow crystals melting at 218° separate.

The p-Bromophenylhydrazone of Dimethoxyphthalonic Acid.—The unusual behaviour of dimethoxyphthalonic acid towards phenylhydrazine, just described, is not observed when *p*-bromophenylhydrazine is employed, as, in this case, the normal *p*-bromophenylhydrazone results. This substance is readily prepared by adding a hot aqueous solution of *p*-bromophenylhydrazine (1 gram) to a hot solution of dimethoxyphthalonic acid (1 gram), when a mass of pale yellow crystals soon separates. After washing with water, alcohol, and ether, the substance melts at 222° with decomposition (Found: C = 48.6; H = 3.9. $C_{17}H_{15}O_4N_2Br$ requires C = 48.2; H = 3.6 per cent.). This substance is sparingly soluble in most of the usual solvents and dissolves readily in dilute sodium carbonate solution. The solution in sulphuric acid is red; on the addition of water, the colour is destroyed and a white precipitate separates.

4:5-Dimethoxyphthalonic Acid 1-Phenylhydrazone 2-Phenylhydrazide (Formula VIII).—When dimethoxyphthalonic anhydride (1.5 grams) is digested with a benzene solution of phenylhydrazine (3 grams), rapid combination takes place with rise of temperature and a viscid syrup forms which, on rubbing with a glass rod, soon crystallises. After cooling, the mass was rubbed with alcohol, collected, and washed with ether; the colourless, crystalline residue melted at 260° (Found: C = 63.7; H = 5.2. $C_{23}H_{22}O_5N_4$ requires C = 63.6; H = 5.1 per cent.).

This substance is soluble with difficulty in sodium carbonate or dilute ammonia solution in the cold, but dissolves readily in hot dilute sodium hydroxide solution. The solution in concentrated sulphuric acid is red and the colour is not destroyed nor does any precipitate separate on diluting with water.

Action of Aniline on the Anhydride of 4:5-Dimethoxyphthalonic Acid.

Aniline α -Anilino- α -hydroxy-4:5-dimethoxyhomophthalanilate (Formula, p. 2096).—When dimethoxyphthalonic anhydride (1 gram), suspended in a little benzene, is mixed with aniline (3 c.c.), reaction takes place readily with rise of temperature and a viscous liquid is formed which, on standing, deposits small crystals and, on adding ether, the whole becomes filled with crystals. These were collected with the aid of the pump and washed with ether (Found: C = 67.2; H = 5.6; N = 8.2. $C_{29}H_{28}O_6N_3$ requires C = 67.6; H = 5.6; N = 8.2 per cent.).

This curious substance melts at 151° and solidifies again, probably owing to conversion into 4:5-dimethoxyphthalondianilide (see below), and the melting point rises to 238° . It is soluble in benzene, chloroform, or acetone, but attempts to recrystallise it were not successful; on boiling with solvents, a change suddenly takes place and crystals of 4:5-dimethoxyphthalon-2-anilic acid (m. p. 208°) separate. The substance (m. p. 151°) dissolves in sodium carbonate solution in the cold with liberation of aniline and on the addition of hydrochloric acid, the anilic acid (m. p. 208°) separates.

Dimethoxyphthalon-2-anilic acid (Formula, p. 2097) is readily prepared by boiling the substance of melting point 151° with chloroform for a few minutes, when, on standing, needles separate which are collected, washed with ether, and recrystallised from alcohol (Found: C = 61.8; H = 4.5; N = 4.2. $C_{17}H_{15}O_6N$ requires C = 62.0; H = 4.5; N = 4.2 per cent.).

This anilic acid melts at 208° , is soluble in sodium carbonate solution and is reprecipitated unchanged on the addition of hydrochloric acid. Titration with *N*/10-sodium hydroxide gave numbers

showing that the substance is a monobasic acid. Suspended in benzene and mixed with aniline, this substance is converted into the aniline salt melting at 151°.

Heated in a sulphuric acid bath at its melting point, this anilic acid became yellow and underwent a complex decomposition. The product dissolved in boiling acetone and the solution, on standing, deposited crystals. These were collected by the aid of the pump (filtrate A), digested with sodium carbonate solution, again filtered (filtrate B), and the residue recrystallised from acetone (Found: C = 65.4; H = 4.3; N = 4.1. $C_{17}H_{13}O_5N$ requires C = 65.6; H = 4.2; N = 4.5 per cent.).

4 : 5-Dimethoxyphthalonanil (Formula, p. 2097) melts at 238° and is sparingly soluble in ether or benzene, and more readily soluble in acetone, from which it crystallises in pale yellow needles; it is insoluble in aqueous sodium carbonate or hydroxide in the cold.

m-Hemipinanilic Acid (Formula, p. 2097).—The acetone filtrate (A, above), on exposure to the air, deposited a yellow syrup and, on rubbing with sodium carbonate solution, a small quantity of a yellow powder separated which is a mixture and has not been further investigated. The filtrate from this yielded, on acidifying, a crystalline substance which separated from benzene in needles, melted at 160°, and evidently consists of *m*-hemipinanilic acid (Found: C = 64.1; H = 5.1. $C_{16}H_{13}O_5N$ requires C = 63.8; H = 5.1 per cent.). Filtrate B (see above) yielded, on acidifying, a very small quantity of a colourless substance which crystallised from methyl alcohol, melted at 280°, and gave on analysis: C = 62.5; H = 5.4 per cent., but the substance has not been identified.

4 : 5-Dimethoxyphthalondianilide (Formula, p. 2097).—When 4 : 5-dimethoxyphthalonic anhydride, mixed with excess of aniline, was heated on the steam-bath, a clear liquid was obtained which, on cooling and rubbing, quickly crystallised. The product was stirred with ether, the crystalline mass collected, washed with ether, and recrystallised from nitrobenzene (Found: C = 67.8; H = 5.6; N = 7.0. $C_{23}H_{20}O_5N_2$ requires C = 68.3; H = 5.1; N = 7.0 per cent.). This dianilide melts at 238°, is very sparingly soluble in the usual solvents, and insoluble in sodium carbonate solution, but, when boiled with aqueous sodium hydroxide, it dissolves with separation of aniline. Its solution in concentrated sulphuric acid has a red colour.

Derivatives of Phthalonic Acid.

The Anhydride of Phthalonic Acid (Formula, p. 2098).—This anhydride is readily prepared by heating anhydrous phthalonic

acid* (3 grams) with acetyl chloride (7 c.c.) substantially under the conditions recommended for the preparation of the dimethoxy-derivative (p. 2099). It separates from the product in pale yellow crystals, which are collected, rapidly washed with dry ether, and transferred to a vacuum desiccator containing phosphoric oxide (Found: C = 61.1; H = 2.5. $C_8H_4O_3$ requires C = 61.3; H = 2.3 per cent.). Phthalonic anhydride melts at 186° and is much more readily hydrolysed than the corresponding dimethoxy-derivative. Thus, whilst the latter is stable on exposure to air, phthalonic anhydride is slowly hydrolysed to phthalonic acid under these conditions. Hydrolysis is very rapid when the anhydride is warmed with water, and the solution yields, on extraction with ether, drying over anhydrous sodium sulphate, and evaporation, pure phthalonic acid melting at 146° .

The difficulty in preparing phthalonic acid free from traces of phthalic acid is well known; it may be readily overcome by converting the nearly pure acid into the anhydride and then hydrolysing by contact with water. Phthalonic anhydride is rather sparingly soluble in benzene and may be recrystallised from this solvent under anhydrous conditions, but the least trace of moisture leads to an impure product.

Acetyl- ψ -phthalonic Acid (Formula, p. 2098).—The yield of phthalonic anhydride obtained under the conditions just described is about 2.4 grams, and the acetyl chloride mother-liquors deposit, on concentration, colourless prisms (0.2 gram) of the acetyl- ψ -acid. This is collected and washed with ether; it may then be recrystallised by adding ether to the solution in glacial acetic acid (Found: C = 55.6; H = 3.6. $C_{11}H_8O_5$ requires C = 55.9; H = 3.6 per cent.).

On heating in a capillary tube, acetyl- ψ -phthalonic acid gradually turns yellow and melts at 185 – 186° , decomposition into phthalonic anhydride and acetic acid taking place. This behaviour, coupled with the small amount produced when phthalonic acid is digested with acetyl chloride, may easily lead to the acetyl- ψ -acid being overlooked. Acetyl- ψ -phthalonic acid is not readily hydrolysed by cold water, and may, in fact, be accurately titrated if the operation is rapidly carried out. Thus 0.1010 gram, dissolved in water, required for neutralisation 3.41 c.c. of $N/10$ - Na_2CO_3 , using methyl-orange as indicator, whereas this amount of a monobasic acid, $C_{11}H_8O_5$, should neutralise 3.41 c.c.

The following experiment shows that the acetyl- ψ -acid is quantitatively hydrolysed to acetic and phthalonic acids on boiling with

* Anhydrous phthalonic acid (m. p. 146°) is obtained by dissolving the hydrated acid, $C_8H_4(CO_2H)_2 \cdot CO \cdot CO_2H \cdot 2H_2O$, in ether, leaving for some hours, or digesting, with anhydrous sodium sulphate, and then evaporating.

water. The substance, 0.2118 gram, was distilled in steam and the acetic acid in the distillate estimated with $N/10$ -NaOH, using phenolphthalein as indicator, when 9.1 c.c. was required for neutralisation, whereas the calculated amount is 9.1 c.c. The residue in the distillation flask neutralised 18.2 c.c. of $N/10$ - Na_2CO_3 .

Action of Aniline on the Anhydride of Phthalonic Acid.

Aniline α -Anilino- α -hydroxyhomophthalanilate (compare Formula, p. 2096).—When phthalonic anhydride (3 grams) is warmed with benzene (5 c.c.) and aniline (13 c.c.), interaction takes place readily with rise of temperature and a viscous syrup separates, but, on standing and rubbing, this solidifies and the liquid becomes filled with crystals. These crystals were collected by the aid of the pump, washed with ether, and dried in a vacuum desiccator. The yield is nearly theoretical (Found: C = 71.7; H = 5.6; N = 9.3. $\text{C}_{27}\text{H}_{25}\text{O}_4\text{N}_3$ requires C = 71.2; H = 5.5; N = 9.2 per cent.).

This substance melts at 115° and is soluble in benzene, chloroform, alcohol, or acetone, but, when the solutions are heated, rapid change occurs and colourless needles separate which melt at 176° and consist of phthalon-2-anilic acid (see below). The substance of melting point 115° dissolves readily in sodium carbonate solution with separation of aniline and, on acidifying, the anilic acid (m. p. 176°) separates.

Phthalon-2-anilic Acid (compare Formula, p. 2097).—This substance is readily prepared by boiling the chloroform solution of the aniline derivative (m. p. 115°) just described. The needles which separate are collected, washed with ether, and recrystallised from methyl alcohol (Found: C = 66.8; H = 4.1; N = 5.2. $\text{C}_{15}\text{H}_{11}\text{O}_4\text{N}$ requires C = 66.9; H = 4.1; N = 5.0 per cent.). Phthalon-2-anilic acid melts at 176° , dissolves readily in sodium carbonate solution, and is reprecipitated on acidifying with hydrochloric acid. The aniline salt is obtained when phthalon-anilic acid, dissolved in hot water, is mixed with aniline (3 c.c.) and separates in colourless crystals which, after being washed with water and crystallised from methyl alcohol, melt at 178° (Found: C = 69.6; H = 5.0; N = 7.3. $\text{C}_{21}\text{H}_{18}\text{O}_4\text{N}_2$ requires C = 69.6; H = 5.0; N = 7.7 per cent.).

When phthalon-2-anilic acid was heated above its melting point in a sulphuric acid bath, the syrup gradually crystallised and on grinding with dilute sodium carbonate solution, about half dissolved. The alkaline solution, acidified with hydrochloric acid, deposited a colourless, crystalline substance, which separated from benzene in needles, melted at 158° , and consisted of phthalanilic acid. Zincke (*Annalen*, 1889, 255, 375) first obtained this substance by the partial hydrolysis of phthalanil and states that it melts at 158° .

Phthalondianilide (compare Formula, p. 2097).—This substance is obtained when phthalonic anhydride (1 gram) is heated with aniline (3 c.c.) in the steam-bath until solution takes place. The product is rubbed with ether, the crystals collected, washed with ether, and recrystallised from alcohol or benzene, from which the substance separates in needles melting at 206–208° (Found: C = 73.1; H = 4.7; N = 8.1. $C_{21}H_{16}O_3N_2$ requires C = 73.3; H = 4.7; N = 8.1 per cent.).

4 : 5-Dimethoxy-o-tolylglyoxylic Acid (Formula, p. 2098).

This acid, the preparation of which has already been described (T., 1921, 119, 1735), is much more readily soluble in hot than in cold water, and melts, when rapidly heated, at about 155° with considerable previous softening as in the case of other glyoxylic acids.

The Methyl Ester, $(MeO)_2C_6H_2Me \cdot CO \cdot CO_2Me$.—The acid (1.6 grams), methyl alcohol (15 c.c.), and concentrated sulphuric acid (1.5 c.c.) were digested on the water-bath for an hour and the clear solution was mixed with water, when an oil separated which was extracted with ether. The ethereal solution was well washed with water and then with aqueous sodium carbonate, which removed very little unchanged acid, and dried over calcium chloride. During the removal of the ether by distillation, the methyl ester began to separate in crystals and, on evaporating to dryness, a solid cake remained. This methyl ester is sparingly soluble in light petroleum and separates from a mixture of this solvent with benzene in striated prisms melting at 98–99° (Found: C = 60.8; H = 5.9. $C_{13}H_{14}O_5$ requires C = 60.5; H = 5.9 per cent.).

The Phenylhydrazone, $(MeO)_2C_6H_2Me \cdot C(N_2H \cdot C_6H_5) \cdot CO_2H$.—The boiling aqueous solution of the glyoxylic acid yields, on the addition of phenylhydrazine, a syrup which gradually crystallises, and does so immediately on warming with methyl alcohol. This hydrazone is very sparingly soluble in boiling methyl alcohol and separates in groups of colourless prisms which shrink at 195° and melt at 196° with decomposition and evolution of gas (Found: N = 8.6. $C_{17}H_{18}O_4N_2$ requires N = 8.9 per cent.). It gives, with excess of ammonia, a sparingly soluble ammonium salt which dissolves readily in hot water.

Action of Semicarbazide on 4 : 5-Dimethoxy-o-tolylglyoxylic Acid.—When the suspension of this acid in a little water is warmed with a large excess of semicarbazide hydrochloride and sodium acetate, a clear solution results which, on standing, gradually deposits round, warty masses of the semicarbazide of the semicarbazone,

$(MeO)_2C_6H_2Me \cdot C(N \cdot NH \cdot CO \cdot NH_2) \cdot CO_2H, NH_2 \cdot NH \cdot CO \cdot NH_2$
(Found: C = 43.0; H = 5.7; N = 23.0. $C_{13}H_{20}O_6N_4$ requires

C = 43.8; H = 5.6; N = 23.6 per cent.). This curious substance melts at about 125° and is readily soluble in hot water. On mixing the hot aqueous solution with an equivalent amount of dimethoxy-*o*-tolylglyoxylic acid, the clear solution soon deposits a sandy mass of crystals of the normal semicarbazone,

and the same substance is obtained when the aqueous solution of the acid is mixed with the theoretical amount of semicarbazide hydrochloride and sodium acetate (Found: N = 14.5. $\text{C}_{12}\text{H}_{15}\text{O}_5\text{N}_3$ requires N = 14.9 per cent.).

This semicarbazone is sparingly soluble in hot water, from which it gradually separates as a hard crust. It softens at 215° and melts at about 220° with vigorous effervescence, due to evolution of carbon dioxide and ammonia. The yellow residue is very sparingly soluble in methyl alcohol and crystallises in bright yellow spangles melting at 228° without decomposition. This change was not further studied.

Attempts to prepare 4:5-dimethoxy-*o*-tolualdehyde from the glyoxylic acid by decomposition with sodium hydrogen sulphite in the usual manner were unsuccessful. After the acid had been heated on the steam-bath with a large excess of the sulphite, there was little change, since almost all the acid was recovered on acidifying with hydrochloric acid.

*Action of Aniline on 4:5-Dimethoxy-*o*-tolylglyoxylic Acid.*

When the ethereal solution of the glyoxylic acid is mixed with aniline, a mass of needles rapidly separates which melts at 117° after being washed with ether. The substance is the aniline salt of the acid, since, on dissolving in aqueous sodium carbonate, it yields aniline, and hydrochloric acid precipitates the original acid from the alkaline solution (Found: C = 64.2; H = 6.0; N = 4.4. $\text{C}_{17}\text{H}_{19}\text{O}_5\text{N}$ requires C = 64.4; H = 6.0; N = 4.4 per cent.). This aniline salt (5 grams) dissolves readily in hot xylene (25 c.c.). On boiling the solution, carbon dioxide is eliminated and, after removal of the xylene by distillation under reduced pressure, a syrup remains which soon crystallises. This substance separates from light petroleum in colourless needles, melts at 97°, and is 4:5-dimethoxy-*o*-tolylideneaniline, $(\text{MeO})_2\text{C}_6\text{H}_2\text{Me}\cdot\text{CH}:\text{N}\cdot\text{C}_6\text{H}_5$ (Found: C = 75.6; H = 6.9. $\text{C}_{16}\text{H}_{17}\text{O}_2\text{N}$ requires C = 75.3; H = 6.6 per cent.). When this substance (5 grams) is heated on the steam-bath with water (25 c.c.) and concentrated hydrochloric acid (12 c.c.), a heavy syrup is formed which, on rubbing, gradually crystallises and the liquid becomes filled with a voluminous mass of yellow needles. After washing and drying, this curious substance crystallises from ethyl acetate in orange needles, and in yellow

needles from dilute hydrochloric acid. Analysis shows that it is the *hydrochloride* of 4:5-dimethoxy-o-tolylideneaniline of the composition $[(\text{MeO})_2\text{C}_6\text{H}_3\text{Me}\cdot\text{CH}\cdot\text{N}\cdot\text{C}_6\text{H}_5\cdot\text{HCl}]_2\cdot\text{H}_2\text{O}$ (Found: C = 64.2; H = 6.6; N = 4.9; Cl = 11.8. $\text{C}_{22}\text{H}_{28}\text{O}_5\text{N}_2\text{Cl}_2$ requires C = 63.9; H = 6.3; N = 4.7; Cl = 11.8 per cent.). This hydrochloride shrinks at 160–162° and melts at about 192° with decomposition. It is remarkable that this tolylidene derivative may be boiled with concentrated hydrochloric acid without change and that, when the solution is diluted and excess of sodium acetate is added, dimethoxy-o-tolylideneaniline separates. Whilst it is therefore not possible, in this way, to hydrolyse the tolylidene derivative with separation of the sparingly soluble aldehyde, the latter may nevertheless be obtained in almost quantitative yield from the tolylidene derivative under the following interesting conditions (compare p. 2099).

The tolylidene derivative (5 grams) is heated with water (25 c.c.) and concentrated hydrochloric acid (12 c.c.) for half an hour, and the solution diluted with an equal volume of water and repeatedly extracted with ether. During this operation some of the hydrochloride separates at first, but this gradually disappears and the aldehyde passes into the ether. The ethereal solution is dried over calcium chloride, and the ether removed, when the residue solidifies and, after crystallisation from light petroleum, melts at 76° and consists of 4:5-dimethoxy-o-tolualdehyde (Found: C = 66.8; H = 6.7. $\text{C}_{10}\text{H}_{12}\text{O}_3$ requires C = 66.7; H = 6.7 per cent.). This aldehyde separates from water in slender needles.

The *oxime*, described by Gattermann (*Annalen*, 1907, 357, 371) as melting at 124°, is readily prepared by boiling the aldehyde with sodium acetate and hydroxylamine hydrochloride in the usual manner, and it is remarkable that it is also produced when the hydrochloride of 4:5-dimethoxy-o-tolylideneaniline is boiled with hydroxylamine hydrochloride and sodium acetate. It may be crystallised from alcohol and then melts at 128°.

The semicarbazone had already been prepared from the aldehyde by means of sodium acetate and semicarbazide hydrochloride (T., 1906, 89, 128). It is also obtained when a concentrated solution of the hydrochloride of the tolylidene derivative is warmed on the steam-bath with semicarbazide hydrochloride and sodium acetate. The chalky precipitate is collected and recrystallised from alcohol, from which the semicarbazone separates in needles melting at 218°.

β -4:5-Dimethoxy-o-tolylacrylic Acid,

—This acid is obtained when 4:5-dimethoxy-o-tolualdehyde (3 grams) is heated with acetic anhydride (11 grams) and anhydrous sodium acetate (3 grams) in a sealed tube at 180° for twelve hours.

The product is boiled with water and sodium carbonate, and the solution extracted with ether to remove dissolved aldehyde. On acidifying with hydrochloric acid, the new acid separates in a crystalline condition and is purified by crystallisation from benzene (Found: C = 64.6; H = 6.4. $C_{12}H_{14}O_4$ requires C = 64.8; H = 6.3 per cent.).

This acid melts at 117° and is sparingly soluble in boiling water, from which it separates as a crystalline powder consisting of thin plates. It is readily soluble in glacial acetic acid and crystallises well from 40 per cent. acetic acid in glistening laminae. The solution in aqueous sodium carbonate instantly decolorises permanganate at 0°, and, on boiling, the odour of 4 : 5-dimethoxy-*o*-tolualdehyde becomes perceptible.

[Received, July 2nd, 1923.]

CCXXXIV.—*Studies of Electrovalency. Part II. Co-ordinated Hydrogen.*

By THOMAS MARTIN LOWRY and HENRY BURGESS.

1. *Co-ordination of Hydrogen.*

The selection of hydrogen as a standard of valency is often justified on the ground that this element "possesses only one bond, and therefore is not capable of joining together other atoms." The object of the present paper is to show that this idea is false and to point out some applications of the theory that hydrogen, like oxygen, is capable of forming co-ordination compounds. The real existence of this type of co-ordination can be proved both by crystallographic and by chemical evidence and may therefore be regarded as an experimentally-established fact rather than as a plausible hypothesis.

(a) *Crystallographic Evidence.*—The X-ray analysis of ice has proved (i) that each atom of oxygen is surrounded symmetrically by four atoms of hydrogen, (ii) that each atom of hydrogen is placed symmetrically between two atoms of oxygen. This arrangement can be explained in terms of Werner's theory of valency by assigning to each oxygen atom two principal and two subsidiary valencies; but the further assumption must be made that each hydrogen atom also possesses a principal and a subsidiary valency. The distinction between these two types of valency cannot, however, be maintained in the light of the electronic theory of valency, and the simplest way of regarding the crystal structure of ice is to suppose (i) that a proton is attached to each of the four duplets of the octet of each

oxygen atom, (ii) that each proton is attached in this way simultaneously to two oxygen atoms. Whatever theoretical views may be adopted, however, it is clear that the crystal of ice is held together just as much by the ability of hydrogen to link together two atoms of oxygen as by the ability of oxygen to link together four atoms of hydrogen.

(b) *Chemical Evidence*.—The simplest chemical evidence for the co-ordination of hydrogen is to be found in potassium hydrofluoride, $\text{KHF}_2 \rightleftharpoons \text{K}^+ + \text{HF}_2^-$. A complex anion is here formed by the union of two fluoride-ions and one hydrogen-ion. Since the fluoride-ions are both negatively charged, and each ion carries a complete octet of electrons, there can be no direct attraction between them. Since, however, both fluoride-ions have an attraction for the positively-charged hydrogen-ion, this may very well act as a link between them as in the formula $\text{:}\ddot{\text{F}}\text{:H:}\ddot{\text{F}}\text{:}$ or $\text{F}^-\text{H}^+\text{F}^-$, where the two fluorines are linked together by a hydrogen nucleus, in just the same way as the oxygen atoms in ice.*

2. Applications to Homopolar Ions.

(a) *Anomalous Properties of Carboxylic Acids*.—The idea that the anomalous optical and chemical properties of the carboxylic acids could be explained by means of subsidiary valencies was put forward in 1909 by Dr. Ida Smedley (T., 1909, 95, 218, 231), who suggested that whilst the oxygen in acetone possesses free residual affinities, the residual affinities of the two oxygen atoms in the carboxylic acids neutralise one another. Hantzsch in 1917 (Ber., 1917, 50, 1422), following up Werner's view that the oxy-acids and their salts should be formulated as co-ordination compounds, made the further suggestion that the carboxylic acids may actually exist in two forms, an unsymmetrical and non-ionisable form, $\text{R}\cdot\text{CO}\cdot\text{OH}$, from which the esters are derived, and a symmetrical co-ordinated and ionisable form, $\text{R}\cdot\text{C}\begin{smallmatrix} \text{O} \\ \diagup \quad \diagdown \\ \text{O} \end{smallmatrix} \text{H}$, from which the salts are derived. The polar formula recently assigned to acetic acid (this vol., p. 822) shows four electrically-charged atoms in a closed circuit like a ring magnet, $\text{CH}_3\text{--}\overset{+}{\text{C}}\begin{smallmatrix} \text{O} \\ \diagup \quad \diagdown \\ - \quad + \\ \text{O} \end{smallmatrix} \text{H}$. The peculiarities of the carboxylic acids are here ascribed, not to the direct interaction of two oxygens as

* Latimer and Rodebush (J. Amer. Chem. Soc., 1920, 42, 1431) have given a similar explanation of the association of liquid water; the same idea is also developed under the heading of "Bivalent Hydrogen," by G. N. Lewis in a forthcoming book on "Valency," of which he has very kindly allowed me to see the proofs.—T. M. L. 17/8/23.

Dr. Smedley supposed, but to the co-ordination of both oxygens with hydrogen, as suggested by Hantzsch. Whereas, however, both Werner and Hantzsch place the hydrogen atoms of the oxyacids outside the sphere of co-ordination, the chief object of the present paper is to develop the idea that the hydrogen itself can form a co-ordinated complex, and may act like a metal in providing a link for binding together atoms of other elements.

(b) *Ring Formation*.—Tschugaev directed attention in 1907 (*J. pr. Chem.*, 1907, [ii], 75, 153) to the importance of ring-formation in stabilising co-ordination compounds, and to the fact that the ordinary laws of ring formation apply also in these less familiar cases. This factor is of special importance in the case of hydrogen, where other factors favouring co-ordination are weak. The co-ordination formula for oxalic acid is therefore shown as containing a five-atom ring-system as in I rather than a four-atom ring-system as in II.

Moreover, since Morgan and Smith (T., 1922, 121, 1956) have shown that a hydrogen-ion and a molecule of water are often mutually replaceable in co-ordination complexes, it is reasonable to suppose that the dihydrates of sulphuric acid and of oxalic acid may be represented as III and IV, where the water molecules form conjugated rings containing six atoms.

The competition between hydrogen nuclei and water molecules for the negative poles of the anion, which is indicated by these formulae, is obviously important in connexion with the study of the strength of acids, and throws some light on the fact that strong acids generally have a strong affinity for water.

3. Application to Heteropolar Ions.

The preceding paragraph deals with homopolar anions in which all the negative poles are identical, for example, the two oxygens of

acetic acid or the four oxygens of sulphuric or of oxalic acid. Heteropolar ions, in which the various poles are dissimilar, differ from these in that the ions are tautomeric, that is, they can be formulated in two (or more) ways, corresponding with the fact that they can yield two (or more) types of derivatives by the attachment of hydrogen or an alkyl group to the different poles. In a recent paper (this vol., p. 822), I have pointed out that multipolar ions often give co-ordination compounds, since a metallic ion can attach itself simultaneously to two poles even when the ion is only univalent. The further suggestion is now made that multipolar ions can give co-ordination compounds also with hydrogen. This explains the fact, of which some typical illustrations are discussed under (a) and (b) below, that heteropolar ions containing three dissimilar negative poles usually give only two hydrides, although at least three are theoretically possible.

(a) *Ethyl Acetoacetate*.—According to the ordinary conventions, this ester should exist in three forms, namely, a ketone and two isomeric enols, I and II.

On asepatic distillation, however, the ester behaves as a binary rather than as a ternary mixture, in spite of the fact that the enols might be expected to be more nearly equal in stability than the enolic and ketonic form. The failure to detect a second enol is more remarkable when polar formulæ are used, since it then appears that the tripolar anion (III) can attract a hydrogen nucleus to the positions 1 and 3, but is unable to attract it to the position 5. A simple interpretation of the facts is, however, available if it be supposed that the hydrogen nucleus may either (i) settle down on the carbon atom 3, giving rise to the ketone IV or (ii) be co-ordinated with both the oxygen poles 1 and 5, giving rise to the co-ordinated enol V.

(IV.) Ketone.

(III.) Ion.

(V.) Co-ordinated enol.

The question has often been asked, "What are the conditions that give rise to enolisation of ketones?" Thiele (*Annalen*, 1899, 306, 87) suggested that conjugation is the principal factor; but the additional suggestion can now be made that the most stable enolic compounds are co-ordinated as well as conjugated. Under these

conditions, not only the ions, but the two enols themselves, may be regarded as tautomeric, since, although they are usually written in two different ways, they are in fact "not isomeric, but identical." This does not mean that the existence of the unco-ordinated enols is impossible, but rather that, when the conditions are such as to favour co-ordination, the difficulty of isolating them would be so great as to make the task a hopeless one, in view of the readiness with which both enols would pass into the more stable co-ordinated form.

(b) *Nitrocamphor and Benzoylcamphor*.—Confirmation of the view that tripolar ions usually yield only two out of three possible hydrides is afforded by the study of solid ketones such as nitrocamphor and benzoylcamphor, each of which is theoretically capable of existing in at least three isomeric forms as follows :

Evidence that the dynamic isomerism of these compounds is dominated by only two forms, out of three or more which are possible, is given in the experimental section below.

It is therefore suggested that the ions VI and X each yield only two isomeric hydrides, namely, (i) the ketones VII and XI, by the attachment of a proton to the carbon pole at the centre of the conjugated system, and (ii) the co-ordinated enols VIII and XII, by the attachment of a proton simultaneously to both of the terminal oxygen poles, exactly as in the case of ethyl acetoacetate.

(c) The various formulæ that have been suggested for the much-discussed ester of Goss, Ingold, and Thorpe (this vol., p. 327) can all be summarised by formulating the ester as a dihydride of the quinquepolar ion XIII.

Since it is assumed that the hydrogen in the "normal" form is not specifically attached to any one atom of carbon or oxygen, the positions assigned to the two hydrogen atoms by the authors are as follows:

Enolic form = 1 : 3. Ketonic form = 1 : 2. Normal form = 1 : 0. Perkin's formula represents the normal form as 2 : 2'.

The co-ordination of hydrogen leads, as usual, to no alteration in the method of representing the ketonic form of the ester; but there is no obvious reason why, in the enolic form, the mobile atom of hydrogen should not be attached simultaneously to the two oxygen poles 3 and 3', or even to the four negative poles 2, 2', 3, and 3'. There is, however, a very grave objection to the view that the most stable form of the ester is one in which the hydrogen atom is not specifically attached to other atoms, since if this were correct this phenomenon should be of very widespread occurrence in organic chemistry instead of being so rare as to have escaped detection until comparatively recent years. A much more plausible view is that the hydrogen in this form of the ester is held with crab-like firmness (Morgan, T., 1920, 117, 1457, footnote) as part of a co-ordinated complex, in which it is gripped, not by one other atom, but by at least two. The stability of the compound suggests that all the factors favouring co-ordination must be called into play, for example, conjugation and co-ordination, as well as the formation of a stable ring-system of five or six atoms. A formula in which all these factors are shown can be obtained, as in XIV, by attaching one hydrogen atom to the carbon pole at 2', whilst the other is co-ordinated (just as in the three compounds discussed above) with the carbon pole 1 as well as with the oxygen pole 3. The fact that evidence derived from the formation of lactones points to one formula for the normal form of the ester, whilst the evidence from the action of ozone points to another, may be explained on the ground that when the ring is split the co-ordinated hydrogen may remain attached either to carbon or to oxygen. In any case,

the difficulty of finding conclusive evidence as to the structure of this ester recalls Forster's experience in the case of benzoylcamphor, and may be due to a similar cause, namely, the unsuspected co-ordination of a hydrogen atom, which causes it to act as if it occupied two different positions in the molecule.

(d) *Unsaturated Acids*.—The question has been asked frequently, "What explanation can be given of the equilibrium of $\alpha\beta$ - and $\beta\gamma$ -unsaturated acids?" The most interesting case is that of the hydrocinnamylidene-acetic and -malonic acids studied by Riiber (*Ber.*, 1905, **38**, 2742), where isomeric change proceeds in one direction in the malonic acid (i), and in the reverse direction (ii) when this is converted into the corresponding acetic acid. Under the influence of hot caustic soda the double bond in the last acid moves back (apparently reversibly) as in (iii) to the $\alpha\beta$ -position (Fittig, *Annalen*, 1894, **283**, 47, etc.), although some of the $\gamma\delta$ -acid is also formed, in which the double bond is conjugated with the aromatic nucleus.

These changes can be explained in part by Thiele's theory of conjugation, on the ground that the $\alpha\beta$ -acid is conjugated in the "ketonic," and the $\beta\gamma$ -acid in the "enolic" form; but this explanation appears inadequate in view of the extremely slight tendency to enolisation of the carboxylic acids. The theory of co-ordinated hydrogen provides a more powerful motive for the change, since the enolic form (IX) can be represented as being not merely conjugated, but also co-ordinated, and containing a pseudo-aromatic six-atom ring, just as in the four preceding cases. A similar formula (X) may be assigned to the enolic form of itaconic acid.

Since there is no reason to suppose that any of these acids are stable in the enolic form, the formulæ IX and X should be regarded as intermediate stages in the isomeric change. The fact that these changes are promoted by strong sodium hydroxide solution, whereas isomeric change in unsaturated hydrocarbons such as the iso-

butylenes requires the use of concentrated sulphuric acid (Butlerow, *Annalen*, 1877, 189, 44) finds an explanation in the mechanism suggested above, since the alkali would tend to stabilise the co-ordinated complex. The different mechanism of isomeric change which is rendered possible by the carboxylic group may also account for the much greater ease with which isomeric change takes place in the unsaturated fatty acids as compared with the unsaturated hydrocarbons.

(e) *Tartaric Acid*.—In the Bakerian Lecture of 1922 (Lowry and Austin, *Phil. Trans.*, 1922, [A], 222, 249) the anomalous rotatory dispersion of tartaric acid and its derivatives was attributed to the existence of two dissimilar forms of the acid. After ten years' search, the co-ordination of hydrogen has at last provided a satisfactory formula for the elusive labile form of the acid, which may now be written as XV, whilst the co-ordinated form of the ethyl ester is shown in XVI. These formulæ are supported by a considerable amount of new experimental evidence, which will be published shortly.

4. Steric Hindrance.

Many of the phenomena on which the conception of steric hindrance has been based find a simple explanation in the present extension of the theory of co-ordination, for example, (i) the absence of free rotation about a single bond in tartaric acid, in the diphenic acids, and in some compounds of the sugar group, (ii) the abnormal physical properties of ortho-derivatives of benzene, (iii) the abnormal ionisation of many organic acids, both of the fatty and aromatic series, for example, 2:6-dihydroxybenzoic acid. Although a full discussion of these phenomena is not possible in the present paper, it is clear that formulæ based on the co-ordination of hydrogen must be taken into account in future discussions of the subject.

EXPERIMENTAL.*

The experimental evidence, that the dynamic isomerism of α -benzoylcamphor and of π -bromonitrocamphor is dominated by

* This section was rewritten and new experimental data added July 25th, 1923.

two isomerides only, may be set out under three headings as follows :

5. *Crystallisation.*

(a) When π -bromonitrocamphor is dissolved in chloroform, it undergoes isomeric change so slowly that the equilibrium mixture can be crystallised out almost as if the isomerism were static instead of dynamic. Two kinds of crystals can then be picked out, separated, and measured (Lapworth and Kipping, T., 1896, 69, 304); but a repetition of this operation, in order to secure samples of the two isomerides for experiments on mutarotation, did not disclose any third form of crystal, although the two dominant forms were easily picked out.

(b) In the case of benzoylcamphor also, two isomeric forms, a ketone and an enol, have been submitted to a complete crystallographic examination (Forster, T., 1901, 79, 991), but without the discovery of any third form. Even more important is the fact that Vixseboxse (*Diss.*, Amsterdam, 1920; *Rec. trav. chim.*, 1921, 40, 1; compare Smits, "Allotropy," 1922, p. 186) has plotted a complete pseudo-binary equilibrium diagram for this compound without encountering any of the complications that would arise from the presence of a third form in the equilibrium mixture. Recent experiments in this laboratory, with a view to the preparation of materials for experiments on mutarotation, have also given no evidence of complications arising from the presence of a second form of the enol; the only important complication is due to the ready conversion of the material into a purple decomposition product, the formation of which is unfortunately non-reversible, since it cannot be got rid of by the simple process of evaporating the solution to dryness and thus converting the equilibrium mixture into the least soluble of the dynamic isomerides.

6. *Mutarotation.*

The logarithmic law of mutarotation (*Brit. Assoc. Rep.*, 1904, 198) has been verified in the case of π -bromonitrocamphor (T., 1899, 75, 211), although the two forms did not converge towards the final equilibrium at the same rate in two independent experiments. In the case of benzoylcamphor, Forster's mutarotation curves (T., 1901, 78, 999), although of similar form, showed a still larger discrepancy in the velocity of convergence towards a final value. This discrepancy is easily explained, since the mutarotation of benzoylcamphor, like that of nitrocamphor, appears not to be spontaneous, but to depend on the presence of a catalyst. Under normal conditions, the catalyst is probably benzoic acid, formed by hydrolysis in presence of a trace of moisture, and particularly under

the influence of light (Lowry and Courtman, T., 1913, 103, 1214). This hydrolysis appears to be autocatalytic, and to take place more rapidly in the case of the enol than in the case of the ketone.* It was therefore not practicable to control the catalysis completely,

FIG. 1.

either in neutral solutions, or in solvents containing added benzoic acid, and satisfactory results could only be obtained by employing an alkaline catalyst.

* Thus two samples with equal initial velocities showed a six-fold increase in the case of the enol as compared with a two-fold increase in the case of the ketone.

In Forster's experiments, chloroform containing 0.05 per cent. of piperidine was used as solvent; but this solvent is now known to give rise to complications, as a result of the formation, by oxidation of the chloroform, of carbonyl chloride (Lowry and Magson, T., 1908, 93, 119) which eliminates the catalyst in the form of a carbamide. That something of this sort actually occurred in Forster's experiments is very probable in view of the relatively low velocity of change which he observed. In our experiments, 0.01 per cent. of piperidine was found to be sufficient to bring about a very rapid mutarotation in chloroform, whilst in benzene 0.005 per cent. of the catalyst produced an even more rapid change. The results are set out in Tables I and II and are shown graphically in Fig. 1.

The observed rotations were one-tenth of the specific rotations shown in the tables, where 0.1° represents 0.01° in the original readings.

In considering these results, it would be of no value to compare the velocity constants with those which may be obtained with more stable materials. In the present case, reasonable constancy can only be obtained by adding sufficient piperidine to drown the effects of casually-formed catalysts, such as benzoic acid, whilst avoiding the use of so large a quantity as to make the mutarotation too rapid for accurate observation. A more just comparison is obtained by contrasting the behaviour of benzoylcamphor with that of the closely-related amide and piperidide of camphorcarboxylic acid, which differ from benzoylcamphor only in containing the groups $\cdot\text{CO}\cdot\text{NH}_2$ and $\cdot\text{CO}\cdot\text{NC}_5\text{H}_{10}$ instead of $\cdot\text{CO}\cdot\text{C}_6\text{H}_5$.^{*} In the first compound, many opportunities for the formation of new isomerides exist, which do not occur in the second, where the tertiary nitrogen does not carry a directly-attached hydrogen atom. Even here, however, the possibility of transferring a mobile hydrogen atom from carbon to nitrogen (and conversely) instead of to oxygen only, is sufficient to produce a series of most striking anomalies in the mutarotation curves (Lowry and Glover, T., 1913, 103, 913). In particular, the mutarotation curves of this substance exhibit the periods of induction and points of inflexion which are amongst the most conspicuous evidences of actions depending on a series of successive unimolecular changes (Lowry and John, T., 1910, 79, 2634). The absence of any such features in the case of the closely-related benzoylcamphor may therefore be regarded not as a mere accident, but as definite evidence in favour of the view that the dynamic isomerism is dominated by two only of the many possible forms

^{*} The last two compounds, in addition to having similar formulae, exhibit important morphotropic relationships (Glover and Lowry, T., 1912, 101, 1902).

of the compound. At the same time, it must be recognised that the complete absence of a third form cannot be inferred directly from the unimolecular character of a series of mutarotation curves. Thus, if the third form were only a minor constituent, or if it had the same rotatory power as the equilibrium mixture of the other two forms, its presence might be masked completely. This masking of a third form is, however, much less likely to occur in the camphor series, where even the rotatory dispersions are often anomalous, than in the sugar series, where simple numerical relationships between optical rotatory powers are the rule rather than the exception (Tanret, *Compt. rend.*, 1901, **132**, 487; Maltby, T., 1922, **121**, 2608; this vol., p. 1404), whilst simple rotatory dispersion may be observed even in compounds containing five asymmetric atoms (Lowry and Abram, *Trans. Faraday Soc.*, 1914, **10**, 106).

7. Chemical Evidence.

The prediction made in the first paper of this series, that compounds which have been studied as examples of dynamic isomerism should afford excellent material for the preparation of co-ordinated derivatives, has been fully verified in the case of benzoylcamphor. The metallic derivatives already prepared include the lithium, glucinum, aluminium, manganese, iron, cobalt, and copper compounds; these are all obviously co-ordinated, whilst the sodium compound behaves more like a metallic salt. Detailed descriptions and analyses of these co-ordinated derivatives of benzoylcamphor will form the subject of a later paper; but the further suggestion of the present paper, that the enolic compound may itself be co-ordinated, already receives experimental support from the fact that, after a laborious attempt to determine which of the two possible enols he was dealing with, Forster (T., 1903, **83**, 89) was unable to discriminate clearly between them. This result would receive a natural explanation if the two enols are, in fact, both co-ordinated and therefore identical, although this would not preclude the possibility that the co-ordinated ring might break preferentially in one way, and so yield predominantly derivatives of one enol only.

8 Summary.

(a) The co-ordination of hydrogen is proved by the X-ray analysis of ice, and by the existence of the complex ion $\overline{F}H\overline{F}$, where two fluorine-ions are held together by their mutual attraction for a hydrogen-ion.

(b) The co-ordination of hydrogen-ions with the homopolar ions of oxy-acids explains many of the anomalous properties of these acids. Molecules of water may also be co-ordinated with these

ions; their competition with protons may be an important factor in determining the strength of acids.

(c) The co-ordination of hydrogen with heteropolar ions gives rise to tautomeric enols which are "not isomeric but identical." In this way an explanation is given of the fact that only two of three or more possible forms of ethyl acetoacetate, nitrocamphor, or benzoyl-camphor are known.

(d) The co-ordination of hydrogen provides an alternative explanation of many phenomena that have been ascribed hitherto to steric hindrance.

CCXXXV.—*The Diffusion of Oxygen through Silver.*

By LEO SPENCER.

TROOST (*Compt. rend.*, 1884, 98, 1427) found that, at 778°, oxygen and air diffused through two silver tubes of different thicknesses, the rates, in c.c. per sq. metre per hour, being 1700 and 890, respectively, through the thicker tube, and 3330 and 1640 through the thinner. Sieverts (*Z. physikal. Chem.*, 1905, 50, 198) reports that hydrogen, oxygen, and nitrogen do not diffuse through silver at 640°. Nernst and von Wartenburg, in their researches on the dissociation of water vapour, found that, after a few hours' heating at 800°, a silver tube became porous, at room temperature, to all gases; and this they attributed to oxygen diffusing through and breaking up the structure of the metal.

In view of the indefinite state of our knowledge it was decided to reinvestigate the subject. The present paper contains an account of the preliminary work. The experiments have, however, been unavoidably interrupted.

The apparatus (Fig. 1) employed in the experiments consisted of a silver tube, 500 mm. long, 3.6 mm. in external diameter, and 0.3 mm. thick, closed at one end and wound into a spiral 13.2 mm. in external diameter, with each coil almost touching the next. The length of the finished spiral was about 70 mm. The open end of the spiral was welded to a thick capillary tube of silver 40 cm. long, 3.0 mm. in external and 0.5 mm. in internal diameter. A silica thermo-couple tube, 6 mm. in diameter, situated along the central axis of the spiral and projecting on either side, enabled the temperature gradients to be determined; the highest and the lowest temperature of the spiral were within 5° to 6° of the mean temperature.

The coil was heated in a glazed porcelain tube and, to avoid any possible contamination, was so mounted that it touched nothing but silver, being held by three silver rods riveted to two silver disks. For the same reason, the silica tube of the thermo-couple was wrapped in silver foil.

The porcelain tube passed through an outer fireclay tube, electrically heated; by varying the resistance, the temperature of the coil could be kept steady to $1-2^{\circ}$.

Two rubber stoppers closed the porcelain tube. Through one passed the thermocouple and a glass tube connected to an open mercury gauge. This allowed the porcelain tube to be filled with

FIG. 1.

oxygen or other gas at known pressures. Through the other passed the capillary of the silver spiral, which was connected to a gauge containing olive oil and further on to an open mercury gauge. By means of the connexions shown in the sketch, both the silver spiral and the porcelain tube were connected to the Topley pump.

The apparatus was designed so as to be as sensitive as possible. The area of the silver tube was large (50.0 sq. cm.). The volume of the spiral and of the connecting tubes was made as small as possible (10.1 c.c.). The gauge contained a liquid of low density (0.93), and the level was read by means of a telescope enabling a change of 0.01 mm. to be detected.

For the purpose of making a measurement, the porcelain tube was filled with gas at the required pressure, the temperature regulated, and the spiral kept evacuated. When it was considered that

equilibrium conditions had set in, the tap on the oil gauge was closed and the rate of rise of pressure observed by means of the telescope.

At room temperature, the silver spiral was gas-tight, but at a sufficiently high temperature and pressure, gas was observed to pass through it. The rate of diffusion was very slow and the amount of gas passing through very small, but the following experiments showed that diffusion of oxygen was really occurring. (1) In the case of air, the gas that diffused through was almost pure oxygen, the percentage of this gas being 90 at 337°, 95 at 400°, and 97 at 500°. (2) When the oxygen or air was displaced by hydrogen or carbon dioxide, diffusion stopped. (3) When the hydrogen or carbon dioxide was again displaced by oxygen or air, diffusion recommenced.

Estimations of the rate of diffusion were made; but it has since been surmised that the olive oil in the gauge dissolved a certain amount of gas and therefore the values given below cannot be regarded as trustworthy. The total amount of gas entering the whole spiral at an average rate during one hour was only 0.07 c.c. Unfortunately, it has not been possible to repeat the experiments with another liquid in the gauge.

After the pressure had risen somewhat, in order to set the gauge back to zero the tap had to be opened and then closed again. After this, at the commencement, a higher rate of diffusion was usually observed, due probably to the gas dissolving in the oil. It was overcome by making all the measurements over a small range of pressures. Concordant results were obtained when measurements were made over the range of pressure 0.53—0.66 mm. of mercury.

The effect of temperature on the rate of diffusion is shown by the values given in Table I.

TABLE I.

Air at 760 mm.

Temperature.	Rate of diffusion in c.c. per sq. cm. per second $\times 10^7$.	Temperature.	Rate of diffusion in c.c. per sq. cm. per second $\times 10^7$.
292°	0.05	400°	2.0
315	0.13	450	5.3
348	0.59	483	9.6
379	1.2	503	15.2

*These rates are very slow; the average is 4.3×10^{-7} c.c. per sq. cm. per second, which is a hundred times smaller than the slowest rate measured by Richardson, Nichol, and Parnell in their researches on the diffusion of hydrogen through platinum (*Phil. Mag.*, 1904, [vi], 8, 1).

The results obtained for air and for oxygen at different pressures at 400° are given in Table II (P = pressure in mm. of mercury, and x = rate of diffusion in c.c. per sq. cm. per second).

TABLE II.

P .	$x \times 10^7$.	P .	$x \times 10^7$.	P .	$x \times 10^7$.
Air at 400°.					
760	2.13	421	1.32	221	0.84
758	1.94	379	1.36	198	0.70
740	1.85	370	1.16	154	0.56
650	1.83	357	1.12	113	0.35
632	1.76	349	1.14	103	0.35
595	1.59	300	0.94	77	0.18
495	1.65	252	0.86	43	0.04
436	1.28	230	0.84		
Oxygen at 400°.					
785	4.58	157	1.58	67	0.82
776	4.32	152	1.58	57	0.46
630	4.23	127	1.45	51	0.61
430	3.00	104	1.20	47	0.61
275	2.45	85	1.10	29	0.27
189	1.90	85	0.95	20	0.15
171	1.80	73	0.81	19	0.17

It will be seen that the rate of diffusion with air is slower, at a given pressure, than the rate with oxygen, the difference increasing with increasing pressure. If the rates of diffusion are plotted against pressure, it will be found that the two curves (starting at $P = 10$ mm. for oxygen and at $P = 45$ mm. for air) are parabolic they are, in fact, well represented by the equations $x + 6.6 \times 10^{-8} = 0.95 \times 10^{-8} \sqrt{P}$ for air and $x + 6.6 \times 10^{-8} = 1.85 \times 10^{-8} \sqrt{P}$ for oxygen. The axes of the parabolas lie below the pressure axis, (abscissa), but parallel to it.

If it can be assumed that, between the pressures 0.53 mm. and .66 mm. of mercury, the oil in the gauge absorbs gas at the rate of $6 \times 10^{-8} \times 50$ c.c. per second (50 sq. cm. being the area of the silver spiral), then, this correction having been applied, the curves would pass through the origin and would show definitely that the rate of diffusion is proportional to the square root of the pressure. In experiments carried out at other temperatures, however, a different rate of absorption has to be assumed and therefore the explanation is not wholly satisfactory.

The results obtained at other temperatures are of the same character as those already given, so only the equations need be recorded. These are $x + 8.5 \times 10^{-8} = 2.25 \times 10^{-8} \sqrt{P}$ for air at 450°; $x + 1.58 \times 10^{-7} = 4.08 \times 10^{-8} \sqrt{P}$ for air at 483°; and $x + 2.57 \times 10^{-7} = 6.62 \times 10^{-8} \sqrt{P}$ for air at 503°. The correctness of all these equations (including the 400° results) was proved by

plotting the experimental values of the rates of diffusion against the square roots of the pressures, when straight lines were obtained.

The values obtained by Troost (*loc. cit.*) agree with those calculated on the assumption that the rate of diffusion is strictly proportional to the square root of the pressure of the oxygen.

The evidence as it stands seems to indicate that the rate of diffusion is proportional to the square root of the pressure and, consequently, that the oxygen in the silver is in the atomic, not molecular form. This deduction is interesting in view of the results of Sieverts and Hagenacker (*Z. physikal. Chem.*, 1909, **68**, 115) and of Donnan and Shaw (*J. Soc. Chem. Ind.*, 1910, **29**, 987), who found that the solubility of oxygen in molten silver also obeys the same law. It is further interesting that the rate of diffusion of hydrogen through hot platinum was shown by Richardson, Nichol, and Parnell (*loc. cit.*) also to be proportional to the square root of the pressure. The theoretical significance of this law, with regard to silver, is discussed in the paper by Donnan and Shaw just mentioned.

Summary.

- (1) An apparatus to demonstrate the diffusion of oxygen through silver is described.
- (2) The rates of diffusion are very small.
- (3) The quantitative measurements, so far as they are trustworthy, indicate that the rate of diffusion of oxygen is proportional to the square root of the pressure.
- (4) In the case of air, the diffusion is preferential, the nitrogen being held back.

[Received, June 22nd, 1923.]

CCXXXVI.—*The Properties of Ammonium Nitrate.*
Part VI. The Reciprocal Salt Pair Ammonium Nitrate and Potassium Sulphate.

By EDGAR PHILIP PERMAN and WILLIAM JOHN HOWELLS.

IN Part V, a system was described containing one set of mixed crystals (ammonium nitrate and potassium nitrate). The system now under consideration is much more complex; three sets of mixed crystals have been proved to exist, namely, ammonium nitrate and potassium nitrate, ammonium nitrate and ammonium sulphate, ammonium sulphate and potassium sulphate. It would appear, therefore, that the four salts are more or less isomorphous, or at least capable of forming mixed crystals with each other, so

that there is the possibility of the formation of six pairs of mixed crystals and also of more complex combinations. A special difficulty encountered in this system was the slight solubility of the sulphates in fused ammonium nitrate. It was often necessary to heat for many hours in an oil-bath at about 170° before a clear solution could be obtained. The range of the experiments is therefore comparatively small.

Binary Systems.—Three binary systems have been investigated :

(1) Ammonium nitrate and potassium nitrate (see Part V, this vol., p. 841).

(2) Ammonium nitrate and ammonium sulphate; no eutectic is formed.

(3) Potassium nitrate and potassium sulphate, showing a eutectic at 337.6° with 1.6 per cent. of sulphate.

Ternary Systems.—There is only one ternary system, consisting of the three pairs of mixed crystals already mentioned, which are in equilibrium with one another at the ternary point 156.5° .

The following are the various systems studied :

- (a) Ammonium nitrate and potassium nitrate.
- (b) Ammonium nitrate and ammonium sulphate.
- (c) Potassium nitrate and potassium sulphate.
- (d) Ammonium nitrate and potassium sulphate.
- (e) (Ammonium nitrate and potassium nitrate) eutectic and potassium sulphate.
- (f) (Ammonium nitrate and potassium nitrate) eutectic and ammonium sulphate.
- (g) (Ammonium nitrate + 4% potassium nitrate) and ammonium sulphate.
- (h) (Ammonium nitrate + 8% potassium nitrate) and ammonium sulphate.
- (k) (Ammonium nitrate + 11% potassium nitrate) and ammonium sulphate.
- (l) (Ammonium nitrate + 17% potassium nitrate) and ammonium sulphate.
- (m) (Ammonium nitrate + 19% potassium nitrate) and ammonium sulphate.
- (n) (Ammonium nitrate + 20.5% potassium nitrate) and ammonium sulphate.
- (o) (Ammonium nitrate + 22% potassium nitrate) and ammonium sulphate.

Curve (a). See Part V (*loc. cit.*), p. 842.

Curve (b). The freezing point of ammonium nitrate is raised

steadily on addition of ammonium sulphate. The salts therefore are either isomorphous or sufficiently alike in character to form mixed crystals. Fig. 1 shows the experimental results. There is only one solid phase, namely, mixed crystals of ammonium nitrate and ammonium sulphate. The majority of the curves

are very similar to this one, namely, curves *d*, *e*, *g*, *h*, *k*. The solid phases are as follows:

In (*d*), (*g*), (*h*), (*k*), mixed crystals of ammonium nitrate and ammonium sulphate; in (*e*) and (*f*), mixed crystals of ammonium sulphate and potassium sulphate.

Curve (*l*) is of the usual two-branch type; the solid phase on the left is mixed crystals of ammonium and potassium nitrates, and on the right ammonium and potassium sulphates. The curves are convex above.

Curves (*m*), (*n*), and (*o*) are also of the two-branch type, but convex below and forming a poorly defined minimum. The solid phases are the same as in curve (*l*).

The general diagram (see Part IV, T., 1922, 121, 2477) is shown in Fig. 2; the concentrations were read for every 2°. There are two well-defined areas: mixed crystals of ammonium and potassium nitrates and mixed crystals of the two sulphates. A third area, consisting of mixed crystals of ammonium nitrate and ammonium

FIG. 2.

sulphate, is ill-defined and appears to merge gradually into the second named.

It is unfortunate that the whole system cannot be realised, as it would be an exceptionally interesting one.

Potassium nitrate and potassium sulphate form a eutectic, so that the boundary line will run to that point, but it is impossible to say whether ammonium and potassium sulphates form a eutectic or not; if so, the boundary line would branch and run to that point. Fig. 3. It would seem more probable, however, from the results obtained that there are only two main areas, viz. (1) mixed crystals of ammonium and potassium nitrates; (2) mixed crystals

of ammonium and potassium sulphates, merging gradually into mixed crystals of ammonium sulphate and ammonium nitrate.

The four salts of this system appear capable of forming mixed crystals all together, in triplets, or in pairs, and it is therefore hazardous to make any predictions as to the remainder of the diagram.

Summary.

(1) The freezing point of ammonium nitrate is raised steadily by the addition of ammonium sulphate.

(2) An equilibrium diagram is given for the system $2\text{NH}_4\text{NO}_3 + \text{K}_2\text{SO}_4 \rightleftharpoons 2\text{KNO}_3 + (\text{NH}_4)_2\text{SO}_4$.

FIG. 3.

This shows a ternary point, at 156.5° , at which three pairs of mixed crystals are in equilibrium, namely, ammonium nitrate and ammonium sulphate, ammonium sulphate and potassium sulphate, and ammonium nitrate and potassium nitrate. The experimental results are given in an appendix.

Freezing Points of Binary Mixtures.

[Received, June 8th, 1923.]

CCXXXVII.—Complex Formation in Lead Nitrate Solutions. Part I. The Ternary Systems Lead Nitrate–Sodium Nitrate–Water, and Lead Nitrate–Potassium Nitrate–Water.

By SAMUEL GLASSTONE and HAROLD NICHOLAS SAUNDERS.

LEBLANC and NOYES (*Z. physikal. Chem.*, 1890, 6, 386) appear the first to have noted that the solubility of lead nitrate in water at the ordinary temperature is increased by the presence of potassium nitrate, but decreased by sodium nitrate. The difference was ascribed to the existence of potassium nitrate in solution as double molecules, and cryoscopic measurements were recorded in favour of this view. The cases mentioned were, however, isolated examples. Lewis (*Diss.*, Breslau, 1908) determined the solubility of a series of mixtures of lead nitrate with sodium and potassium nitrate respectively, in water at 25.3°; he concluded that in the presence of the sodium salt the solubility of lead nitrate was in agreement with Nernst's law on the influence of a common ion, but that in the case of potassium nitrate there was evidence of the formation of complex ions. It may be pointed out that Nernst's law would scarcely be applicable to such concentrated solutions as are being considered here. The different behaviour of the sodium and potassium salts led Lewis to suggest that in the latter case the alkali metal itself formed part of a complex positive ion, to which, from potential measurements, was given the formula KPbNO_3^{++} ; similar complex formation was thought not to occur with sodium nitrate. This view, however, is not in accordance with the strong electro-positive

nature of potassium; in fact, according to the modern electron theory of valency, the existence of such a stable complex ion as KPbNO_3^{++} would scarcely be expected. It is much more probable that the lead enters into a complex anion, for example, $\text{Pb}(\text{NO}_3)_4^{--}$, which may exist to some extent, according to unpublished measurements, in a solution of pure lead nitrate in water.

The addition of either sodium or potassium nitrate to a solution of lead nitrate causes a considerable diminution of the plumbous-ion concentration, measured electromotively (Lewis, *loc. cit.*; Cumming, *Trans. Faraday Soc.*, 1907, 2, 199; Abegg and von Labendzinski, *Z. Elektrochem.*, 1904, 10, 77; Fernau, *Z. anorg. Chem.*, 1898, 17, 327), thus indicating complex formation in each case, although to a greater extent with the potassium salt. In view of this similarity in behaviour of the alkali nitrates, the object of this work was to investigate the factors affecting the solubility relationships of lead nitrate in the presence of either of these salts.

Miss Isaac (T., 1908, 93, 384) has determined the saturation temperatures of solutions containing varying amounts of lead nitrate and a fixed ratio of sodium nitrate to water; from these results it has been calculated that 100 parts of water dissolve 43.01 and 57.99 parts by weight of lead nitrate at 32° and 65°, respectively, in the presence of a constant amount (75 parts) of sodium nitrate. The ratio of solubilities is thus 1.35, whilst in pure water for the same two temperatures the ratio is 1.48. The effect of sodium nitrate is apparently to cause a relative decrease in solubility as the temperature rises, and an increase as the temperature falls. At a sufficiently low temperature we should expect to find that sodium nitrate increases the solubility of lead nitrate just as potassium nitrate does at the ordinary temperature, and that if potassium nitrate behaves in a similar manner, at high temperatures it will cause a diminution in the solubility of lead nitrate. To test this possibility, the ternary systems $\text{KNO}_3\text{-Pb}(\text{NO}_3)_2\text{-H}_2\text{O}$ and $\text{NaNO}_3\text{-Pb}(\text{NO}_3)_2\text{-H}_2\text{O}$ were investigated completely at 25° and 50°, and partly at 0° and 100°. Lewis (*loc. cit.*) determined the isotherms at 25.3°, but made no analysis of the solid phases; his results are expressed as gram-mols. per litre, which is a very unsatisfactory method of expression when dealing with such concentrated solutions. In the present work, the liquid and wet solid phases were analysed; the results were plotted on the usual triangular diagram, and extrapolation to the dry solid phase was carried out according to the method of Schreinemakers (*Z. physikal. Chem.*, 1893, 11, 81).

EXPERIMENTAL.

General Procedure.—In most cases the salts were mechanically mixed in known proportions, and water was added until they were

just dissolved at temperatures about 10° higher than that of the isothermal. These mixtures were then stirred in a gas-regulated thermostat for two or three days; after allowing time to settle, samples of the clear liquid and of the wet solid were removed for analysis. For the 50° isothermal, unsaturated solutions were often allowed to evaporate slowly, until sufficient solid for analysis had separated out.

Method of Analysis.—A weighed amount of the liquid or wet solid was heated first on a water-bath, then in an air-oven at 110° , and finally on a hot plate at about 130° ; in this way, the amount of water was determined. The dried solid was then dissolved in a known volume of water, an aliquot part taken and the lead in this estimated gravimetrically as sulphate by the method described in Treadwell's "Quantitative Analysis," 1919, p. 174. Hydrolysis of lead nitrate was negligible, and caused no trouble during the evaporation; further, the general analytical method was tested on mixtures made up from known weights of lead nitrate with sodium nitrate and potassium nitrate, respectively. The results obtained were in very good agreement with theory, provided sufficient care was taken to wash the lead sulphate precipitate very thoroughly with 5 per cent. sulphuric acid.

The results obtained for this system are represented in Fig. 2. Many tie-lines have been omitted for the sake of clearness.

An examination of the isothermal curves shows that in general the addition of sodium nitrate to a solution of lead nitrate decreases the solubility of the latter, and the slope of the left hand portion of the curves indicates that this effect is greater at increased temperatures. Further, as the amount of sodium nitrate increases, the decrease in solubility becomes smaller; for example, at 25° an increase in the sodium nitrate from 30 to 40 per cent. alters only very slightly the relative amounts of lead nitrate and water. At lower temperatures, in the presence of a fairly large amount of sodium nitrate, the solubility of the lead salt will probably be increased. Potassium nitrate, on the other hand, always appears to increase the solubility of lead nitrate, but the curves show that this effect decreases greatly with increasing temperature. The change in the isothermal curve from 25° to 50° is very marked; at the higher temperature the slope is less, and the isothermal invariant point moves over to the potassium nitrate side of the diagram. Thus, the potassium nitrate curves for high temperatures begin to resemble more closely those of sodium nitrate. By performing experiments under pressure at still higher temperatures, it might be possible to observe a decrease in the solubility of lead nitrate as a result of adding potassium nitrate.

The marked differences between the sodium nitrate and the potassium nitrate isotherms are only partly accounted for by the fact, already mentioned, that in the latter case complex ion formation takes place to a greater extent than in the former; it is very probable that other important factors are also operative. Quite recently, von Weimarn (*Koll. Z.*, 1923, **32**, 145) discussed the influence of one salt on the solubility of another, and stated that when two or more salts are dissolved in a given solvent, a competition for the solvent takes place between the salts, so that a decrease in the solubility of the salt which takes up least of the solvent follows. In the case under discussion, the sodium forms the most heavily hydrated ion (compare Washburn, *J. Amer. Chem. Soc.*, 1909, **31**, 322; Kraus, "Properties of Electrically Conducting Systems," 1922, p. 201); a recent estimate (Lenard, Weick, and Mayer, *Ann. Physik*, 1920, [iv], **61**, 665) gives the number of molecules of water associated with the sodium-ion as twelve, and seven with the potassium-ion. The lead-ion, with a relative mass of 207 and an ionic mobility of 58.6 at 18°, is probably only very slightly hydrated. When sodium nitrate is added to a solution of lead nitrate, the ions (and probably the undissociated molecules, too) of the former become heavily hydrated, with the result that a certain amount of the solvent water is removed. Less water is now available for the dissolution of lead nitrate, and

so its solubility may be diminished in spite of complex ion formation occurring at the same time. That the activity of the water is much less in sodium nitrate solutions than in those containing potassium nitrate, is shown by the fact observed during the course of these investigations, that the latter solutions evaporate much more rapidly than do the former. A series of experiments will be commenced shortly with the object of investigating this matter further. Since hydration and complex ion formation act in opposite directions as far as the solubility of lead nitrate is concerned, the effect of increasing temperature may be to increase the former (Kraus, *op. cit.*, pp. 125, 202), or to decrease the latter, or both; in any case, the result would be a relative decrease in the solubility of the lead salt. A fuller discussion of this matter must be left for the present.

Summary.

(1) The ternary systems $\text{NaNO}_3\text{-Pb(NO}_3)_2\text{-H}_2\text{O}$ and $\text{KNO}_3\text{-Pb(NO}_3)_2\text{-H}_2\text{O}$ have been investigated completely at 25° and 50° , and partly at 0° and 100° .

(2) Sodium nitrate, in general, causes a decrease in the solubility of lead nitrate; this decrease becomes smaller at lower temperatures.

(3) Potassium nitrate causes the solubility of lead nitrate to increase, but the effect decreases considerably as the temperature rises.

(4) The difference in behaviour between the two alkali nitrates is probably due to variation in degree of complex ion formation and of hydration; these factors act in opposite directions, and either or both may be influenced by temperature.

The authors wish to express their thanks to the Council of the University College of the South West for the award of an Andrew Simons Research Scholarship, which enabled one of them (H. N. S.) to collaborate in this work.

CCXXXVIII. — *The Preparation of N-Derivatives in the Carbazole Series.*

By THOMAS STEVENS and STANLEY HORWOOD TUCKER.

THE fact that 3-nitrocarbazole dissolves in alcoholic potassium hydroxide solution with a deep red colour suggests that a salt is formed of the type (I), and that, as in the parallel case of hexanitrodiphenylamine (*Ber.*, 1908, 41, 1745), it might be possible to

isolate a coloured *aci*-ether. Preliminary experiments with this object in view were unsuccessful; the action of the alkyl iodides on

the alcoholic solution of sodium hydroxide and 3-nitrocarbazole giving rise to *N*-alkyl derivatives (II). As a result of this observation, successful attempts were made to prepare *N*-alkyl derivatives of the carbazole series. With slight modifications, the method was tried and found to be applicable to the preparation, not only of *N*-alkyl and *N*-acyl derivatives of 3-nitrocarbazole, but also of carbazole, 3-bromo- and 3-iodo-carbazole, and *N*-alkyl derivatives of tetrahydrocarbazole.

The only methods * which have been described for the preparation of *N*-alkyl, *N*-aryl, and *N*-acyl derivatives of carbazole involve direct action of the reagent on (i) carbazole itself, (ii) magnesium carbazole iodide, and (iii) potassium carbazole. The applicability of (i) is limited; (ii) is somewhat tedious; whilst (iii), which necessitates a fusion with potassium hydroxide, evidently cannot be applied to compounds such as nitro- and halogeno-carbazoles. The improvement introduced by Clark (*J. Ind. Eng. Chem.*, 1919, 11, 204) into this last method, in which he uses a mixture of potassium and sodium hydroxides, does not obviate the drawback mentioned.

The difficulty has been completely surmounted by the use of aqueous solutions of potassium or sodium hydroxide acting upon carbazole, or its derivative, dissolved in alcohol or acetone, in presence of the appropriate alkylating or acylating reagent at, or slightly above, room temperature. By this method, practically quantitative yields of *N*-derivatives are obtained.

The products prepared by the alkylation of 3-nitrocarbazole were identical with those obtained by the direct nitration of the corresponding alkylcarbazoles (M.L.B., D.R.-P. 259504, 294016; Morgan and Read, T., 1922, 121, 2715); whence these substances are proved to be 3-nitro-*N*-alkylcarbazoles. The identity of the nitrocarbazole obtained from nitro-*N*-nitrosocarbazole (Ruff and Stein, *Ber.*, 1901, 34, 1677) with that prepared by direct nitration in nitrobenzene (M.L.B., D.R.-P. 294016) and in acetic acid (Ziersch, *Ber.*, 1909, 42, 3797) was confirmed by the melting points of mixtures

* Since the preparation of this paper there has come to our notice a patent specification (*Illustrated Official Patents Journal*, March 28th, 1923, No. 1784) which describes the preparation of alkylcarbazoles by the action of solid potassium hydroxide on carbazole.

of the alkyl derivatives, which are more readily characterised than 3-nitrocarbazole itself.

It is noteworthy that the properties of 3-nitro-*N*-ethylcarbazole, prepared by us by the ethylation of 3-nitrocarbazole, agree with those of the compound prepared according to the German patent 259504 (M.L.B.), but not with those of the compound made by Delétra and Ullmann and assumed by them to be 3-nitro-*N*-ethylcarbazole (*Arch. Sci. phys. nat. Geneve*, 1904, [iv], 17, 90). Delétra and Ullmann describe the compound isolated by them as a red, crystalline powder, melting at 108° and decomposing above that temperature, soluble in acetic acid or benzene, sparingly soluble in alcohol or ether. On the other hand, 3-nitro-*N*-ethylcarbazole isolated by us is yellow, melts at 126–128°, and is unchanged after heating for a short time at a hundred degrees above its melting point, and is readily soluble in ether. It is to be noted that Blom (*Helv. Chim. Acta*, 1921, 4, 1036) failed to obtain nitrocarbazoles by Ullmann's method.

As already mentioned, this process of alkylation can also be advantageously applied to carbazole. The *N*-alkylcarbazoles are obtained in almost quantitative yield by the action of a concentrated aqueous solution of sodium or potassium hydroxide on an acetone solution of carbazole and the appropriate alkyl iodide or sulphate. Furthermore, the method has been successfully applied to the alkylation of 3-bromo- and of 3-iodo-carbazole (to be described in a forthcoming communication by one of us), and of tetrahydro-carbazole.

It was not found possible to obtain *N*-methyl-diphenylamine by this method, probably owing to the weaker acidity of diphenylamine.

Carbazole and 3-nitrocarbazole are readily acetylated and benzoylated by the same process, using the required acid chloride in place of the alkylating reagent.

In general, the reaction proceeds more readily the more acidic the imino-compound and the smaller the alkyl group to be introduced. Thus dilute alkali may be employed with little disadvantage in the case of the alkylation of 3-nitrocarbazole; whereas, even in presence of concentrated potassium hydroxide solution, diphenylamine is scarcely affected. The retarding effect of large alkyl groups, particularly the secondary radicals, is in agreement with the work of Levy (*Monatsh.*, 1912, 33, 177) on the interaction of solid potassium carbazole and alkyl iodides.

EXPERIMENTAL.

3-Nitrocarbazole was prepared from (i) 3-nitro-*N*-nitrosocarbazole by the method of Ruff and Stein (*loc. cit.*), or by the following slight

modification: 3-Nitro-*N*-nitrosocarbazole (6 grams) was boiled with acetic acid (100 c.c.) and fused sodium acetate (6 grams) until nitrous fumes ceased to be evolved (about forty-five minutes). The hot liquid was filtered, and 3-nitrocarbazole separated on cooling. A further quantity was obtained from the mother-liquor.

(ii) Carbazole directly nitrated in nitrobenzene (M.L.B., *loc. cit.*).

N-Derivatives of 3-Nitrocarbazole.

3-Nitro-*N*-methylcarbazole.—(a) 3-Nitrocarbazole (5 grams), alcohol (100 c.c.), 10 per cent. aqueous sodium hydroxide (25 c.c.), and methyl iodide (7 grams) are gently boiled under reflux. Crystals soon separate. Heating is continued for two hours, and the solution allowed to crystallise. The crystals of 3-nitro-*N*-methylcarbazole are washed with aqueous alcohol, and recrystallised from alcohol or slightly dilute acetic acid. The yield is 70 per cent. of theory.

(b) 3-Nitrocarbazole (1 gram) is dissolved in 66 per cent. aqueous potassium hydroxide solution (1 c.c.) and acetone (10 c.c.) by warming, and methyl sulphate (1 c.c.) added. The mixture is well shaken for a few seconds until the deep red colour of potassium nitrocarbazole has been replaced by yellow. Warm water (5 c.c.) is added to the semi-solid product, which is then set aside to crystallise, and the 3-nitro-*N*-methylcarbazole isolated and purified as described above. The yield is 90–95 per cent. of theory.

(c) 3-Nitrocarbazole (2 grams) is boiled with methyl iodide (10 c.c.), and silver oxide (2 grams) gradually added; the boiling is continued for an hour. The excess of methyl iodide is then distilled off, and the 3-nitro-*N*-methylcarbazole extracted from the residue by means of alcohol. The yield is 80 per cent. of theory.

3-Nitro-*N*-methylcarbazole forms long, yellow needles, m. p. 169–171°. [M.L.B. give the melting point as 147–148° (D.R.-P. 259504); 160–161° (D.R.-P. 294016).] 3-Nitro-*N*-methylcarbazole, prepared by the method of D.R.-P. 259504—nitration of methylcarbazole in benzene solution with hydrochloric acid and aqueous sodium nitrite—was shown by a mixed melting point to be identical with the product obtained by the methylation of 3-nitrocarbazole.

3-Nitro-*N*-ethylcarbazole.—(a) 3-Nitrocarbazole (5 grams), alcohol (120 c.c.), 10 per cent. aqueous sodium hydroxide solution (40 c.c.), and ethyl iodide (10 grams) are boiled under reflux for a day, and the product is isolated as described in the preparation of 3-nitro-*N*-methylcarbazole (a).

(b) The preparation is carried out as in the second method described under 3-nitro-*N*-methylcarbazole, using an equivalent quantity of ethyl sulphate.

3-Nitro-*N*-ethylcarbazole crystallises from alcohol or slightly dilute acetic acid in long, yellow needles, m. p. 126–128°: it remains undecomposed at 230°. A specimen prepared by the method of Morgan and Read (*loc. cit.*; compare also M.L.B., *loc. cit.*) was shown by a mixed melting point to be identical with the product of ethylation of 3-nitrocarbazole.

3-Nitro-*N*-*n*-propylcarbazole.—3-Nitrocarbazole (1 gram) is dissolved in 66 per cent. aqueous potassium hydroxide solution (1 c.c.) and acetone (10 c.c.), and *n*-propyl iodide (1.2 grams) added. The mixture is boiled under reflux until the red colour is replaced by yellow (forty-five minutes). The product is isolated in the usual manner, and forms yellow needles from alcohol, m. p. 101–103° (Found: C = 70.8; H = 5.9; N = 11.3. $C_{15}H_{14}O_2N_2$ requires C = 70.9; H = 5.5; N = 11.0 per cent.).

3-Nitro-*N*-isopropylcarbazole is prepared similarly to its isomeride, except that the reaction requires six hours' boiling. It forms yellow needles, m. p. 149–152°, from alcohol or slightly dilute acetic acid (Found: C = 70.7; H = 5.7; N = 11.3. $C_{15}H_{14}O_2N_2$ requires C = 70.9; H = 5.5; N = 11.0 per cent.).

3-Nitro-*N*-*n*-butylcarbazole is prepared in the same manner as its next lower homologues, *n*-butyl iodide (1.3 grams) being used, and the mixture boiled for forty-five minutes. It forms yellow leaflets or long, pointed laminae from alcohol; m. p. 97–100° (Found: C = 71.3; H = 6.1; N = 10.8. $C_{16}H_{16}O_2N_2$ requires C = 71.6; H = 6.0; N = 10.4 per cent.).

The foregoing nitro-compounds behave in a very similar manner towards solvents; the solubility in alcohol, however, falls noticeably with rising melting point. They are very soluble in ether, acetone, chloroform, benzene, xylene, or nitrobenzene, moderately soluble in alcohol or acetic acid, and almost insoluble in light petroleum. They dissolve in concentrated sulphuric acid, giving deep violet solutions. Great difficulty was experienced in the estimation of nitrogen in these substances: the values cited are probably fortuitous, as the results of other estimations were frequently 0.6 to 0.8 per cent. high. Each of the compounds was prepared from 3-nitrocarbazole, obtained, as stated, from 3-nitro-*N*-nitroso-carbazole, and from that made by nitration of carbazole in nitrobenzene, and the identity of the products confirmed by mixed melting points.

3-Nitro-*N*-benzoylcarbazole.—3-Nitrocarbazole (1 gram) is dissolved in 60 per cent. aqueous potassium hydroxide solution (1 c.c.) and acetone (15 c.c.), and benzoyl chloride (1 c.c.) is added. On shaking, the red colour is discharged and a yellow solid separates. The mixture is poured into water, the product filtered, and recrystal-

lised from glacial acetic acid, from which it separates in white needles, m. p. 181—183°. It is readily hydrolysed by warm 60 per cent. aqueous potassium hydroxide solution. Mazzara (*Ber.*, 1891, 24, 278), by the nitration of *N*-benzoylcarbazole, obtained a compound which he described as glistening yellow leaflets, m. p. 181°, decomposed by alcoholic, but not by aqueous, potassium hydroxide solution. Since Mazzara's compound gives rise to 3-nitrocarbazole on hydrolysis, the two substances are probably identical, the discrepancy in properties being due to impurities in the original *N*-benzoylcarbazole, which he describes as chrome-green in colour.

3-Nitro-*N*-acetylcarbazole.—3-Nitrocarbazole (1 gram) is dissolved in acetone (15 c.c.) and 66 per cent. aqueous potassium hydroxide solution (3 c.c.) by warming. Acetyl chloride (2 c.c.) is added to the cold solution, and the mixture shaken until the violent reaction has subsided. The product is then poured into water and filtered. In order to remove traces of unaltered 3-nitrocarbazole, the solid is boiled with acetone (10 c.c.) for a few seconds, a little dilute sodium hydroxide solution added, and the mixture at once filtered. The almost white product is now recrystallised from xylene or acetic acid. The yield is nearly theoretical.

A more convenient method of preparing 3-nitro-*N*-acetylcarbazole is to heat 3-nitrocarbazole with acetic anhydride containing a trace of concentrated sulphuric acid. The method originally used by Mazzara and Leonardi (*Gazzetta*, 1892, 22, ii, 443) for the acetylation of 3-nitrocarbazole involves heating the reaction mixture in a sealed tube.

N-Derivatives of Carbazole.

***N*-Methylcarbazole.**—(a) Carbazole (15 grams), methyl sulphate (15 c.c.), and acetone (75 c.c.) are mixed with a solution of sodium hydroxide (15 grams) in water (10 c.c.). The mixture is vigorously shaken for a few minutes and poured into water. The product precipitated is recrystallised from alcohol, and gives an almost quantitative yield of *N*-methylcarbazole.

(b) Pure carbazole (4 grams) is boiled with methyl iodide (40 grams), and silver oxide (6 grams) gradually added. The mixture is boiled for an hour. The excess of methyl iodide is distilled off, and *N*-methylcarbazole extracted from the residue by means of boiling alcohol. The yield is 80 per cent. of theory.

***N*-Ethylcarbazole** is prepared by the method (a) used to obtain *N*-methylcarbazole.

***N*-*n*-Propylcarbazole.**—Carbazole (2 grams), acetone (10 c.c.), 66 per cent. aqueous potassium hydroxide solution (2 c.c.), and *n*-propyl iodide (4 grams) are boiled under reflux for twelve hours.

On pouring into water, *N-n*-propylcarbazole separates as an oil, which soon solidifies, and is recrystallised from alcohol. The yield is 85 per cent. of theory.

N-Benzoylcarbazole.—Carbazole (3.3 grams) is dissolved in acetone (20 c.c.), and potassium hydroxide (5.6 grams) in 66 per cent. aqueous solution added. The mixture is well shaken, and boiled under reflux. Boiling is interrupted, and benzoyl chloride (5.6 grams) added (through the condenser) in three portions, the mixture being well shaken after each addition. The pasty solution is poured into water and the solid which separates is crystallised from alcohol. *N-Benzoylcarbazole* is very soluble in hot, and only slightly soluble in cold alcohol; it is best crystallised from dilute alcoholic solution, from which it separates in colourless needles, m. p. 98°. The yield is 80—90 per cent. of theory.

It was found to be very difficult to isolate pure *N*-benzoylcarbazole by the method employed by Mazzara (*loc. cit.*) on account of resinous products and coloured substances formed in the reaction.

N-Derivatives of Halogenocarbazoles.

3-Bromo-N-methylcarbazole.—3-Bromocarbazole (1 gram) is dissolved in 66 per cent. aqueous potassium hydroxide solution (1 c.c.) and acetone (10 c.c.), and methyl sulphate (1 c.c.) is added. The mixture is shaken, warmed, and poured into water. The oil which separates solidifies in a freezing mixture, and is recrystallised from alcohol in white needles, m. p. 76—79° (Found: Br = 30.9. $C_{13}H_{10}NBr$ requires Br = 30.7 per cent.).

3-Bromo-N-ethylcarbazole is prepared as 3-bromo-*N*-methylcarbazole. It melts at 81—84° (Found: Br = 29.3. $C_{14}H_{12}NBr$ requires Br = 29.1 per cent.).

3-Bromo-N-benzoylcarbazole.—3-Bromocarbazole (0.3 gram) is dissolved in acetone (5 c.c.), 66 per cent. aqueous potassium hydroxide solution (1 c.c.) is added, and then a solution of benzoyl chloride (0.5 c.c.) in acetone (5 c.c.). The reaction mixture boils, is finally shaken and poured into water. The product is recrystallised from a mixture of alcohol and benzene, m. p. 124°.

3-Iodo-N-methylcarbazole.—3-Iodocarbazole, m. p. 192—194° (3 grams) is mixed with acetone (15 c.c.), methyl sulphate (2 grams), and a 60 per cent. aqueous solution of potassium hydroxide (2 grams of potassium hydroxide). The mixture is treated as in the preparation of 3-bromo-*N*-methylcarbazole. 3-Iodo-*N*-methylcarbazole crystallises from much alcohol in colourless crystals, m. p. 77—79°. The yield is nearly theoretical [Found: by the Baubigny-Chavanne method (*Compt. rend.*, 1903, 136, 1197), I = 41.7. $C_{13}H_{10}NI$ requires I = 41.4 per cent.].

3-Iodo-*N*-ethylcarbazole is prepared as 3-iodo-*N*-methylcarbazole, ethyl sulphate being used in place of methyl sulphate. It crystallises from alcohol in long needles, m. p. 83–84° (Found: by Carius's method, I = 39.2. $C_{14}H_{12}NI$ requires I = 39.5 per cent.).

p-Toluenesulphonylcarbazole (Cassella, 1909, D.R.-P. 224951; Herz, 1910, A.P. 966092).

Carbazole (2 grams), *p*-toluenesulphonyl chloride (4 grams), and acetone (20 c.c.) are warmed to give a clear solution, and 66 per cent. aqueous potassium hydroxide solution (5 c.c.) is added. The liquor is poured into water, and the product recrystallised from alcohol.

N-Methyltetrahydrocarbazole.—Tetrahydrocarbazole (1.7 grams) is dissolved in acetone (10 c.c.), and potassium hydroxide (6.6 grams) in 66 per cent. aqueous solution added. The mixture is shaken, and methyl sulphate (5 grams) is introduced in the course of fifteen minutes. The liquid on each addition of methyl sulphate turns pink, and, on shaking, gradually back to yellow. The mixture is poured into water, and a yellow oil separates. It solidifies in the cold, and can be crystallised from methyl alcohol in long sword blades melting at 50°, as found by Perkin and Plant (T., 1921, 119, 1834).

Summary.

1. A general method has been elaborated for the alkylation and acylation of carbazole and its derivatives in solution at moderate temperatures.

2. A series of 3-nitro-*N*-alkylcarbazoles has been prepared and examined, of which only the two lowest members had been even superficially described.

3. The identity of the nitrocarbazole prepared by different methods has been confirmed.

ORGANIC CHEMISTRY DEPARTMENT,

CCXXXIX.—*Tesla-luminescence Spectra. Part III.* *Some Mono-substitution Products of Benzene.*

By WILLIAM HAMILTON MCVICKER, JOSEPH KENNETH MARSH,
and ALFRED WALTER STEWART.

It has been shown (McVicker, Marsh, and Stewart, this vol., p. 642) that benzene vapour, when traversed by a Tesla discharge, emits a spectrum consisting of seven groups of fine bands with limits at

the wave-numbers 3257, 3357, 3454, 3554, 3652, and 3752; and it has been found (McVicker and Marsh, this vol., p. 817) that changes of temperature and pressure over wide ranges appear to have comparatively slight influence upon the essential characteristics of the benzene spectrum. The work has now been extended by the examination of a number of mono-substitution products of benzene; and certain general rules governing the character of Tesla-luminescence spectra have come to light.

1. *Apparatus.*

In the light of experience gained, some modifications in the details of the apparatus have been made. Since some substances had to be examined at high temperatures and low pressures, it seemed advisable to eliminate rubber-glass joints; and in the type of cell now employed a ground-glass junction connects the cell with the pump, while the gauge and the vaporising flask containing the substance to be examined are sealed directly on to the cell itself. When high-boiling liquids were examined, a special cell was used having a bulb attached to each end of the cell-tube; and the liquid was boiled in one of these bulbs and condensed in the other by a cooling bath. This complication of the cell necessitated a fresh type of heating-jacket; and it was found best to use a tin casing within which the cell-tube was imbedded in flock asbestos. By heating the tin casing with a Bunsen burner, an even temperature can be maintained in the cell.

The firm attachment of the quartz window of the cell has proved to be a matter of considerable difficulty. The best method devised up to the present has been to make an air-tight join between the quartz and the glass end of the cell by means of a solution of "dope" in amyl acetate, several coats being applied in succession with due time for hardening between the applications. When this join is complete, the dope film can be protected and supported by a coating of heat-resisting cement. This method works as well as can be expected; but we should be grateful for any helpful suggestions in the matter, as even with care the window is apt to break loose in the middle of an experiment, if the temperature be high.

With regard to the electrical arrangements, a 12-inch induction coil has been used instead of the 18-inch one described in the previous paper. Apparently this alteration in the apparatus makes no detectable difference in the spectra obtained. The Tesla transformer employed was the large one, of which the dimensions have already been given.

In order to detect any possible sources of discrepancy, a series of

photographs of toluene was taken. The temperature and pressure in the cell and also the exposure were kept uniform throughout the series, but the primary of the transformer was altered with each exposure. On inspection, it was found that the character of the spectrum remained unaltered over the whole range of the exposures, although the intensity of it varied slightly. Again, an examination of the spectrum of aniline showed that it remained essentially the same whether it was excited by the large Tesla transformer with primary and secondary in series or by the smaller laboratory-made transformer described in our first paper, which has the primary and secondary circuits independent of each other. From this it seems clear that the nature of the transformer is a very minor factor—if, indeed, it be a factor at all—in the problem of these Tesla-luminescence spectra; and that the spectra are characteristic of the substances producing them, independent of the precise nature of the Tesla discharge which is employed.

Since some of the benzene mono-substitution products emit visible rays, it has been found necessary to use panchromatic plates in order to photograph the spectra. These plates have been developed with the aid of "desensitol" in order to avoid the trouble of working entirely in the dark.

2. *The Bands of the "Blue Series."*

In certain of the spectra investigated, a new series of bands has been observed; and it will be convenient at this point to describe the main features of this fresh part of the spectrum, so as to avoid repetition in later sections of the paper.

This "blue series" (as it may be termed for convenience in reference) appears (except in the case of acetophenone) to be essentially the same whenever it is observed. Its principal bands occur at the same wave-lengths in the spectra of very different compounds; and the only alteration found in it is that the series of bands is sometimes incomplete owing to the fainter bands not making their appearance in certain cases. The blue series as a whole is very much fainter than the benzene bands, requiring about four times the exposure to bring it out sharply.

With the Hilger spectrograph employed, the reading of the wave-lengths of the blue series cannot be very accurate, on account of the small dispersion of the instrument in this region of the spectrum; for the 1000 Å.U. covered by the series is represented by only 2 cm. on the photographic plate. The following figures are therefore not absolutely exact, although they are accurate enough for the present purpose.

TABLE I.

Wave-lengths of the Blue Series Bands.

Group IV.	Group III.	Group II.	Group I.	
	4595	4237—4252	3940	Strong bands.
4990	4600—4615	4257—4278	3970—3980	Very strong bands.
	4645—4670	4307—4332	4010—4025	Strong bands.
	4705—4725	4342—4397	4045—4090	Broad, faint bands.
		4417—4437	4105—4130	Faint bands.
	4835	4465	4142	Sharp, narrow bands.
	4875	4505	4173	
		4540	4197	Very faint bands.
		4565	4203	" "

When, instead of wave-lengths, the wave-numbers of the bands are compared, a striking regularity in the series becomes apparent.

TABLE II.

Wave-numbers of the Blue Series Bands.

Group I.		Group II.		Group III.		Group IV.
2538	<i>178</i>	2360	<i>183</i>	2177		
2519	<i>170</i>	2349	<i>175</i>	2174	<i>170</i>	2004
2494	<i>170</i>	2324	<i>171</i>	2153		
2472	<i>171</i>	2301	<i>175</i>	2126		
2436	<i>172</i>	2264				
2414	<i>175</i>	2239	<i>176</i>	2063		
2396	<i>176</i>	2220	<i>169</i>	2051		
2383	<i>180</i>	2203				
2379	<i>188</i>	2191				

The italicised figures show the differences between corresponding bands in adjacent groups. In view of the difficulty of making exact measurements of the bands, it does not seem worth while at present to attempt to find any formula corresponding to the band-series; but the above table is sufficient to show that there is an obvious regularity among the bands.

From the data given above it is evident that the blue series is built up from four groups of bands, the separate bands of each group having their congeners in the other groups. The wave-numbers of the bands show that corresponding members are situated at about 175 units from each other. This recalls the state of affairs in the benzene spectrum, where the same regularity was observed, although in that case the constant difference was 99 units.

It is intended, as soon as possible, to examine the bands of the blue series by means of a new spectrograph giving much larger dispersion in the visible; and it may then be possible to find some formula which will fit the complete blue series.

3. *cycloHexane*.

In beginning this investigation of the influence exerted by substitution upon the benzene spectrum, it seemed desirable in the first place to establish the fact that the benzenoid nucleus was necessary for the production of the regular emission spectrum which is yielded by benzene vapour. The complete reduction of the benzene ring alters the chemical character of the substance completely; and therefore it was of interest to examine the behaviour of *cyclohexane* under the Tesla discharge. When examined under a pressure of 1 mm. and at a temperature of 16°, *cyclohexane*—as was anticipated—showed no visible luminescence and produced no effect on the photographic plate. This conclusively establishes the fact that the six-membered ring-system in itself is incapable of yielding Tesla-luminescence; and therefore the origin of such luminescence in benzene and its substitution products is to be found in the peculiarities of the unsaturated nucleus or the side-chain.

4. *Toluene*.

Throughout a large part of the benzene spectrum, the bands are sharply delimited and stand out clearly on a dark background. Toluene, on the other hand, exhibits at 2—3 mm. pressure and 16°, a continuous luminous background running from wave-length 2682 to about 3440 and fading off at the long wave-length end of the spectrum. Upon this luminous background, the heads of twenty-three bands were observed, some of them very faint.

TABLE III.

Wave-lengths of Bands in the Toluene Spectrum in the Ultra-violet.

2682	2687	2693	2705	2713	2718	2726**
2731	2742*	2747	2756	2760	2773	2785
2791	2803**	2819*	2835	2852	2869	2886
2903	2920					

Examination of the plates seemed to show that the bands marked * were similar in character, as also were those marked **. Taking this as a basis and using wave-numbers instead of wave-lengths, it has been possible to arrange the bands into four groups with a frequency difference of about 100 units between corresponding bands. Absolute uniformity cannot be expected, owing to the difficulty of reading the positions of some of the fainter bands on the plates.

TABLE IV.

Wave-numbers of Bands in the Toluene Spectrum in the Ultra-violet.

		3668	101	3567	102	3465
		3662				
		3647	99	3548	103	3445
		3641				
3728	100	3628	100	3528	103	3425
3721	98	3623				
3713	107	3606	99	3507		
3697						
3686	96	3590				
3679	96	3583	97	3486		

The italicised numbers give the differences between the corresponding bands in the different groups; and although the series is by no means complete, there seems to be sufficient evidence to make it probable that a regular series is present.

In addition to the above bands in the ultra-violet—which appear to represent a modification of the benzene spectrum—toluene showed also the three principal bands of the blue series and traces of some of the minor members. The blue series bands come out much better at higher pressures than at lower ones. They appear clearly on plates taken at 1 cm. pressure, whilst on some plates taken at pressures about 1.5 mm. they are entirely absent.

5. Ethylbenzene.

At 16° and under a pressure of 2–3 mm., ethylbenzene showed a continuous background between wave-lengths 2663 and 3370, fading off at the latter end into darkness. Indistinct heads of bands were visible at approximately the following wave-lengths.

TABLE V.

2691	2711	2725**	2740*	2787	2802**	2817*
------	------	--------	-------	------	--------	-------

There is a darkening in the spectrum from wave-length 2876 to 2887. The bands marked * and ** appear to be corresponding pairs; and by using this as a basis and taking wave-numbers as before, it is possible to arrange the bands into four groups.

TABLE VI.

Wave-numbers of Ethylbenzene Bands in the Ultra-violet.

3755	105	3669	100	3569	(3477–3463)
3716		3650	100	3550	
3689	101	3588			

There is a close resemblance—amounting almost to identity—between these groups and certain of the bands in the toluene spectrum which were given in Table IV; and the constant frequency

PLATE I.

The scale is an approximate one of wave-lengths. The plate is intended to show the nature of the spectra and not the relative intensities.

difference is approximately 100 in both cases. Bearing in mind the difficulty of exact reading in the case of these spectra, it seems not unwarranted to suppose that there is a traceable relationship between the two spectra; and that both are modifications of the fundamental benzene spectrum.

In addition to these bands in the ultra-violet region, ethylbenzene shows the three principal bands of the blue series and also traces of some of the others.

6. *Benzyl Alcohol.*

In the spectrum of benzyl alcohol at 2—3 mm. pressure and 100°, there is a very faint continuous background lying between the wave-lengths 2800 and 3200. No definite bands are detectable in the ultra-violet region at all.

The three main bands of the blue series make their appearance; and some of the fainter bands in the series are also visible on the plate.

7. *Benzaldehyde.*

At 50° and under 2—3 mm. pressure, benzaldehyde showed no spectrum at all in the benzene region.

On the other hand, the blue series was fully developed, all the bands recorded in Table I being clearly visible. Up to the present, benzaldehyde exhibits the most brilliant blue series of all the compounds we have examined.

8. *Ethyl Benzoate.*

At 100° and under 2—3 mm. pressure, ethyl benzoate shows no spectrum in the benzene region. The main bands of the blue series were present.

All the foregoing spectra are shown in the photographs reproduced in Plate I and examination will reveal the broader differences between the various groupings better than verbal description can do. The relative intensities of the benzene region and the blue series region can be seen quite readily; and the varying brightness of the blue series is also clearly visible.

9. *Benzonitrile.*

Between 80° and 100° and under a pressure of 2—3 mm., benzonitrile showed a continuous luminous background running between the wave-lengths 2740 and 3490 and fading off into darkness at the end of greater wave-length. Indistinct bands were observable at the following wave-lengths: 2740*; 2774; 2818*; 2833; 2853; 2902*; 2917. The three bands marked * appear to be

congeners; and by using them as a basis and taking wave-numbers instead of wave-lengths, it has been found possible to group the bands as shown below.

TABLE VII.

Wave-numbers of Benzonitrile Bands in the Ultra-violet.

3650	101	3549	103	3446
		3530	102	3428
3605	101	3505		

Here, apparently, as in previous cases, the constant difference is approximately 100 units.

Benzonitrile shows no trace of the blue series spectrum.

10. Phenol.

At 120° and 1–2 mm., phenol showed a spectrum consisting of a very faint continuous background lying between the wave-lengths 2813 and 3720 and fading off like the other spectra at the end of greater wave-length. Two indistinct heads of bands were visible at wave-lengths 3178 and 3323; and in addition there were six very indistinct bands at the wave-lengths 2831; 2850; 2873; 2900; 2918; and 2938.

When the wave-numbers are taken, the last six bands can be arranged either into two groups with a constant difference of about 80 units or into two groups with a constant difference of approximately 105 units:

TABLE VIII.

Wave-numbers of Phenol Bands in the Ultra-violet.

3532	84	3448				3448
3510	83	3427	or	3532	105	3427
3480	77	3403		3510	107	3403
				3480		

It is at present impossible to decide which of these is the more probable arrangement, owing to the fact that the spectrum as a whole is very faint (see Plate I) and thus even if further bands be present they cannot be delimited.

The blue series of bands do not make their appearance in the phenol spectrum at all.

11. Thiophenol.

Thiophenol was examined at a temperature of 120° and 1–2 mm. pressure. No spectrum of the continuous type appeared on the plate; but four faint lines or thin bands appeared at the wave-lengths 3133, 3658, 4052, and 4354. These lines do not correspond to the members of the blue series, nor can they be identified as prominent air-lines.

12. *Acetophenone.*

This was examined at 120° under 2 mm. pressure. The spectrum extends from wave-length 3822 to wave-length 4975. In place of the usual sharp bands of the blue series, acetophenone displays three broad bands which are indistinct at both edges. The faintest of the three occupies the region 3880—3967; the most marked one lies at 4140—4255; whilst the third, intermediate in intensity, is found between 4467 and 4573. These readings are very approximate ones, as no sharp heads or lines are visible in the spectrum.

13. *Aniline.*

Aniline, examined at 100° under 3 mm. pressure, shows a continuous bright spectrum laying between wave-length 2970 and wave-length 4050, and fading off at both ends. On this continuous background there are faint indications of three bands lying at wave-lengths 3036, 3055, and 3072.

14. *Nitrobenzene, Chlorobenzene, and Benzyl Chloride.*

All three substances were examined under a pressure of 1—2 mm. Nitrobenzene and benzyl chloride were investigated at 100°; whilst or chlorobenzene the temperature was 16°. None of the substances gave any photographable spectrum even with exposures up to an hour in length.

15. *The Origin of the Blue Series Bands.*

In considering the possible origin of the blue series bands, it will be best to proceed step by step and eliminate as far as possible some obvious suggestions which might be put forward to account for the phenomena.

(a) *The blue series bands are not due to the presence of traces of air in the apparatus.* This seems to be established by the following facts. First, the spectrum is not the same as the spectrum of air under the same conditions. A comparison of the blue series and air bands has been made and the two have been found to be quite distinct from each other.

(b) *The blue series is not produced by carbon monoxide or carbon dioxide.* The Tesla spectra of carbon monoxide and carbon dioxide have been examined; and it was found that they do not coincide with the blue series. Since the blue series to some extent resembles the Swan spectrum, the Swan spectrum wave-numbers were examined (Eder and Valenta, *Sitzungsber. Akad. Wiss. Wien*, 1910, 119, IIa, 544). As can be seen from the table below, the Swan spectrum can be grouped into an arrangement giving a constant

difference of about 167 units, whereas in the blue series the difference is 175 units.

TABLE IX.

Wave-lengths of the Swan Spectrum.

		2135				
2291	162	2129				1805
2287	166	2121	171	1950	160	1790
2282	171	2111	175	1936	162	1774

(c) *The blue series does not arise from decomposition-oxidation.* Since the blue series is exhibited by toluene and ethylbenzene, neither of which contains any oxygen in the molecule; and since, further, it is not shown by either phenol or aniline, which are easily attacked by external oxygen, it seems a reasonable inference that the blue series is not the result of oxidation. This evidence, in itself, would tend to show that the blue series and the Swan spectrum are not the same.

(d) *The blue series is connected with the benzene system.* This appears quite clearly in the fact that with change from one substituent to another, the blue series may increase in brilliancy whilst simultaneously the benzene region of the spectrum undergoes profound alteration. An examination of Plate I* will show this gradual alteration in the character of both regions simultaneously, the clean-cut bands of benzene being entirely deleted in the spectrum of benzaldehyde, where the blue series alone is shown. If the blue series were produced by any progressive oxidation, etc., it would be reasonable to expect the appearance of the original spectrum of the unaltered benzenoid type to be superposed on the blue series spectrum in every case. The actual results, however, seem to point to a close interrelation between the benzenoid system and the mechanism producing the blue series such that when one is at its best the other is reduced to impotence. From this it seems an obvious inference that the blue series is not due merely to the side-chain, but takes its rise in the molecular structure as a whole.

(e) *The blue series is not the benzene series projected into the visible region by the auxochromic action of the substituent.* If the blue series were merely the vibration of the benzene nucleus slowed down by the substituent's action, then it might be expected that the constant difference between the benzene bands would be retained in the blue series; and that the blue series, like the benzene series, would consist of seven band-groups. Neither of these assumptions

* Plate I is intended to illustrate the difference in character between the spectra and not to show differences in intensity. For example, the benzaldehyde spectrum is shown much brighter than it actually is in comparison with the benzene spectrum.

coincides with the experimental results. The constant difference in the benzenoid series is 99, whereas that in the blue series is approximately 175. There seem to be only four main groups of bands in the blue series as against seven groups in the benzene series; and the alternation of strong and weak bands is not the same in the two sets.

(f) *The benzenoid structure alone is insufficient to produce the blue series.* This is evident from the fact that benzene itself has no blue series bands in its spectrum. Further, the blue series is not exhibited by all mono-substitution products of benzene.

From the foregoing, it seems clear that the blue series is not attributable to accidental impurity of the vapours in the cell; but is actually characteristic of the compounds themselves. It cannot be attributed to the side-chain alone or to the benzene nucleus *per se*. The only remaining possibility is that the blue series originates in the molecular structure as a whole and that it is produced only by certain types of molecule.

16. *The Effect of Substituents on the Benzene Spectrum.*

The introduction of substituents into the benzene ring has in every case the effect of influencing the Tesla spectrum; and examination shows that substituent groups can be roughly divided into three classes according to their action. The first class contains those side-chains which have a saturated carbon atom directly attached to the ring.* Members of the second class have directly attached to the benzene ring a non-carbon atom like oxygen. In the third class lie substituents like the nitro-group, which seem to exert a special influence upon the machinery which produces luminescence in the benzenoid region.

So far as the first class is concerned, the progressive changes in the spectrum produced by substitution can readily be seen by comparing the numbers of bands detected in the spectra of a series of compounds. Benzene itself exhibits fifty-two bands; the spectrum of toluene contains only twenty-three; in ethylbenzene and benzonitrile, the number is reduced to seven; whilst in benzyl alcohol the only trace of benzenoid character is to be found in a faint continuous background upon which no bands can be distinguished. It is perhaps worth noting that this order of diminishing complexity in the spectrum corresponds roughly to the increasing weight of the side-chain, the various groups being Me = 15; CN = 26; Et = 29; CH₂OH = 31. It may also be pointed out that in all these cases the introduction of the substituent group produces

* The group -CH₂Cl is an exception to this rule.

a blurring of the benzenoid spectrum, with the production of a more or less bright continuous background.

That the benzenoid spectrum retains some of its characteristics in these particular substitution products may be seen by examining the quantitative relations between the band-positions in the various spectra. It has been shown above that certain of the observed bands can be arranged into groups; and if this grouping be accepted, a series of constant differences can be detected between the wave-numbers of analogous bands. The following table shows the wave-numbers of the well-defined band-heads in the groups E, D, and C of the benzene spectrum and also the values of what appear to be corresponding bands in the spectra of the substitution products.

TABLE X.
Wave-numbers of corresponding Bands of Benzene and some substitution-products.

	Group E.	Group D.	Group C.
Benzene	3652	3554	3454
Toluene	3668	3567	3465
Ethylbenzene	3669	3569	—
Benzonitrile	3650	3549	3446

From these figures it is clear that in each of the four cases there is a constant difference of approximately 100 units between corresponding bands in consecutive groups; and that, for example, the toluene bands can be brought into coincidence with the benzene set by shifting the whole toluene spectrum about thirteen units towards the visible region. This suggests that the spectrum of the substitution-product is derived from that of benzene itself partly by blurring or obliteration of the benzene bands and partly by a slight shift of the whole spectrum by a few units either to right or left.

Turning now to the second type of substituent, in which a non-carbon atom is directly attached to the benzene nucleus, it is found that this produces a fundamental change in the vibrational character of the system. Aniline shows a bright continuous background extending far further towards the visible region than the benzene spectrum stretches and having superimposed upon this only three extremely faint bands which cannot definitely be identified as benzenoid in character. These bands are not shown on Plate I, as they are too faint for reproduction; but the plate shows at a glance that the aniline spectrum lies in a region different from that of benzene. Plate I also shows that the phenol spectrum occupies a position where no benzene bands are to be seen; and, as has been shown above, the seven very faint bands of the phenol spectrum cannot definitely be identified with the benzenoid system. Finally, in the case of thiophenol, the continuous spectrum fades out com-

pletely; and the only marks on the plate are four faint lines or bands which do not correspond to benzene vibrations. Now in all these cases, the atom directly attached to the benzene nucleus is exerting a lower valency than the element is capable of exhibiting. In aniline, the nitrogen is trivalent, whereas nitrogen can show quinquivalence; in phenol there is bivalent oxygen, but oxygen is capable of quadrivalence; whilst in thiophenol the sulphur atom is exerting four valencies less than its possible maximum. It seems a fair inference that this latent affinity is the cause of the disturbance of the benzenoid vibration which is noticeable in these three cases.

With the third class of substituent—the nitro-group, the chlorine atom, and the radicle CH_2Cl a stage is reached in which all vibration in the molecule seems to be inhibited. Nitrobenzene, chlorobenzene, and benzyl chloride exhibit no photographable spectrum of any kind. The carbethoxy-group, the aldehyde radicle, and the acetyl group also seem to stop the benzenoid vibration, but their influence is not so marked as that of the nitro-group, since ethyl benzoate, benzaldehyde, and acetophenone all show the blue series bands which are absent from the spectrum of nitrobenzene and its congeners.

17. *The Substitution Problem in the Spectra as a Whole.*

Hitherto the benzenoid and “blue” regions of the spectrum have been considered separately in order to simplify the matter; but it seems desirable now to indicate certain general relations which emerge when the whole range of the photographed spectrum is taken into account. The clearest method is to take up in turn some of the more influential substituents and examine their effects.

In the first place, the nitro-group and a chlorine atom completely obliterate the whole emission spectrum; so that nitrobenzene yields no more than *cyclohexane* does. Now in the case of nitrobenzene there is definite chemical evidence tending to show that the introduction of the nitro-group produces a profound alteration of character in the benzene ring; the exceptional reactivity of the halogen atom in *o*-chloronitrobenzene is the commonest example. The presence of the nitro-group appears to deprive the ring of its normal aromatic character to a greater or less extent; and thus it is not surprising to find that nitrobenzene emits no spectrum whatever.

The introduction of a hydroxyl group or an amino-radicle has less influence on the spectrum, for in these cases there is emission, although not in the precise region of the true benzene spectrum. Here again there is chemical evidence that the substituent alters the chemical character of the benzene nucleus, since both aniline

and phenol are much more readily attacked by halogens than benzene itself.

None of the foregoing substituents appears to have the power of exciting emission in the blue region. We now come to the cases of ethyl benzoate, benzaldehyde, and acetophenone, where the side-chain appears to inhibit the benzene vibration whilst at the same time producing emission in the blue region. In each of these cases there is a double bond in the side-chain, and the atom carrying the double bond is directly attached to the benzene ring. This group of compounds appears to form a connecting link between the non-carbon substituents and the hydrocarbons. The unsaturation in the side-chain allies them to the nitrobenzene type sufficiently to permit the extinction of the benzenoid vibration; whilst at the same time the grouping $\text{Ph}\cdot\text{C}$ brings them into line with toluene, which also gives the blue series. Benzonitrile is not a member of this intermediate class, since instead of a double bond it has a triple linkage on the carbon atom attached to the ring.

A point of considerable interest in this group is the effect of replacing a hydrogen atom by a methyl radicle in the cases of benzaldehyde and acetophenone. As has been pointed out, this substitution produces a marked blurring of the sharp benzaldehyde bands in the blue region. Now in the final group of substituents, an analogous effect can be traced, though in their case the blurring takes place in the benzenoid spectrum. The exchange of a hydrogen atom for a methyl group in the case of benzene results, as has been mentioned above, in a decrease in the sharp bands from 52 to 23 and a simultaneous development of a bright continuous background which can only be due to a blurring of the normal benzene spectrum. Further, the attachment of methyl, ethyl, or the group $-\text{CH}_2\cdot\text{OH}$ to the benzene ring leads to a development of the blue series with a simultaneous blurring and fading of the normal benzene spectrum, which seems to show that a declension in the one form of vibration goes hand in hand with a stimulation of the other.

Now if attention be confined to those cases where there is no great store of residual affinity in the side-chain, it appears as though the weight of the substituent has a perceptible influence upon the results. An inspection of Plate I will show that the declension of the benzenoid spectrum occurs increasingly as we go up the series: toluene, ethylbenzene, benzyl alcohol; whilst benzyl chloride shows no trace of benzenoid vibration. This is exactly the order of weight of the substituents: $\text{Me} = 15$; $\text{Et} = 29$; $\text{CH}_2\cdot\text{OH} = 31$; and $\text{CH}_2\text{Cl} = 49$. Thus one factor in the problem appears to be the weight of the substituent group. The other factor, as has already been shown, is the residual affinity of the

atom next the benzene ring; and this second factor frequently outweighs the first when the production of the blue region spectrum is concerned. For example, the weights of the ethyl and aldehyde groups are identical; but whilst ethylbenzene shows a marked residuum of the benzene spectrum and only a faint blue series, benzaldehyde exhibits no trace of the benzenoid type and has the most brilliant "blue" spectrum of all the compounds yet examined.

This constitutional factor is further shown in the cases of benzaldehyde and ethyl benzoate. Both side-chains contain the carbonyl linking; but in ethyl benzoate the carbonyl radicle shows no true carbonyl character in its chemical properties. Despite the fact that the carbethoxy-group has a weight of 73 against 29 for the aldehyde group, the ester shows a comparatively feeble blue series. This shows conclusively that the chemical factor predominates over the mere weight of the group when the two are pitted against each other.

In conclusion, attention may be directed to another matter. Kauffmann (*Ber.*, 1901, **34**, 682; "Die Valenzlehre" p. 498; "Beziehungen zw. physikal. Eigenschaften u. chem. Konstitution," p. 405) endeavoured to trace a parallelism between visible Tesla-luminescence of compounds and their magneto-optical anomaly, that is, the difference between the observed and the calculated values for their magnetic rotations as compared with the same property for benzene, which is taken as a basis. According to Kauffmann, compounds showing negative anomalies exhibited no Tesla-luminescence; whereas with a positive anomaly the intensity of the luminescence went hand in hand with the value of the anomaly. Kauffmann was working merely by eye; and all his experiments were made under atmospheric pressure, so that his results are scarcely comparable with our exact spectral measurements. But under the conditions employed by us, there is certainly no traceable parallelism between the magneto-optical anomaly and the type of spectrum which we have observed. The following table shows the matter clearly.

TABLE XI.

<i>Magneto-optical Anomalies and Spectral Character.</i>		
Compound.	Anomaly.	Spectrum.
Nitrobenzene	- 2.15	Completely dark.
Phenol	- 0.66	Long, faint continuous. No blue.
Ethyl benzoate ...	- 0.38	No benzene spectrum. Marked blue.
Chlorobenzene ...	- 0.253	Completely dark.
Benzonitrile	- 0.201	7 benzene bands. No blue.
Benzaldehyde ...	- 0.196	No benzene spectrum. Strong blue.
Toluene	- 0.15	23 benzene bands. Feeble blue.
Benzene	+ 0.00	52 benzene bands. No blue.
Ethylbenzene ...	+ 0.084	7 benzene bands. Blue bands.
Benzyl chloride ...	+ 0.228	Completely dark.
Aniline	+ 3.82	Bright continuous spectrum. No benzene bands. No blue.

It is obvious that there is no real parallelism in the two properties so far as these substances are concerned. Nor can any parallel be traced between the Tesla spectra and dielectric constant, magnetic double refraction, or optical anomaly.

18. Summary.

1. It was found that modification of the Tesla apparatus exercised practically no influence upon the spectra of compounds examined; from which it may be inferred that the spectra are characteristic of the compounds which produce them.

2. Fourteen benzene derivatives have been investigated. *cyclo*. Hexane emits no spectrum. The monosubstitution products of benzene exhibit differences from each other according to the nature of the substituent.

3. Total extinction of the spectrum is found in the cases of the nitro-group, a chlorine atom, or the group $-\text{CH}_2\text{Cl}$. When the substituent is linked to the benzene nucleus through a non-carbon atom, the usual spectrum in the benzene region is obliterated completely or else is replaced by a faint continuous spectrum.

4. With the exception of benzonitrile and benzyl chloride, every compound containing the grouping $\text{Ph}\cdot\text{C}\cdot$ exhibits a series of bands in the blue region of the spectrum; and the brilliancy of these bands varies with the nature of the substituent group. It is observed that increase in the intensity of this blue series goes hand in hand with the diminution in brilliancy of the benzenoid part of the compound's spectrum; so that there is an evident relationship between the two.

5. The entry of an alkyl group into benzene produces a more or less marked blurring of the sharp benzene system of bands; and a similar blurring of the blue series of bands is observed when an alkyl group replaces a hydrogen atom in benzaldehyde.

6. The bands of the blue series are independent of the benzenoid series and cannot be considered as benzene bands which have been pushed up into the visible region by the auxochromic action of the substituent groups, since the two spectra are different in character and both of them may coexist in the spectra of certain compounds.

7. It has been definitely established that the Tesla-luminescence spectra are highly constitutional in character, each compound yielding its own specific emission spectrum. Thus by the discovery of these spectra a new constitutional property of compounds has been brought to light and takes its place along with optical rotatory power, anomalous electric absorption, magnetic rotation, etc.

We wish to express our thanks for a grant towards the expenses of the research which has been made to us out of the Research Fund.

CCXL.—*The Isomerism of the Oximes. Part XIII.*
Phenylethyl-, Diethyl-, and α -Naphthyl-Carbamyl
Derivatives.

By OSCAR LISLE BRADY and DUDLEY RIDGE.

THE formation of acyl derivatives of the aromatic aldoximes is a more complex reaction than appears at first sight, as isomeric change not infrequently takes place at the same time; that is, from an *anti*-oxime, there is formed a derivative which on hydrolysis gives a nitrile and therefore may be presumed to have the *syn*-configuration (compare Brady and McHugh, this vol., p. 1190). This change of configuration is capricious, and no underlying principle is at present apparent.

When phenylcarbimide is added to an ethereal solution of an *anti*-oxime, in some cases a phenylcarbamyl (carbanilino)*antialdoxime* is obtained; for example, from the three nitrocinnamantialdoximes (Brady and Thomas, T., 1922, 121, 2098); in others, from benzantialdoxime and *m*-nitrobenzantialdoxime, for example, a mixture of the *anti*- and *syn*-isomerides is formed (Brady and Dunn, T., 1916, 109, 650); and in yet others a phenylcarbamyl-*syn*-aldoxime is produced, for example, from *p*-dimethylamino- and 3:4-dimethoxybenzantialdoxime (Brady and Dunn, T., 1914, 105, 2874; 1916, 109, 674). In the case of the carbethoxy-compounds, obtained by the action of ethyl chloroformate on the sodium salts of the *anti*-aldoximes, benzantialdoxime, *m*-nitro-, and *p*-dimethylamino-benzantialdoximes, for example, give *anti*-derivatives, whilst *p*-nitro-, *p*-methoxy-, and 3:4-methylenedioxy-benzantialdoximes, for example, give *syn*-derivatives (Brady and McHugh, *loc. cit.*). Finally, when the sodium salts of *anti*-oximes are acted upon by diphenylcarbamyl chloride, *syn*-derivatives are invariably obtained (Brady and Dunn, T., 1913, 103, 1613). On the other hand, treatment of the *anti*-oximes with acetic anhydride at a low temperature invariably gives *anti*-derivatives.

The present investigation was undertaken to ascertain whether steric hindrance effects were coming into play on account of the size of the group introduced. Consequently, phenylethylcarbamyl,

diethylcarbamyI, and α -naphthylcarbamyI compounds have been prepared.

The phenylethylcarbamyI and diethylcarbamyI derivatives were prepared in a similar manner to the diphenylcarbamyI compounds (compare Brady and Dunn, *loc. cit.*), by heating the dry sodium salt of the *anti*-oxime in chloroform suspension with phenylethylcarbamyI chloride and diethylcarbamyI chloride, respectively :

The orientation of the compounds formed was determined by their hydrolysis :

Considerable difficulty was experienced, however, with a number of oximes, as the products of reaction could not be obtained crystalline, especially in the case of the diethylcarbamyI derivatives, and consequently the number of examples is rather limited. With phenylethylcarbamyI chloride, the sodium salts of benzantialdoxime and of *m*-nitro- and 3:4-methylenedioxy-benzantialdoximes gave the corresponding phenylethylcarbamyIantioximes, whilst with diethylcarbamyI chloride the sodium salt of *m*-nitrobenzantialdoxime gave diethylcarbamyI-*m*-nitrobenzantialdoxime. On the other hand, the sodium salt of *p*-nitrobenzantialdoxime gave phenylethylcarbamyI- and diethylcarbamyI-*p*-nitrobenzantialdoximes with these reagents. Attempts to prepare derivatives of the *syn*-oximes by acting on their sodium salts were unsuccessful, except in the case of *p*-nitrobenzantialdoxime, which, with phenylethylcarbamyI and diethylcarbamyI chlorides, gave the same compound as was obtained from the sodium salt of the *anti*-oxime. In other cases either an uncrystallisable oil was obtained, or the corresponding nitrile.

These first results seemed partly to support the view that the diphenylcarbamyIantialdoximes could not be obtained owing to the large diphenylcarbamyI group being unable to take up a position near to the phenyl group in the oxime. When, however, the action of α -naphthylcarbimide on the oximes was investigated, it was found that *anti*-derivatives were invariably produced, even from *p*-dimethylamino- and 3:4-dimethoxy-benzantialdoximes, which with phenylcarbimide give phenylcarbamyIantialdoximes, and from

p-nitrobenzantialdoxime, the sodium salt of which with ethyl chloroformate, phenylethylcarbamyI chloride, and diethylcarbamyI chloride gives the corresponding *syn*-derivatives. In addition to the above oximes, the action of α -naphthylcarbimide on benzantialdoxime, *m*-nitro-, *o*-methoxy-, *p*-methoxy-, and 3:4-methylenedioxy-benzantialdoximes has been studied. Careful search has been made to ascertain if any of the *syn*-isomeride was formed first and then transformed into the *anti*-compound, as in the case when phenylcarbimide acts on certain *anti*-oximes, but no indication of this was obtained.

α -Naphthylcarbimide reacts readily with ethereal solutions of benzsynaldoxime, 3:4-methylenedioxy-, *p*-methoxy-, *m*-nitro-, and *p*-nitro-benzsynaldoximes, giving the corresponding α -naphthylcarbamyIsynaldoximes.

The α -naphthylcarbamyI derivatives are rather more stable than the corresponding phenylcarbamyI compounds, those from the *anti*-oximes keeping fairly well in the dark, but the *syn*-derivatives decompose in a few days and the odour of α -naphthylamine becomes apparent. It was not found possible, as in the case of some phenylcarbamyI-synaldoximes, to convert the *syn*- into the *anti*-isomerides by boiling with solvents. Such treatment with alcohol results in hydrolysis, but boiling with benzene usually does not bring about isomeric change, although in most cases slight decomposition occurs, whilst in others the decomposition is more profound.

On hydrolysis, the two series of compounds behave in a similar manner to the phenylcarbamyI compounds. The *anti*-derivatives give the *anti*-oxime, α -naphthylamine, and $\alpha\beta$ -di- α -naphthylcarbamide; whilst the *syn*-derivatives give the nitrile in place of the oxime, although this is usually hydrolysed further to the corresponding acid:

As the result of these experiments, it seems that the size of the substituting group is not the main factor that determines the configuration of the compound obtained.

EXPERIMENTAL.

In the following preparations, it is important to exclude moisture on account of its action on the carbamyI chlorides and α -naphthyl-
4 D*

carbimide producing substituted carbamides, which, owing to their insoluble nature, are difficult to remove from the products; the ether and chloroform used must be dried.

Phenylethylcarbamybenzantialdoxime, $\text{C}_6\text{H}_5\cdot\overset{\text{CH}}{\underset{\text{CH}_3}{\text{C}}}$. — The
 $\text{PhEtN}\cdot\text{CO}\cdot\text{ON}$

sodium salt of benzantialdoxime was prepared by adding a solution of 0.895 gram of sodium in the minimum amount of alcohol to an ethereal solution of 5 grams of benzantialdoxime. The precipitated sodium salt, washed with dry ether and rapidly dried by pressing it on a porous tile, was suspended in dry chloroform and 7.2 grams of phenylethylcarbamy chloride were added. The mixture was boiled for four hours under reflux, cooled, the precipitated sodium chloride separated, and the solvent allowed to evaporate at room temperature. In this way, an oil was obtained which, on being cooled in a freezing mixture and scratched, slowly solidified. The product, after being pressed on a porous tile, crystallised from light petroleum in colourless, microscopic prisms melting at 74° (Found: N = 10.6. $\text{C}_{18}\text{H}_{18}\text{O}_2\text{N}_2$ requires N = 10.4 per cent.).

The *phenylethylcarbamybenzantialdoxime* so obtained was hydrolysed by heating it on the water-bath for an hour with 2N. sodium hydroxide. The resulting solution, in which a solid was suspended, was cooled and filtered. The solid was washed with dilute hydrochloric acid, crystallised from dilute alcohol, and identified as $\alpha\beta$ -diphenyl- $\alpha\beta$ -diethylcarbamide. The solution was extracted with ether and the ethereal extract evaporated, when an oil was obtained which was shown to be ethylaniline by conversion into its acetyl derivative. The aqueous solution was saturated with carbon dioxide, when benzantialdoxime separated as an oil of characteristic odour, and was identified, after extraction with ether, by conversion into the hydrochloride and into benzsynaldoxime. Since the compound gave benzantialdoxime on hydrolysis, the *anti*-configuration was assigned to it.

Phenylethylcarbamy-3:4-methylenedioxybenzantialdoxime,
 $\text{CH}_2\text{:O}_2\text{:C}_6\text{H}_3\cdot\overset{\text{CH}}{\underset{\text{CH}_3}{\text{C}}}$
 $\text{PhEtN}\cdot\text{CO}\cdot\text{O}\cdot\text{N}$

—The sodium salt, prepared as above, from 6.8 grams of 3:4-methylenedioxybenzantialdoxime was suspended in chloroform with 7.2 grams of phenylethylcarbamy chloride, and the mixture boiled under reflux for five hours. After the sodium chloride had been separated, the solution was evaporated at room temperature, and the oil obtained solidified by cooling in a freezing mixture and scratching. After being pressed on a porous tile, the compound was crystallised from acetone and water, when it

was obtained in colourless, microscopic prisms melting at 109° (Found: N = 9.1. $C_{17}H_{16}O_4N_2$ requires N = 9.0 per cent.).

On hydrolysis as above, the compound gave ethylaniline, $\alpha\beta$ -diphenyl- $\alpha\beta$ -diethylcarbamide, and 3:4-methylenedioxybenzanti-aldoxime.

Phenylethylcarbamyl-m-nitrobenzantialdoxime,
$$\begin{array}{c} \text{NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{CH} \\ | \\ \text{PhEtN}\cdot\text{CO}\cdot\text{O}\cdot\text{N} \end{array} \text{---}$$

The sodium salt, prepared as before, from 6.9 grams of *m*-nitrobenzantialdoxime was boiled in chloroform under reflux with 7.2 grams of phenylethylcarbamyl chloride for twenty-four hours. The solution, after filtering and removal of the solvent, gave a solid which crystallised from acetone and water in yellow needles melting at 65° (Found: N = 13.5. $C_{16}H_{15}O_4N_3$ requires N = 13.4 per cent.).

On hydrolysis, as before, ethylaniline, $\alpha\beta$ -diphenyl- $\alpha\beta$ -diethylcarbamide and *m*-nitrobenzantialdoxime were obtained.

Phenylethylcarbamyl-p-nitrobenzsynaldoxime,

—The sodium salt from 5 grams of *p*-nitrobenzantialdoxime in dry chloroform was boiled under reflux for twenty hours with 5.2 grams of phenylethylcarbamyl chloride. The pasty solid obtained from the solution in the usual way, after being pressed on a porous tile, crystallised from alcohol in long, yellow needles melting at 130° (Found: N = 13.7. $C_{16}H_{15}O_4N_3$ requires N = 13.4 per cent.).

When this compound was hydrolysed in the usual way, ammonia was evolved, and in the separation of the products no oxime was precipitated by carbon dioxide, but with hydrochloric acid *p*-nitrobenzoic acid was obtained, which, after crystallisation from hot water, was identified by the method of mixed melting points. The formation in the hydrolysis of, not the oxime, but the acid, a hydrolytic product of the nitrile, indicated that the compound possessed the *syn*-configuration.

The same compound was obtained when the sodium salt of *p*-nitrobenzsynaldoxime, suspended in ether, was left in contact with phenylethylcarbamyl chloride for four months in the dark. An attempt to prepare phenylethylcarbamyl-*p*-nitrobenzanti-aldoxime from the silver salt of the *anti*-oxime was unsuccessful, the only solid material which was obtained being $\alpha\beta$ -diphenyl- $\alpha\beta$ -diethylcarbamide.

Diethylcarbamyl-m-nitrobenzantialdoxime,
$$\begin{array}{c} \text{NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{CH} \\ | \\ \text{Et}_2\text{N}\cdot\text{CO}\cdot\text{O}\cdot\text{N} \end{array} \text{---}$$
The

sodium salt from 7 grams of *m*-nitrobenzantialdoxime was suspended in chloroform, 5 grams of diethylcarbamyl chloride were

added, and the mixture was boiled under reflux for twelve hours. After the sodium chloride had been removed and the solvent evaporated at room temperature, a solid and an oil remained; the former on separation was found to be *m*-nitrobenzantialdoxime. The oil was dissolved in ether, the solution dried with anhydrous sodium sulphate, and the ether removed, when a pasty solid was obtained. This was pressed on a porous tile, and after crystallisation from xylene formed colourless crystals melting at 80° (Found: N = 15.9. $C_{12}H_{15}O_4N_3$ requires N = 15.8 per cent.).

The compound was hydrolysed by heating it on the water-bath with 2*N*-sodium hydroxide, when it dissolved completely. On saturating the solution with carbon dioxide, *m*-nitrobenzantialdoxime was precipitated. In this case no attempt was made to detect diethylamine or tetraethylcarbamide.

Diethylcarbamyl-p-nitrobenzsynaldoxime,
$$\text{NO}_2 \cdot \text{C}_6\text{H}_4 \cdot \underset{\text{N} \cdot \text{O} \cdot \text{CO} \cdot \text{NEt}_2}{\text{CH}}$$

—The sodium salt from 5 grams of *p*-nitrobenzantialdoxime suspended in chloroform, was boiled under reflux with 4 grams of diethylcarbamyl chloride for ten hours. After filtration and removal of the solvent, the solid residue crystallised from acetone and water in microscopic, flat plates melting at 146° (Found: N = 16.0. $C_{12}H_{15}O_4N_3$ requires N = 15.8 per cent.).

On hydrolysis by the same method used with the *m*-nitro-compound above, *p*-nitrobenzoic acid, but no oxime, was obtained, indicating the *syn*-configuration of the compound.

The same compound was obtained when the sodium salt of *p*-nitrobenzsynaldoxime was left with a solution of diethylcarbamyl chloride in ether for three days.

Action of Phenylethylcarbamyl and Diethylcarbamyl Chlorides on the Sodium Salts of other Oximes.—The sodium salt of *p*-methoxybenzantialdoxime in chloroform suspension, on treatment with phenylethylcarbamyl chloride and diethylcarbamyl chloride, and the sodium salts of benzantialdoxime and 3:4-methylenedioxybenzantialdoxime, on treatment with diethylcarbamyl chloride, gave uncrystallisable oils, which were not further investigated. 6-Nitro-3:4-methylenedioxy- and 3-nitro-*p*-dimethylaminobenzantialdoximes usually give derivatives of high melting point, but in this case, when their sodium salts were treated with the chlorides, no derivative was obtained, the oxime being ultimately recovered unchanged.

Diphenylcarbamyl-p-methoxybenzsynaldoxime,

—The sodium salt prepared from 6.2 grams of *p*-methoxybenz-

antialdoxime, and 10.4 grams of diphenylcarbonyl chloride were boiled in chloroform for eight hours under reflux. After filtering, the solution was evaporated and the greenish-yellow product crystallised from acetone and water, when the diphenylcarbonyl compound was obtained in colourless needles melting at 143–144° (Found: N = 8.1. $C_{21}H_{18}O_3N_2$ requires N = 8.1 per cent.).

The compound was hydrolysed by heating it for an hour on the water-bath with 2*N*-sodium hydroxide. The solution was cooled, and the solid residue found to be a mixture of diphenylamine and tetraphenylcarbamide. These were separated by washing the mixture with cold alcohol, in which the former was readily soluble and the latter practically insoluble. The solution on saturation with carbon dioxide gave no precipitate of oxime, but hydrochloric acid precipitated from it *p*-methoxybenzoic acid.

α-Naphthylcarbonylbenzantialdoxime, $\begin{matrix} C_6H_5 \cdot CH \\ | \\ C_{10}H_7 \cdot NH \cdot CO \cdot O \cdot N \end{matrix}$. —To a solution of 5 grams of benzantialdoxime in ether in a stoppered bottle, an ethereal solution of 7 grams of *α*-naphthylcarbimide was added. After an hour the crystalline precipitate was separated. Further crops of crystals were obtained after three hours and again after three days, but proved to be identical with the first crop. There was, therefore, no indication of the formation of the *syn*-isomeride (compare Brady and Dunn, T., 1916, 109, 654, for the action of phenylcarbimide on benzantialdoxime). *α*-Naphthylcarbonylbenzantialdoxime crystallises from acetone and water in microscopic, rectangular plates melting at 149° (Found: N = 9.5. $C_{18}H_{14}O_2N_2$ requires N = 9.6 per cent.).

The compound was hydrolysed by heating it for an hour on the water-bath with 2*N*-sodium hydroxide; at the end of that time the mixture was cooled and filtered. The solid residue was washed with dilute hydrochloric acid, crystallised from nitrobenzene, and found to be *αβ*-di-*α*-naphthylcarbamide,* whilst from the hydrochloric acid washings, by the addition of alkali, *α*-naphthylamine was isolated. The filtrate was extracted with ether to remove dissolved *α*-naphthylamine, and the alkaline liquid saturated with carbon dioxide, when benzantialdoxime was precipitated and identified in the usual way.

* As this compound, which is a product of hydrolysis of the *α*-naphthylcarbonyl derivatives of the oximes, has not been previously described, it has been prepared for the purpose of comparison. Twenty grams of *α*-naphthylcarbimide were boiled with water until no trace of oil remained. The solid formed was separated, and crystallised from boiling nitrobenzene; after being washed with alcohol and ether, *αβ*-di-*α*-naphthylcarbamide was obtained as a white, crystalline powder melting at 284° (Found: N = 9.3. $C_{17}H_{14}ON_2$ requires N = 9.0 per cent.).

α-Naphthylcarbamybenzsynaldoxime, $\text{C}_6\text{H}_5\cdot\text{CH}$
 $\text{N}\cdot\text{O}\cdot\text{CO}\cdot\text{NH}\cdot\text{C}_{10}\text{H}_7$

Three grams of benzsynaldoxime were dissolved in ether, and an ethereal solution of 4 grams of *α*-naphthylcarbimide was added. The *α*-naphthylcarbamy derivative was precipitated immediately, and after being well washed with dry ether was practically pure. Some difficulty is experienced in recrystallising the *syn*-derivatives, as they tend to decompose in hot solvents, and as the *αβ*-di-*α*-naphthylcarbamide formed is so very sparingly soluble, most of it separates out with the first crop of crystals. In this case, as had been previously observed where diphenylcarbamide was the impurity, the result of repeated recrystallisations is the isolation of the pure carbamide derivative. *α-Naphthylcarbamybenzsynaldoxime* may, however, be crystallised by dissolution in warm benzene (the temperature must not exceed 25°) and precipitation by the cautious addition of light petroleum, when it crystallises in colourless, microscopic needles melting and decomposing at 105° (Found: N = 9·4. $\text{C}_{13}\text{H}_{14}\text{O}_2\text{N}_2$ requires N = 9·6 per cent.).

The compound, after being kept for several days, acquired a pronounced odour of *α*-naphthylamine. The product was shaken with ether; the residual solid, after being washed with acetone to remove unchanged *α*-naphthylcarbamybenzsynaldoxime, proved to be *αβ*-di-*α*-naphthylcarbamide. The ethereal extract was washed with dilute hydrochloric acid, and from the acid solution *α*-naphthylamine isolated. The ethereal solution, having been dried and evaporated, gave an oil with the characteristic odour of benzonitrile, which on hydrolysis with concentrated sodium hydroxide solution gave ammonia and benzoic acid. The decomposition seems, therefore, to follow the same lines as that of the phenylcarbamy derivatives (compare Brady and Dunn, T., 1916, 109, 673). On boiling with benzene, the compound was decomposed into *α*-naphthylamine, *αβ*-di-*α*-naphthylcarbamide, and benzonitrile.

α-Naphthylcarbamybenzsynaldoxime was hydrolysed with 2*N*-sodium hydroxide in a similar manner to the *anti*-derivative, and the products were examined in the same way. *αβ*-Di-*α*-naphthylcarbamide and *α*-naphthylamine were isolated; carbon dioxide gave no precipitate of benzantialdoxime from the alkaline solution, but hydrochloric acid precipitated benzoic acid.

*α-Naphthylcarbamy*l-3 : 4-methylenedioxybenzantialdoxime,

—To a solution of 6·3 grams of 3 : 4-methylenedioxybenzantialdoxime in ether in a stoppered bottle, an ethereal solution of 7 grams of *α*-naphthylcarbimide was added. After two hours the

precipitate formed was separated. On more prolonged keeping, further crops of crystals were formed which were, however, identical with the first lot. There appears, therefore, to be no indication of the formation of the *syn*-derivative. The product crystallised from acetone and water in colourless, rectangular plates sintering at 172° and melting at 224° (Found: N = 8.6. $C_{18}H_{14}O_4N_2$ requires N = 8.4 per cent.).

On hydrolysis and separation of the products in the usual way, α -naphthylamine, $\alpha\beta$ -di- α -naphthylcarbamide, and 3:4-methylenedioxybenzantialdoxime were obtained.

α -Naphthylcarbamyl-3:4-methylenedioxybenzsynaldoxime,
 $CH_2:O_2:C_6H_5\cdot\overset{\text{CH}}{\underset{\text{N}\cdot\text{O}\cdot\text{CO}\cdot\text{NH}\cdot C_{10}H_7}{\text{C}}}$

—This compound was immediately precipitated on mixing an ethereal solution of 5 grams of 3:4-methylenedioxybenzsynaldoxime with one of 5.3 grams of α -naphthylcarbimide. It crystallises from acetone and water in colourless, rectangular plates melting at 118° (Found: N = 8.5. $C_{19}H_{14}O_4N_2$ requires N = 8.4 per cent.).

On hydrolysis, α -naphthylamine, $\alpha\beta$ -di- α -naphthylcarbamide, and 3:4-methylenedioxybenzoic acid were produced. On boiling with benzene, the compound was not converted into the *anti*-isomeride. A certain amount of decomposition occurred, with the production of $\alpha\beta$ -di- α -naphthylcarbamide, but most of the α -naphthylcarbamyl derivative was recovered unchanged. Boiling with alcohol resulted in decomposition to nitrile, etc. (compare Brady and Dunn, T., 1914, 105, 2878).

*α -Naphthylcarbamyl-*p*-methoxybenzantialdoxime,*

—This was obtained by keeping a mixture of ethereal solutions of 2.7 grams of *p*-methoxybenzantialdoxime and 3.5 grams of α -naphthylcarbimide in a stoppered bottle. Several crops of crystals were obtained, the first after one hour and the last after three days, but all were found to be identical. The compound crystallised from acetone and water in colourless, rectangular plates melting at 160° (Found: N = 9.0. $C_{19}H_{16}O_3N_2$ requires N = 8.8 per cent.).

On hydrolysis, α -naphthylamine, $\alpha\beta$ -di- α -naphthylcarbamide, and *p*-methoxybenzantialdoxime were obtained.

*α -Naphthylcarbamyl-*p*-methoxybenzsynaldoxime,*

—This was immediately precipitated when ethereal solutions of 3 grams of *p*-methoxybenzsynaldoxime and 3.7 grams of α -naphthylcarbimide were mixed. The precipitate was collected and thoroughly

washed with ether; attempts at recrystallisation resulted in decomposition, but the method of preparation probably gave a pure compound. As precipitated, it consisted of microscopic, colourless, rectangular plates, melting and decomposing at 110° (Found: $N = 8.9$. $C_{19}H_{16}O_3N_2$ requires $N = 8.8$ per cent.).

On hydrolysis, it gave α -naphthylamine, $\alpha\beta$ -di- α -naphthylcarbamide, and *p*-methoxybenzonitrile. The last was isolated from the ethereal extract after removing the α -naphthylamine with acid. On keeping for a few days, the compound decomposes in the usual way.

*α -Naphthylcarbamyl-*m*-nitrobenzantialdoxime,*

—This compound was obtained by keeping in a stoppered bottle a mixture of ethereal solutions of 3 grams of *m*-nitrobenzantialdoxime and 3.5 grams of α -naphthylcarbimide. The crystals which formed were collected at intervals, but all proved to be the same. The compound crystallised from acetone and water in pale yellow needles, sintering at 168° and charring at about 206° (Found: $N = 12.8$. $C_{18}H_{13}O_4N_3$ requires $N = 12.5$ per cent.).

On hydrolysis, it gave α -naphthylamine, $\alpha\beta$ -di- α -naphthylcarbamide, and *m*-nitrobenzantialdoxime.

*α -Naphthylcarbamyl-*m*-nitrobenzsynaldoxime,*

—Ethereal solutions of 1.5 grams of *m*-nitrobenzsynaldoxime and 1.7 grams of α -naphthylcarbimide were mixed, and after half an hour the crystalline precipitate was separated and well washed with dry ether. The compound, which could not be satisfactorily crystallised, consisted of yellow needles melting and decomposing at 109° (Found: $N = 12.6$. $C_{18}H_{13}O_4N_3$ requires $N = 12.5$ per cent.).

On hydrolysis, it gave α -naphthylamine, $\alpha\beta$ -di- α -naphthylcarbamide, and *m*-nitrobenzoic acid; whilst after it had been kept for fourteen days, $\alpha\beta$ -di- α -naphthylcarbamide and *m*-nitrobenzonitrile were isolated from the material. Boiling with benzene did not bring about isomerisation, but slight decomposition took place.

*α -Naphthylcarbamyl-*p*-nitrobenzantialdoxime,*

—Ethereal solutions of 1 gram of *p*-nitrobenzantialdoxime and of 1.2 grams of α -naphthylcarbimide were mixed in a stoppered bottle and kept for thirty minutes. The crystals which separated were collected and the mother-liquor, on standing, deposited further crops, which, however, were all identical with the one first obtained. The derivative crystallised from xylene in microscopic, yellow

filaments, sintering at 197° and melting at 222° (Found: N = 12·7. $C_{18}H_{13}O_4N_3$ requires N = 12·5 per cent.).

On hydrolysis, it gave α -naphthylamine, $\alpha\beta$ -di- α -naphthylcarbamide, and *p*-nitrobenzantialdoxime.

*α -Naphthylcarbamyl-*p*-nitrobenzsynaldoxime,*

—This compound was precipitated when ethereal solutions of 1·5 grams of *p*-nitrobenzsynaldoxime and 1·8 grams of α -naphthylcarbamide were mixed. It could not be recrystallised, but after being washed with ether, consisted of pale yellow needles, sintering at 178° and charring at 210° (Found: N = 12·8. $C_{18}H_{13}O_4N_3$ requires N = 12·5 per cent.).

On hydrolysis, it gave α -naphthylamine, $\alpha\beta$ -di- α -naphthylcarbamide, and *p*-nitrobenzoic acid. Boiling with benzene did not bring about isomeric change.

*α -Naphthylcarbamyl-*o*-methoxybenzantialdoxime,*

—Ethereal solutions of 2·7 grams of *o*-methoxybenzantialdoxime and 3·5 grams of α -naphthylcarbamide were mixed and kept in a stoppered bottle. Precipitation, in this case, was slow, and after twelve hours the precipitate was collected and washed with ether. The compound crystallised from acetone and water in colourless needles, turning yellow on exposure to light, and melting and decomposing at 143° (Found: N = 9·1. $C_{19}H_{16}O_3N_2$ requires N = 8·8 per cent.).

Hydrolysis gave α -naphthylamine, $\alpha\beta$ -di- α -naphthylcarbamide, and *o*-methoxybenzantialdoxime.

α -Naphthylcarbamyl-3 : 4-dimethoxybenzantialdoxime,

—Ethereal solutions of 1·6 grams of 3 : 4-dimethoxybenzantialdoxime and 1·75 grams of α -naphthylcarbamide were mixed and kept for fifteen hours. The precipitated derivative, after being washed with ether, crystallised from acetone and water in colourless needles, turning yellow on exposure to light, and melting and decomposing at 168° (Found: N = 8·0. $C_{20}H_{18}O_4N_2$ requires N = 8·0 per cent.).

Hydrolysis gave the *anti*-oxime and the usual products.

*α -Naphthylcarbamyl-*p*-dimethylaminobenzantialdoxime,*

—Ethereal solutions of 1·5 grams of *p*-dimethylaminobenzanti-

2174 RÂY: TRIETHYLENE TRI- AND TETRA-SULPHIDES. PART III.

aldoxime and 1.75 grams of α -naphthylcarbimide were mixed and kept for twelve hours. The precipitated derivative, having been washed with ether, crystallised from acetone and water in pale yellow, flat plates, darkening on exposure to light, and melting and decomposing at 151° (Found: N = 12.7. $C_{20}H_{19}O_2N_3$ requires N = 12.6 per cent.).

On hydrolysis, it gave α -naphthylamine, $\alpha\beta$ -di- α -naphthylcarbamide, and *p*-dimethylaminobenzalaldoxime.

In conclusion, we wish to express our thanks to the Department of Scientific and Industrial Research for a grant which has enabled one of us (D. R.) to take part in this work.

UNIVERSITY COLLEGE, LONDON.

[Received, July 2nd, 1923.]

CCXLI.—Triethylene Tri- and Tetra-sulphides. Part III. The Sulphones, Sulphinic and Sulphonic Acids of the Series. Extension of Stuffer's Law.

By Sir PRAFULLA CHANDRA RÂY.

THE preparation and properties of these cyclic polysulphides and their derivatives have already been described (T., 1920, 117, 1090; 1922, 121, 1279). The compounds obtained by their oxidation and the hydrolytic decompositions undergone by these oxidation products form the subject of the present communication.

It has been shown that all sulphones in which the sulphone groups are attached to two adjacent carbon atoms can be hydrolysed (Stuffer's law, *Ber.*, 1893, 26, 1125). Baumann and Walter (*ibid.*, p. 1125) have found that diethylene disulphide yields diethylene-disulphone on oxidation with acid permanganate solution. This disulphone according to Stuffer's law yields β -hydroxydiethylsulphone- β' -sulphinic acid on hydrolysis:

The sulphinic acid contains a sulphone group between two carbon atoms and can be further hydrolysed in two different ways, thus:

The result of oxidation and subsequent hydrolysis of triethylene trisulphide is exactly analogous.

When triethylene trisulphide is oxidised with potassium permanganate in acid solution, triethylenetrisulphone (I) is obtained, all the bivalent sulphur atoms in the ring becoming sexavalent. If, on the other hand, the oxidation is carried out with nitric acid, a compound with the formula $(C_2H_4)_3S_3O_4 \cdot H_2O$ is produced;

only two of the three sulphur atoms become sexavalent, whilst the third one remains unchanged (*vide infra*). It is not easy to account for this absence of reactivity in one of the atoms of sulphur when all three are supposed to be symmetrically disposed with reference to the carbon atoms.

Triethylenetrisulphone undergoes hydrolysis by means of baryta according to the following scheme :

Compound III has been isolated in a pure condition, but compound IV could not be obtained in a sufficiently pure state for purposes of analysis. The disulphone sulphide (II) on similar treatment with baryta yields two products, as shown below.

It will be observed that barium sulphide is produced in the course of this reaction. In fact, a continuous evolution of hydrogen sulphide took place during the removal of excess of baryta by means of carbon dioxide. This could not have occurred if all the sulphur atoms of triethylene trisulphide had been converted into sulphone. Hence, one of the sulphur atoms must have been unacted upon during the oxidation with nitric acid.* Again, it is very difficult to offer any satisfactory explanation of the dibasic character of

* The oxidation products of ethylene sulphide described by Crafts (*Annalen*, 1863, 125, 123) are evidently different from those described in this paper.

the compound (A). It might be assumed that the proximity of the sulphone group renders the hydroxyl group acidic, thus enabling the hydrogen atom of the hydroxyl to be replaced by barium. Even if that is so, it is not clear why in β -hydroxydiethylsulphone. β' -sulphinic acid, a decomposition product of diethylenedisulphone (*vide supra*), a similar phenomenon is not observed.

The β - and γ -triethylene tetrasulphides (*loc. cit.*) have also been similarly oxidised with nitric acid. Each of the sulphur atoms attached to two adjacent carbon atoms is oxidised to a sulphone group, whereas the linking between the two contiguous sulphur atoms is broken with the formation of a disulphonic acid. It may be mentioned here that another cyclic compound, ethylene disulphide, the product of oxidation of dithioglycol, behaves exactly similarly on oxidation with nitric acid; scission takes place at the linking between the two adjacent sulphur atoms, resulting in the formation of ethane- $\alpha\beta$ -disulphonic acid, thus:

The oxidation of the β -tetrasulphide takes place according to the following scheme:

It has been found that the same barium triethylenedisulphone-disulphonate is obtained by the oxidation and subsequent neutralisation with barium carbonate of both the β - and the γ -variety. In the case of the β -compound, the free acid further breaks down into diethylsulphonedisulphonic acid.

By the oxidation of β - and γ -triethylene tetrasulphides by means of potassium permanganate a tetrasulphone is obtained which forms a series of double salts with metallic sulphates. These will form the subject of a further communication.

EXPERIMENTAL.

Oxidation of Triethylene Trisulphide with Potassium Permanganate.—The trisulphide, suspended in a small quantity of water, was treated with a concentrated solution of potassium permanganate and a few c.c. of dilute sulphuric acid. A vigorous reaction ensued with evolution of heat. The mass was cooled and the process repeated until there remained an excess of permanganate solution. The product was heated on the water-bath for three to four hours

to complete the oxidation, the manganese peroxide brought into solution by means of sulphur dioxide, and the sulphone, which remained insoluble, was collected, and crystallised from concentrated nitric acid. It is insoluble in all the ordinary organic solvents and sublimes at a high temperature (Found: S = 34.25; C = 24.93*; H = 4.20. $C_6H_{12}O_6S_3$ requires S = 34.78; C = 26.08; H = 4.35 per cent.).

The trisulphone was heated with an excess of baryta water until it dissolved, the solution was cooled, the excess of baryta removed by means of carbon dioxide, and the filtrate concentrated to a small bulk and treated with an equal volume of alcohol. A syrupy liquid was obtained which on keeping solidified to a crystalline mass. The solid was collected, washed with alcohol, and dried in a vacuum desiccator (Found: Ba = 25.42; S = 23.66. $C_6H_{18}O_{10}S_4Ba$ requires Ba = 25.42; S = 23.75 per cent.).

The mother-liquor from the above salt was concentrated and a large volume of alcohol added to it. A viscous syrup was obtained, which solidified on keeping in a vacuum desiccator. This salt was extremely hygroscopic and could not be sufficiently purified for analytical purposes.

Oxidation of Triethylene Trisulphide with Nitric Acid.—The trisulphide was heated with an excess of fuming nitric acid in a sealed tube at 100° for about an hour. The residue after evaporation of the nitric acid was dissolved in hot water, from which the triethylenedisulphone sulphide crystallised in colourless, well-defined prisms.† It chars at about 250° (Found: C = 27.33; H = 4.76; S = 37.09. $C_6H_{12}O_4S_3 \cdot H_2O$ requires C = 27.48; H = 5.34; S = 36.64 per cent.).

The disulphone sulphide was heated with an excess of baryta water for about 15–20 minutes. Barium sulphide, sulphite, and carbonate were formed during the reaction. The excess of baryta was then removed with carbon dioxide, the filtrate concentrated to a small bulk, and an equal volume of alcohol added to it. The white, crystalline salt that separated was collected and dried in a vacuum (Found: Ba = 34.16; S = 23.77. $C_6H_{12}O_6S_3Ba$ requires Ba = 34.42; S = 24.12 per cent.). The mother-liquor was further concentrated to a viscous syrup, which crystallised on keeping in a vacuum desiccator for a few days (Found: Ba = 23.89; S =

* The substance sublimes at a high temperature. It is generally found that in such cases a trace of it escapes oxidation; hence the percentage of carbon found is a little too low.

† The experiment was repeated several times with identical results. In one instance, however, a small quantity of the insoluble sulphone (which is obtained in the case of oxidation with permanganate) was produced.

26.46. $C_8H_{16}O_8S_3Ba \cdot 3H_2O$ requires Ba = 23.18; S = 27.07 per cent.).

Oxidation of β -Triethylene Tetrasulphide with Nitric Acid.—The tetrasulphide was heated with fuming nitric acid in a sealed tube at 100° for about an hour, the nitric acid was then completely evaporated off, and the residue heated under reflux with acetone, in which a part of it dissolved. The insoluble portion was dissolved in water, and the solution neutralised with barium carbonate and filtered. On concentrating the filtrate, a crystalline barium salt was obtained (Found: Ba = 26.48; S = 25.46. $C_6H_{12}O_{10}S_4Ba$ requires Ba = 26.92; S = 25.15 per cent.).

The acetone solution was evaporated to dryness, the viscous residue dissolved in a small quantity of water, the solution neutralised with barium carbonate, and filtered. The filtrate on evaporation left behind well-defined, white crystals (Found: Ba = 32.89; S = 22.49. $C_4H_8O_8S_3Ba$ requires Ba = 32.85; S = 23.02 per cent.).

Oxidation of γ -Triethylene Tetrasulphide with Nitric Acid.—The oxidation was carried out in exactly the same way as in the case of the β -modification. The residue left after driving away the last traces of nitric acid was dissolved in water and neutralised with excess of barium carbonate. Two salts were formed. One remained in solution (A), whilst the other was precipitated along with the excess of barium carbonate. The insoluble mass was therefore treated with water; the extract on cooling gave a crop of barium salt (Found: Ba = 25.49; S = 24.04. $C_6H_{12}O_{10}S_4Ba \cdot H_2O$ requires Ba = 25.90; S = 24.10 per cent.).

The solution (A) was concentrated and on being cooled gave crystals of a barium salt (Found: Ba = 26.35; S = 25.20. $C_6H_{12}O_{10}S_4Ba$ requires Ba = 26.92; S = 25.15 per cent.).

Oxidation of Ethylene Disulphide with Nitric Acid.—The oxidation was carried out in a sealed tube as before. After removal of the last traces of nitric acid, the syrupy residue was dissolved in water and neutralised with barium carbonate. The barium salt was precipitated from the concentrated solution by means of alcohol (Found: Ba = 42.26. $C_2H_4O_6S_2Ba$ requires Ba = 42.16 per cent.).*

* After the above investigation was ready for publication my attention was directed to a paper by Bennett (L., 1922, 121, 2144, footnote) in which the cyclic triethylene trisulphide, $(C_2H_4)_3S_3$, mentioned in this paper is stated to be diethylene disulphide, $(C_2H_4)_2S_2$, on the strength of the cryoscopic determination of the molecular weight in benzene solution. The present author, however, has reasons to believe it to be cyclic triethylene trisulphide, and hopes to discuss the point critically in a subsequent communication.

CXLII.—*Condensation of Amidines with Ethoxymethylene Derivatives of β -Ketonic Esters and of β -Diketones.*

By PRAFULLA CHANDRA MITTER and JOGENDRA CHANDRA BARDHAN.

In the earlier syntheses of pyrimidine derivatives, the usual starting materials were amidines and β -ketonic esters or β -diketones (Pinner, *Ber.*, 1885, **18**, 759, 2845; 1889, **22**, 1600, 2609; 1893, **26**, 2122; Gabriel, *Ber.*, 1899, **32**, 1525; 1904, **37**, 3638); later, Wheeler, Johnson, and their co-workers prepared a large number of pyrimidine derivatives by condensing thiocarbamide with β -ketonic esters (Wheeler and Merrimann, *Amer. Chem. J.*, 1903, **29**, 478; Wheeler and Johnson, *ibid.*, 1904, **31**, 591, etc.). The action of amidines on ethoxymethylene derivatives of β -ketonic esters and of β -diketones does not, however, appear to have been systematically investigated.

In the literature there are only a few instances of the employment of ethoxymethylene derivatives for pyrimidine formation. By condensing ethyl- ψ -thiocarbamide hydrobromide with ethyl ethoxymethylenemalonate, Wheeler, Johnson, and Johns (*Amer. Chem. J.*, 1907, **37**, 392) obtained ethyl 2-ethylthiol-6-oxypyrimidine-5-carboxylate,

and by condensing ethyl ethoxymethylenecyanoacetate with ethyl- ψ -thiocarbamide, Johnson (*ibid.*, 1909, **42**, 505) obtained 5-cyano-2-ethylthiol-6-oxypyrimidine.

We have investigated the action of benzamidine and of *p*-toluamidine on ethyl ethoxymethyleneacetoacetate and on ethoxymethyleneacetylacetone and have found that the reaction proceeds smoothly in every case, leading to the formation of pyrimidine derivatives according to the equation

where R = C₆H₅ or C₆H₄Me and R' = COMe or CO₂Et.

In extending the study of this reaction, it became necessary to investigate the action of amidines on ethyl ethoxymethyleneacetonedicarboxylate. The latter substance has already been obtained by Errera (*Ber.*, 1897, **31**, 1682) during the condensation of orthoformic ester with acetonedicarboxylic ester, but he does not

seem to have isolated it in a pure state. An attempt to purify the product described by him by distillation under diminished pressure having been unsuccessful, we next tried to condense benzamidine with the crude product itself, and obtained a small quantity of a crystalline product which could neither be purified nor be characterised with certainty. The condensation of benzamidine with ethyl ethoxymethylenemalonate was next attempted. The product in this case proved to be identical in all essential respects with the phenyl- γ -pyrimidonecarboxylic ester obtained by Ruhemann by the condensation of ethyl dicarboxyglutaconate and benzamidine (*Ber.*, 1897, 30, 821). That the same compound are formed by the condensation of ethyl dicarboxyglutaconate and of ethyl ethoxymethylenemalonate with benzamidine is borne out by the fact that *p*-toluamidine gives identical compounds with both substances. It may also be noted here that the action of hydroxylamine on ethyl dicarboxyglutaconate and on ethyl ethoxymethylenemalonate gives rise to the same isooxazolone (Ruhemann, *Ber.*, 1897, 30, 2032). If Ruhemann's formula for the phenyl-pyrimidonecarboxylate mentioned above be correct, then the action of benzamidine on ethyl ethoxymethylenemalonate should be represented thus :

It will be noticed, however, that the alternative mode of representation (compare Wheeler, Johnson, and Johns, *loc. cit.*) leading to the formation of an α -pyrimidone derivative is by no means excluded and we consider that further work will be necessary before the nature of these reactions can be definitely established.

EXPERIMENTAL.

(A).—Pyrimidines from Ethyl Ethoxymethyleneacetoacetate.

Condensation with Benzamidine: Formation of Ethyl 2-Phenyl-4-methylpyrimidine-5-carboxylate, $\text{CPh}\begin{smallmatrix} \diagup \text{N}-\text{CH} \\ \diagdown \text{N}:\text{CMe} \end{smallmatrix} \text{C}\cdot\text{CO}_2\text{Et}$. Sodium (0.5 gram) was dissolved in alcohol, and to the well-cooled solution benzamidine hydrochloride (3.2 grams) was added. Ethyl ethoxymethyleneacetoacetate (Claisen, *Annalen*, 1897, 297, 16) (3.7 grams) was then gradually introduced, care being taken that no rise in temperature took place. The mixture, which assumed a rose-red colour, was gently boiled on the water-bath for an hour. On cooling, the condensation product separated in needles, which purified in boiling alcohol with the aid of animal charcoal, crystallised in clusters of prismatic needles melting at 99–100°. The yield

was good (Found: C = 68.85; H = 5.91; N = 11.81. $C_{14}H_{14}O_2N_2$ requires C = 69.41; H = 5.78; N = 11.57 per cent.). This compound, which dissolves with difficulty in cold alcohol and more readily on warming, is freely soluble in glacial acetic acid. It has basic properties and dissolves readily in concentrated hydrochloric acid. The solution gives a yellow chloroplatinate.

Hydrolysis of the Ethyl Ester.—The hydrolysis was readily effected by heating the foregoing ester (2.4 grams) with alcoholic potassium hydroxide (0.7 gram) for four hours under reflux. The alcohol was then evaporated, the residue dissolved in water, filtered, and the filtrate acidified with dilute hydrochloric acid. The precipitate was collected, washed with water, and purified by crystallisation from alcohol. 2-Phenyl-4-methylpyrimidine-5-carboxylic acid melts at 243° with evolution of carbon dioxide. On account of the small quantity of the acid at our disposal, it could not be submitted to further examination (Found: N = 13.58. $C_{12}H_{10}O_2N_2$ requires N = 13.08 per cent.).

Condensation with p-Toluamidine: Formation of Ethyl 2-p-Tolyl-4-methylpyrimidine-5-carboxylate.—This condensation was brought about as in the preceding case. The product separated from alcohol, diluted with a few drops of water, in long, hair-like needles, somewhat resembling glass-wool in appearance. It melts at 80° to a clear liquid and is soluble in ordinary solvents, more readily in alcohol or benzene and sparingly soluble in light petroleum (Found: N = 10.87. $C_{15}H_{16}O_2N_2$ requires N = 10.93 per cent.).

2-p-Tolyl-4-methylpyrimidine-5-carboxylic acid may be obtained from the ethyl ester by boiling with concentrated hydrochloric acid or more readily by means of alcoholic potassium hydroxide in the usual way. It crystallises from benzene in minute crystals melting with effervescence at 269° (Found: N = 12.5. $C_{13}H_{12}O_2N_2$ requires N = 12.28 per cent.).

(B).—Pyrimidines from Ethoxymethyleneacetylacetone.

Condensation with Benzamidine: Formation of 5-Acetyl-2-phenyl-4-methylpyrimidine, $CPh\langle\begin{smallmatrix} N-CH \\ N: CMe \end{smallmatrix}\rangle C\cdot COMe$.—The action of benzamidine on ethoxymethyleneacetylacetone (Claisen, *loc. cit.*, p. 57) takes place readily when solutions of sodium (1 atom) and of the hydrochloride of the base (1 mol.) in alcohol are mixed, the ethoxymethylene derivative (1 mol.) cautiously added, and the mixture heated on the water-bath in the usual manner. The condensation product which separates is collected, washed with water, and purified by two crystallisations from boiling alcohol. It separates in colourless, silky needles which melt at 107° (Found:

C = 72.96; H = 5.84; N = 13.48. $C_{13}H_{12}ON_2$ requires C = 73.58 H = 5.66; N = 13.20 per cent.).

The *semicarbazone* is precipitated when a solution of the ketone in dilute alcohol is mixed with an aqueous solution of semicarbazide acetate. The precipitate is collected, washed successively with alcohol and water, and finally crystallised from dilute acetic acid. It is obtained in slender needles which melt at 227–228° (Found: N = 25.67. $C_{14}H_{15}ON_5$ requires N = 26.02 per cent.).

Condensation with p-Toluamidine: Formation of 5-Acetyl-2-p-tolyl-4-methylpyrimidine.—The mixture of ethoxymethyleneacetylacetone (3.1 grams), *p*-toluamidine (3.4 grams), and sodium (0.46 gram) dissolved in alcohol, when boiled on the water-bath, deposits a solid after an hour's digestion. The mixture is cooled, and the solid collected and washed with water in the usual way. 5-Acetyl-2-p-tolyl-4-methylpyrimidine separates from alcohol in long needles melting at 123–124° (Found: N = 12.72. $C_{14}H_{14}ON_2$ requires N = 12.39 per cent.).

The *semicarbazone*, obtained in the usual way, is a sparingly soluble substance, but it can be crystallised very easily from dilute acetic acid. It melts with decomposition at 219°, distinctly sintering a few degrees lower (Found: N = 24.51. $C_{15}H_{17}ON_5$ requires N = 24.73 per cent.).

Oxidation of 5-Acetyl-2-phenyl-4-methylpyrimidine: Formation of 2-Phenyl-4-methylpyrimidine-5-carboxylic Acid.—It was hoped that by employing an excess of potassium permanganate it would be possible to oxidise both the acetyl and the methyl group simultaneously, but under the conditions described below only a monobasic acid was obtained, the methyl group evidently remaining unaffected. To a gently boiling mixture of finely powdered 5-acetyl-2-phenyl-4-methylpyrimidine (2 grams) and 150 c.c. of water a solution of potassium permanganate (7 grams) in 250 c.c. of water was gradually added during three to four hours. The whole was then boiled vigorously with occasional shaking, until the pink colour was discharged. The filtrate and washings from the manganese precipitate were evaporated to a small bulk, again filtered, and acidified with dilute hydrochloric acid, when a white amorphous solid (1.2 grams) was obtained; this was collected and recrystallised from alcohol or dilute acetic acid. It melted at 243° and was identified as 2-phenyl-4-methylpyrimidine-5-carboxylic acid by direct comparison with an authentic specimen (Found N = 13.13. Calc., N = 13.08 per cent.).

(C).—*Pyrimidines from Ethyl Ethoxymethylenemalonate.*

Condensation with Benzamidine: Formation of Ethyl 4-Keto-2-phenyl-1:4-dihydropyrimidine-5-carboxylate,

The reaction is brought about by treating benzamidine hydrochloride, suspended in slightly more than the calculated amount of sodium ethoxide solution, with ethyl ethoxymethylenemalonate (Claisen, *loc. cit.*, p. 75) and digesting the mixture for about an hour. The alcohol is then removed by distillation, the residue dissolved in water, the solution filtered, and the condensation product precipitated with dilute hydrochloric acid. It crystallises from benzene in short needles melting at 212° . The substance thus obtained was identified by analysis (Found: N = 11.79. $\text{C}_{13}\text{H}_{12}\text{O}_3\text{N}_2$ requires N = 11.47 per cent.) and by direct comparison and by the melting point of its mixture with a specimen obtained from benzamidine and ethyl dicarbethoxyglutaconate (see next section).

Condensation with p-Toluidine: Formation of Ethyl 4-Keto-2-p-tolyl-1:4-dihydropyrimidine-5-carboxylate.—This condensation was carried out in a manner analogous to the one just described, and gave a quantitative yield of the pyrimidinecarboxylate. This compound is sparingly soluble in most solvents and crystallises with difficulty from methyl alcohol. It also dissolves in a large excess of boiling toluene, from which it is obtained in short, colourless needles melting at $249\text{--}250^\circ$ (Found: N = 11.08. $\text{C}_{14}\text{H}_{14}\text{O}_3\text{N}_2$ requires N = 10.85 per cent.).

The hydrolysis of the ethyl ester described above can be best effected by treating it with an excess of boiling alcoholic potassium hydroxide for five hours on the water-bath. The acid is purified in dilute acetic acid with the aid of animal charcoal, and crystallises in prismatic needles which melt at 281° with rapid evolution of gas (Found: N = 12.45. $\text{C}_{12}\text{H}_{10}\text{O}_3\text{N}_2$ requires N = 12.17 per cent.).

4-Keto-2-p-tolyl-1:4-dihydropyrimidine is obtained when the carboxylic acid (4 grams) described above is heated at 290° for ten minutes. The product, which solidifies on cooling, is extracted with boiling alcohol, the alcohol evaporated, and the residue treated in benzene solution with animal charcoal. It separates from the filtered solution in colourless, glistening needles melting at $212\text{--}213^\circ$ (Found: N = 15.16. $\text{C}_{11}\text{H}_{10}\text{ON}_2$ requires N = 15.05 per cent.).

(D).—*Action of Amidines on Ethyl Sodio- α -dicarboxyglutaconate.*

In order definitely to establish whether ethyl ethoxymethylenemalonate and ethyl α -dicarboxyglutaconate react with amidines

on similar lines, we have brought within the limits of the present investigation the action of amidines on the latter ester. The ethyl sodio- α -dicarboxyglutaconate required for these experiments was obtained by the excellent method of Ingold and Perrin (T., 1921, 119, 1591).

Action of Benzamidine.—The action was brought about according to the prescription given by Ruhemann (*Ber.*, 1897, 30, 1488). The product after crystallisation from benzene melted at 214° and was found to be identical with the substance obtained from ethyl ethoxymethylenemalonate (Found: N = 11.45. Calc., N = 11.47 per cent.).

Action of p-Toluamidine.—This condensation took place on mixing a suspension of the yellow sodium compound of ethyl α -dicarboxyglutaconate (7 grams) with *p*-toluamidine hydrochloride (3.1 grams) dissolved in alcohol, adding an aqueous solution of potassium carbonate (1.7 grams), and heating the mixture on the water-bath for an hour. After cooling, the solution was acidified with dilute hydrochloric acid and the condensation product was collected, thoroughly washed with water, and dried. It was crystallised from a large excess of boiling toluene, from which it separated in short needles melting at 249 – 250° , and was thus identical with the ethyl 4-keto-2-*p*-tolyl-1:4-dihydropyrimidine-5-carboxylate described above (Found: N = 11.01. Calc., N = 10.85 per cent.).

UNIVERSITY COLLEGE OF SCIENCE,
CALCUTTA.

[Received, April 16th, 1923.]

CCXLIII.—The Calorific Value of Carbon Compounds.

By DIMITRI KONOVALOV.

I. Homologous Series.

THIS investigation discusses the relation of the respective net calorific values of carbon compounds to the amounts of oxygen required for their complete combustion. The net values are calculated from the experimentally determined, molecular, gross calorific values by deducting the heat evolved by the condensation of the water vapour formed during the combustion.* If *Q* and *P* represent, respectively, the gross and the net calorific value in

* Prof. Konvalov appears to have employed the value of the latent heat of water vapour at 25° , calculated by Regnault's formula $L_1 = 606.5 - 0.695t$. This gives at 25° , $L_1 = 589.1$ gram-calories. As 1 gram of hydrogen on combustion yields 9 grams of water vapour, the heat evolved on condensation of the water vapour produced per gram of hydrogen is equal to 5.302 kilogram-calories.

kilogram-calories, h the number of hydrogen atoms in the molecule of the substance, n the number of oxygen atoms required for complete combustion per molecule of the substance, and π the net calorific value per atom of this oxygen, then

$$P = Q - 5.3h = n\pi.$$

In the cases of saturated hydrocarbons represented by the formula C_nH_{2n+2} , liquid cyclic hydrocarbons C_nH_{2n} , alcohols $C_nH_{2n+2}O$, and liquid amines $C_nH_{2n+1}NH_2$, the value of π is constant to within a few tenths of 1 per cent., and equal to 48.8. Therefore

$$P = 48.8n \quad (1)$$

Applied to the case of the combustion of carbon represented by $C + O_2 = CO_2$, for which $n = 2$, equation (1) gives $P = 97.6$ kg.-cals., in close agreement with the value 97.3 found by Berthelot and by Thomsen for amorphous carbon.

Equation (1) affords values of P , and hence of Q , in very close agreement with the experimentally determined calorific values of carbon compounds.* In its application to substances containing oxygen, regard must be paid to the following considerations. In the case of compounds, for example, oxalic acid, in which the oxygen is linked with carbon, the value of n is equal to the number of additional atoms required for complete combustion. Thus in the case of oxalic acid $n = 1$. In the case of compounds containing nitrogen, for example, nitro-compounds, in which oxygen is not directly linked with carbon, the oxygen atoms contained in the molecule of the compound retain their energy in the latter, and their number is to be added to the additional number of oxygen atoms required for complete combustion, in determining the value of n to be substituted in (1).

If X represent the positive or negative deviation of the experimental value from the value of P calculated by (1), we may write accurately

$$P = 48.8n \pm X \quad (2)$$

X is termed the *thermal characteristic* of the corresponding compound. When $X = 0$, the calorific value is of normal level.

In homologous series of carbon compounds, corresponding to a constant difference of molecular composition, represented by CH_2 , between adjacent members, physical properties change by equal

* Considering the combustion of ethane represented by the equation

$h = 6$, $n = 7$, and therefore $Q = (48.8 \times 7) + (5.3 \times 6) = 373$ kilogram-calories, in agreement with the values, 370 and 372, found by Thomsen and Berthelot, respectively.

increments or decrements in passing from one member to the next. The difference in the molecular heats of combustion of adjacent members, experimentally determined, is found to be 155–158 kg.-cals. It follows from equation (2) that

$$P_2 - P_1 = 48.8 (n_2 - n_1) + X_2 - X_1,$$

the subscripts 1 and 2 referring to respective members in the series.

For adjacent members, $n_2 - n_1 = 3$, corresponding to the three atoms of oxygen required for the complete combustion of CH_2 , and therefore, the thermal characteristic being assumed constant throughout the series,

$$P_2 - P_1 = 48.8 \times 3 = 146.4, \text{ and } Q_2 - Q_1 = 146 + (5.3 \times 2) = 157,$$

in close agreement with the experimental values. A more correct value of the latter is obtained by considering the experimentally determined calorific values of remote members of the series, and calculating the average value of $Q_2 - Q_1$ for adjacent members throughout the series. This method being applied to series for which the thermal characteristic has any value, zero, positive, or negative, it is found, corresponding to CH_2 throughout such series, $Q_2 - Q_1 = 157 \pm 0.5$. The conclusion may therefore be drawn that in a homologous series the thermal characteristic of the compounds constituting the series is constant.

If equation (2) be written in the form $\pi = P/n = 48.8 \pm X/n$, it will be seen that in a homologous series ($X = \text{constant}$) the difference between the experimental value of π and 48.8 is smaller the greater the value of n , that is, the greater the molecular weight of the substance. It is to be anticipated, therefore, that the most accurate value of the thermal characteristic of a homologous series is that calculated from experimental data referring to members of the series having small molecular weights.

The thermal characteristics of certain homologous series have been determined by calculating the mean value of the characteristics afforded by experimental data referring to the first three members of each series in the same physical state—gaseous, liquid, or solid. In the case of a transition from one state to another, for example, in the fatty acid series, in passing from members below $\text{C}_8\text{H}_{16}\text{O}_2$, which are liquid, to higher homologues which are solid, there is a discontinuity in the value of $Q_2 - Q_1$ for adjacent homologues in the transition region, but a constant value, equal to 157, is obtained by calculation from values of Q appropriate to members both below and above this region.

The following values of X (correct within the limit of experimental error, which is a few tenths of a unit) have been calculated

from the experimental data available for the respective homologous series: for acetic acid and its liquid homologues, $X = -6$; for acetone and its homologues, $X = +6$; for the solid homologues of acetic acid, their amides, and the solid homologues of malonic acid, $X = -12$; for acetaldehyde and its homologues, $X = +12$; for acetonitrile and its homologues, $X = +18$. It is to be observed that the values of X found are in all cases simple positive or negative multiples of 6. This result made it appear desirable to determine the values of X in other series of compounds. These are referred to below.

II. Saturated Compounds.

The thermal characteristics given above refer to compounds containing not less than two atoms of carbon in the molecule. Data referring to the simplest representative of homologous series containing only one atom of carbon are shown in Table I, in which are given the experimentally determined values of Q and those calculated, assuming $X = \pm 3$ in the respective cases.

TABLE I.

Substance.	Formula.	X .	Q (cal.).	Q (obs.).
Methane (gas)	CH_4	-3	213.4	213.3
Methyl alcohol (liquid) ...	CH_3O	+3	170.6	170.7
Formic acid (liquid)	CH_3O_2	+3	62.4	62.6
Formamide.....	$\text{CHO}\cdot\text{NH}_2$	-3	134.9	135.0

Values of Q , observed, and calculated assuming $X = \pm 3$ —a value in agreement with the values of X previously calculated for homologous series containing not less than two carbon atoms—are seen to differ only very slightly. In the passage from a compound containing one carbon atom to the next member of the homologous series there is a discontinuity in the value of X . This is especially characteristic of the alcohol and the acid, for both of which $X = +3$. In the passage from methyl alcohol to ethyl alcohol, the adjacent member of the homologous series of alcohols, for which $X = 0$, the thermal characteristic undergoes a decrease of 3 units, whilst in the corresponding case of the passage from formic to acetic acid, the decrease is from +3 to -6, a fall of 9 units; in each case, the substitution of the methyl group for a hydrogen atom linked with carbon produces a result proportional to the number of valencies of carbon satisfied by oxygen. There occurs a supplementary production of heat due to oxygen atoms the valencies of which are already satisfied and which are not directly influenced.

The same kind of discontinuity occurs in the transition from aldehydes to ketones. If the methyl group be substituted for the

hydrogen atom of the aldehydo-group, the thermal characteristic will decrease from $X = 12$ for the aldehyde to $X = 6$ for the ketone, the decrease again corresponding to the number of valencies of carbon satisfied by oxygen. A further substitution of methyl for hydrogen can occur outside the group containing oxygen, whereby the homologues of acetone with the constant thermal characteristic, $X = 6$, are obtained. The homologous series in this case begins with a compound containing three atoms of carbon.

Among compounds containing nitrogen, the nitriles and amides will be considered. Hydrogen cyanide, containing¹ one carbon atom, is the simplest representative of the former. Experimental and calculated values of Q , and the respective values of X , for three gaseous nitriles are given in Table II.

TABLE II.

Substance.	Formula.	X .	Q (calc.).	Q (obs.).
Hydrogen cyanide.....	HCN	33	160.3	159.7
Cyanogen	(CN) ₂	66	261.2	262.3
Trimethylamine.....	(CH ₃) ₃ N	33	593.1	593.7

Here a very large thermal characteristic, $X = 33$, corresponds to each atom of nitrogen. Substitution of an alkyl group for the hydrogen atom in hydrogen cyanide leads to the homologous series of liquid nitriles, for which, as mentioned on p. 2187, $X = 18$. The heat of condensation of hydrogen cyanide (approximately 6) being taken into account, the thermal characteristic of liquid hydrogen cyanide is found to be 27, so that here again, as in the case of formic acid, the substitution of methyl for hydrogen results in a decrease of X by $27 - 18 = 9$ units. A similar decrease occurs in the case of the amides. Thus for formamide, $X = -3$, whilst for the homologues $X = -12$. In this case it is to be noticed that the decrease accompanies a change of state, for the data relating to the amides, commencing with acetamide, all refer to the solid state.

The possible suggestion that the high value of the thermal characteristic ($X = 33$) in the case of hydrogen cyanide is attributable to the triple linking between carbon and nitrogen is untenable, for the same high value occurs with trimethylamine, in which nitrogen is linked with three separate carbon atoms. The increasing influence of such linking is evidenced when methyl is substituted for hydrogen linked with nitrogen. In the case of the amino-acids, this substitution results in the thermal characteristics acquiring zero or negative values. Thus in the case of sarcosine, the observed value of $Q = 401.1$ corresponds with $X = 0$, whilst in the case of alanine ($Q = 389.7$), $X = -12$. In the case of

theobromine, containing two $\text{N}(\text{CH})$ groups, $X = 24$, whilst for caffeine, with three such groups, $X = 36$.

The maximum effect of the linking of nitrogen with carbon, in increasing the value of X , occurs in the case of the carbylamines. In the simplest of these, methylcarbylamine, according to the modern view of its structure, five nitrogen valencies are linked with carbon atoms. From data relating to the homologous series, commencing with ethylcarbylamine, it is found that $X = 40$. Heats of combustion of members of the series, calculated by employing this value of X , agree with experimental values to within 0.3 per cent., except in the case of methylcarbylamine, for which the difference is 1.25 per cent. The increase of X from 18 in the case of the nitriles to 40 in the case of the carbylamines is attributable to the two additional nitrogen valencies linked with carbon in the latter case.

The dibasic acids, polyhydric alcohols, and certain carbohydrates, for which very accurate determinations of calorific value have been made, will now be considered. Among the dibasic acids a true homologous series is to be found in the substituted malonic acids, beginning with methylmalonic acid and ending with octylmalonic acid, all of which are solid and for which the calorific values of adjacent members in the series differ by 157. For these, the respective experimental values of calorific power agree perfectly with those calculated by equation (2), assuming $X = -12$, as in the case of the solid homologues of acetic acid. This value of X is, however, not applicable to malonic acid itself, neither to other acids of the same general formula, $\text{C}_n\text{H}_{2n-2}\text{O}_4$, and of similar structure. For oxalic acid, the simplest of these, $X = 0$; for malonic acid, $X = -9$; and for succinic acid, $X = -18$. In the transition from formic acid to acetic acid already considered (p. 2187), it was seen that X changes from $+3$ to -6 , a decrease of 9, after which it remains constant for subsequent homologues. In the present case, however, the thermal characteristic decreases from 0 in the case of oxalic acid to -18 for succinic acid in two steps of -9 and thereafter remains constant at this value $X = -18$ for the series of compounds commencing with the one containing four carbon atoms and *not* two as in the case of acetic acid. On the assumption that $X = -18$, the values of Q have been calculated for succinic and sebacic acids, for purposes of comparison with the respective experimental values. For succinic acid, $Q(\text{calc.}) = 355.4$, $Q(\text{obs.}) = 355.6$; for sebacic acid, $Q(\text{calc.}) = 1297.4$, $Q(\text{obs.}) = 1297.7$. Calculated from these values, the corresponding difference in the molecular heats of combustion of adjacent members of the series is found to be 157, as for a homo-

logous series. The series, however, is not truly homologous, but can be regarded as produced by the combination of molecules of monobasic acids; thus:

The transition from monobasic to dibasic acids is accompanied by a change of state from liquid to solid. On the assumption that this corresponds to a decrease of 6 in the thermal characteristic, as in the case of homologues of acetic acid, it is found that for oxalic acid $X = 3 + 3 - 6 = 0$; for malonic acid, $X = 3 - 6 - 6 = -9$; for succinic acid, $X = -6 - 6 - 6 = -18$; and for subsequent members, $X = -18$, in agreement with the values already referred to.

In similar manner the values of X for certain nitriles have been determined. For gaseous cyanogen, $X = 66$, twice the value corresponding to hydrogen cyanide. For the liquid nitrile of malonic acid, $X = 27 + 18 = 45$, whilst for the liquid nitrile of succinic acid, $X = 18 + 18 = 36$. The corresponding calculated and observed values of the respective molecular heats of combustion are: for the liquid nitrile of malonic acid, Q (calc.) = 397.2, Q (obs. for solid nitrile) = 395.6; for the liquid nitrile of succinic acid, Q (calc.) = 545.2, Q (obs.) = 546.3.

The polyhydric alcohols to be considered contain an equal number of hydroxyl groups and carbon atoms and have the general formula $\text{C}_n\text{H}_{2n+2}\text{O}_n$. Applying to the simplest of them, ethylene glycol, the same method of calculation as that used in the case of the dibasic acids, that is, considering ethylene glycol as being produced by the aggregation of molecules of methyl alcohol, one finds for the glycol the value $X = 3 + 3 = 6$. Using this value of X , the calculated value of Q for ethylene glycol is found to be 281.8 kg.-cals., which agrees well with the experimental value, 282.2. Other values of X can be calculated from the differences of the molecular heats of combustion of adjacent members of the series, which differ in molecular composition by CH_2O , representing a heat of combustion equal to 108.2 kg.-cals. If values of $Q_2 - Q_1$ are calculated from the experimental data for members of the series $\text{C}_n\text{H}_{2n+2}\text{O}_n$ from $n = 2$ up to $n = 7$, they will be found to range from 107.3 to 108.5 in the case of three pairs of adjacent members in close agreement with the value 108.2 just referred to, whilst in the case of two pairs of adjacent members the values of $Q_2 - Q_1$ will be found equal to 115.1 and 115.7, respectively, these values being greater than the theoretical value by approximately 6 units. It is seen, therefore, that in this series again, commencing with

ethylene glycol, for which $X = 6$, the thermal characteristic has a series of values, namely, 6, 12, and 18, which are multiples of 6. Applying, therefore, in equation (2) the respective values $X = 6$ for members of the series containing two carbon atoms, $X = 12$ for members containing three, four, or five carbon atoms, and $X = 18$ for members containing six or seven carbon atoms, one is able to calculate values of Q for the respective members which are in very close agreement with experimental results. Values of X for members of the series containing n carbon atoms are given by $X = 3n$ when n is even, as in ethylene glycol, erythritol, and mannitol, and by $X = 3n \pm 3$ when n is odd.

Passing to glucose from the corresponding alcohol, $C_6H_{14}O_6$, a further increase of 6 occurs in the value of X , so that for glucose $X = 24$. A further increase, due to combination of two glucose molecules accompanied by loss of water, occurs in passing from glucose to sucrose. The increased value of X in this case and in the cases of raffinose and cellulose cannot be expressed as multiples of 6. If, however, a constant increase, X' , be assumed in the thermal characteristics of these substances per molecule of water, in accordance with the following scheme,

the following values of X will be obtained: for sucrose, $X = 2 \times 24 + X'$; for raffinose, $X = 3 \times 24 + 2X'$, and for cellulose, $X = n \times 24 + X'$, so that to $C_6H_{10}O_5$ corresponds a value of X equal to $24 + X'$. Experimental data show that in the case of sucrose $X' = 15$, so that for this substance $X = 63$. For raffinose, therefore, $X = 72 + 30 = 102$, and for cellulose, assuming its molecular formula to be $(C_6H_{10}O_5)_n$, $X' = 39n$, or if $n = 1$, $X = 39$. Values of Q calculated for the respective compounds, employing appropriate values of X , together with corresponding experimental values are given herewith: raffinose, Q (calc.) = 2028.4, Q (obs.) = 2026.3; cellulose, Q (calc.) = 677.6, Q (obs.) = 678.6.

It has now been shown that, starting with methyl alcohol, values of X and Q may be calculated for compounds of gradually increasing molecular weight such that, in contradistinction to members of homologous series, the value of X differs increasingly from the zero value, characterising what has been termed the normal level, as the molecular weight increases, the difference in the case of cellulose amounting to as much as 6 per cent. of the calorific value.

III. *Unsaturated Compounds.*

In general, the value of the thermal characteristic X for unsaturated compounds is greater than for saturated compounds. Data relating to ethane, ethylene, and acetylene, and also to propane, propylene, and allylene are given in Table III, the experimental values of Q given being in every case the mean of results obtained by different observers. In the absence of any change in the value of the thermal characteristic throughout a series, the loss of two hydrogen atoms and the establishment of additional linkings between carbon atoms, in passing from one member of either series to the adjacent member, would entail a constant difference in the respective values of the heats of combustion of adjacent members equal to $48.8 + 10.6 = 59.4$. It is seen from Table III, however, that the experimental values of $Q_1 - Q_2$ are less than this by amounts ranging from 29.9 to 30.7. It will also be noticed that values of Q in very close agreement with the experimental values can be calculated by equation (2) on the assumptions that, as in the case of saturated hydrocarbons, $X = 0$ for the first members of the respective series (C_2H_6, C_3H_8) corresponding to single linkings, while corresponding to a double bond $X = 30$, and for a triple bond $X = 60$. Clearly, therefore, within the limits of experimental error, the effect of the production of an additional coupling between the carbon atoms corresponds to an increase of 30 in the value of the thermal characteristic.

TABLE III.

Substance.	Formula.	Q (obs.).	$(Q_1 - Q_2)$ (obs.).	X .	Q (calc.).
Ethane	C_2H_6	372.3		0	373.4
Ethylene	C_2H_4	342.9	29.4	30	344.0
Acetylene	C_2H_2	313.8	29.1	60	314.6
Propane	C_3H_8	528.8		0	530.4
Propylene	C_3H_6	499.3	29.5	30	501.0
Allylene	C_3H_4	470.6	28.7	60	471.6

In order to determine whether this increase of 30 is applicable throughout the various series of unsaturated compounds, and more especially in the case of compounds deviating from the normal level ($X = 0$), the very accurate data available for the unsaturated acids having one or two double bonds have been examined. These are set out in Table IV.

The thermal characteristics of unsaturated acids are greater than those of the corresponding saturated acids, but only in a few cases can the former be calculated from the latter by adding 30.

Thus, considering succinic and maleic acids, it is found that $X = -18$ for the former and $-18 + 30 = 12$ for the latter.

TABLE IV.

Acid.	Formula.	X.	Q (calc.).	Q (obs.).
Acrylic	$C_3H_4O_2$	15	329.0	329.2
Crotonic	$C_4H_6O_2$	6	477.0	478.2
Angelie	$C_5H_8O_2$	6	634.0	635.1
Fumaric	$C_4H_4O_4$	6	320.0	320.3
Mesaconic	$C_5H_6O_4$	6	477.0	477.4
Itaconic	$C_5H_6O_4$	6	477.0	476.1
Maleic	$C_4H_4O_4$	12	326.0	326.4
Citraconic	$C_5H_6O_4$	12	483.0	483.9
Allylmalonic	$C_5H_8O_4$	12	640.0	638.4
Tetraconic	$C_7H_{10}O_4$	12	797.0	796.9
Δ^8 -Hexenoic	$C_8H_{10}O_2$	12	797.0	796.2
Undecenoic	$C_{11}H_{20}O_2$	12	1582.0	1581.3
Oleic	$C_{18}H_{34}O_2$	12	2682.0	2684.5
Sorbic	$C_8H_{12}O_2$	18	743.6	743.7
Stearolic	$C_{18}H_{32}O_2$	18	2627.6	2628.9
Behenolic	$C_{22}H_{40}O_2$	18	3255.6	3255.5

The thermal characteristics of the unsaturated acids are seen to be greater than those of the corresponding saturated acids, but no additive relation exists between the values of X in the former case. An alteration in the position of the carboxyl groups, as in fumaric acid, causes X to decrease and become equal to 6. For the monobasic solid acids, in place of $X = 18$ (that is, $30 - 12$), $X = 6$ or 12. For monobasic acids with two double bonds, for example, sorbic, stearolic, and behenolic acids, in place of $X = 48$ (that is, $60 - 12$), $X = 30 - 12 = 18$. Here again, as in the polyhydric alcohols, although the values of X appear to increase in a complex manner, the numbers 6, 12, and 18 recur.*

Data for acids having triple bonds are not very extensive. For a monobasic acid of this class, namely, tetrolic acid, $X = 42$ (that is, $60 - 18$), whilst for acetylenedicarboxylic acid $X = 51$ (that is, $60 - 9$). These values are respectively less and greater than the values 48 (that is, $60 - 12$) and 42 (that is, $60 - 18$) anticipated from a consideration of the component thermal characteristics.

For saturated aldehydes and ketones, it has been seen that the thermal characteristics are positive and equal to 12 and 6, respectively. The presence of double bonds increases these values according to the number of bonds. This is seen from Table V, where under m are tabulated the respective sums of the number of double bonds and carbonyl groups.

* It is to be noted that acrylic acid, the first representative of a homologous series of unsaturated acids, is an exception to this rule.

TABLE V.

Substance.	Formula.	X.	m.	Q (calc.).	Q (obs.).
Mesityl oxide	$C_9H_{10}O$	12	2	845.8	846.8
Allylacetone	$C_9H_{10}O$	24	2	857.8	857.7
Ethyl allyl ketone .	$C_9H_{10}O$	24	2	857.8	858.1
Crotonaldehyde ...	C_6H_8O	24	2	543.8	542.7
Diallylacetone	$C_9H_{10}O$	36	3	1281.9	1282.3
Citral	$C_{10}H_{14}O$	36	3	1438.9	1458.7
Benzoquinone	$C_6H_4O_2$	48	4	654.8	654.8

The calculated values of Q given in the fifth column, and based on the respective values of X , all multiples of 12, contained in the third column, are in very close agreement with the observed values of Q given in the last column. The largest value of X , namely, 48, characterises benzoquinone, a diketone having two double bonds. For citral and diallylacetone, both having two double bonds, $X = 36$, whilst for crotonaldehyde, ethyl allyl ketone, and allylacetone, each with one double bond, $X = 24$. For all these, $X = 12m$. For mesityl oxide, however, $X = 6m$ only. The various numbers are not derivable by the addition to the thermal characteristic of the corresponding saturated aldehyde or ketone of a constant corresponding to each double bond. It is to be noted, however, that mesityl oxide and crotonaldehyde can be prepared by condensation of the corresponding saturated compounds, and that, regarded from this point of view, their respective thermal characteristics can be readily calculated by addition and are equal, respectively, to 2×6 , corresponding to condensation of acetone, and 2×12 in the corresponding case of the aldehyde. In each case, the double bond is associated with a value of X characterising the double oxygen-carbon bond which it replaces. The thermal characteristics associated respectively with the double carbon bond and the double oxygen-carbon bond vary within wide limits, but the respective series of values are all multiples of a constant.

IV. Aromatic Compounds.

Prior to the examination of aromatic compounds, formed by the combination of benzene nuclei with aliphatic residues, the thermochemical data available for certain saturated cyclic hydrocarbons will be considered. These are given in Table VI, values of Q being calculated on the assumption that for these substances $X = 0$.

It is seen that on this assumption the observed values of Q are in very close agreement with the respective calculated values. In the case of benzene, a similar assumption would lead to a difference of 2 per cent. between the calculated and observed values of Q . In Table VII, thermochemical data for benzene and some of its

TABLE VI.

Substance.	Formula.	Q (calc.).	Q (obs.).	$100 \frac{Q \text{ (calc.)} - Q \text{ (obs.)}}{Q \text{ (obs.)}}$
cyclohexane	C_6H_{12}	942.0	945.1	-0.3
Dimethylcyclohexane.	C_8H_{16}	1256.0	1256.6	-0.05
Methylcycloheptane...	C_7H_{14}	1256.0	1257.1	-0.1
Trimethylcyclohexane	C_9H_{18}	1413.0	1409.9	+0.22
Ethylcycloheptane ...	C_9H_{18}	1413.0	1420.9	-0.5
Methylpropylcyclohexane	$C_{10}H_{20}$	1570.0	1566.5	+0.23

homologues are given. The calculated values of Q are in each case based on the value $X = 15$.

TABLE VII.

Substance.	Formula.	Q (calc.).	Q (obs.).	$100 \frac{Q \text{ (calc.)} - Q \text{ (obs.)}}{Q \text{ (obs.)}}$
Benzene	C_6H_6	778.8	779.7	-0.11
Toluene	C_7H_8	935.8	934.4	+0.15
Xylene	C_8H_{10}	1092.8	1092.0	+0.08
Mesitylene	C_9H_{12}	1249.8	1251.9	-0.17
Propylbenzene	C_9H_{12}	1249.8	1250.6	-0.07
Propyltoluene	$C_{10}H_{14}$	1406.8	1406.9	-0.01

This value of X is seen to be in agreement with the observed values of Q for benzene and its homologues. The thermal characteristic associated with the whole of the six carbon bonds in benzene is exactly one-half of the value of X characterising the double bond in ethylene. In contradistinction to the thermal characteristic of unsaturated compounds, the thermal characteristic associated with the bond remains constant throughout the series of aromatic hydrocarbons and combinations thereof with aliphatic groups having a double or triple bond. Data relating to these are contained in Table VIII.

TABLE VIII.

Substance.	Formula.	X .	Q (calc.).	Q (obs.).
Diphenyl	$C_{12}H_{10}$	30	1498.2	1495.1
Diphenylmethane	$C_{12}H_{12}$	30	1655.2	1656.6
Dibenzyl	$C_{14}H_{14}$	30	1812.2	1812.4
Styrene	C_8H_8	30	1048.4	1047.3
Methylstyrene	C_9H_{10}	30	1205.4	1204.6
α -Phenyl- Δ^8 -butylene	$C_{10}H_{12}$	30	1205.4	1203.8
Stilbene	$C_{14}H_{12}$	45	1767.8	1766.8
Triphenylmethane	$C_{18}H_{16}$	60	2389.6	2388.7
Triphenylbenzene	$C_{18}H_{16}$	60	2937.0	2939.6
Phenylmethylstyrene	$C_{13}H_{14}$	60	1937.8	1940.7
Tolane	$C_{11}H_{10}$	75	1738.4	1738.9
Tetraphenylmethane	$C_{20}H_{16}$	75	3109.0	3105.7
Diphenylstyrene	$C_{20}H_{18}$	90	2514.2	2511.6

The respective values of X are in every case simple multiples of 15, and the calculated values of Q are in very close agreement with experimental values, the difference in one case only—

diphenyl—amounting to as much as 0.2 per cent. The experimental result in this case, it is to be noted, is based on an old and isolated observation. From the cases of styrene and stilbene it is seen that a double bond occasions an increase of 15 in the value of the thermal characteristic. The transition from a double to a triple bond, however, produces an increase of 30 in the value of X , as is seen by comparing the respective values for stilbene and tolane. This value 30 corresponds to the value of X associated with the ethylene linking (see Table III). Generally, the respective values of X are obtained by a process of simple addition, but in the cases of triphenylmethane, diphenylstyrene, and phenylmethylstyrene this is not so. The value $X = 60$ for triphenylmethane gives a value of Q (calc.) in agreement with the value recently determined experimentally by Schmidlin, which is given in the table. The same holds for triphenylcarbinol. Assuming $X = 60$ for this substance, it is found that for this substance Q (calc.) = 2340.8, compared with the experimental value 2341.8. The anticipated value of X for each of these substances, containing three phenyl groups, would be 45. The presence of the third phenyl group therefore occasions an additional increase of 15 in the value of X . Such additional increase is not, however, associated with the introduction of a fourth phenyl group, for in the case of tetraphenylmethane $X = 75$, an increase of only 15 from the value, 60, characterising the triphenyl compounds. The transition from diphenylethylene (stilbene) to diphenylstyrene, with three phenyl groups, occasions an additional increase of 30, for to the latter corresponds a value $X = 90$. A smaller effect of the same nature accompanies the introduction of a methyl group in place of a third additional benzene nucleus. Thus the value of X for phenylmethylstyrene, according to the number of benzene rings, should be 45, but is actually found to be 60.

Among groups combining with benzene nuclei, the amino- and hydroxyl-groups are characterised by the fact that they are without appreciable influence on the value of the thermal characteristic. Thus for toluidine, as for benzene, the value $X = 15$ affords a value of Q in close agreement with the experimental value. In the case of aniline, a considerable difference is found between the calculated and experimental values of Q , but this is to be anticipated, for the experimental values of Q , in this case, differ considerably among themselves. For phenol, the experimental values of Q range from 737.5 to 732.9. The latter value agrees fairly well with that calculated on the assumption $X = 15$, namely, 730.3. For other phenols, in like manner, X being assumed equal to 15, differences of a few tenths of 1 per cent. are found between experi-

mental and calculated values. In the case of phloroglucinol, however, assuming $X = 15$, such difference amounts to 2.6 per cent. It is to be noted that in this case the experimental and calculated values are brought into agreement by assuming $X = 0$, a result probably connected with the tautomerism exhibited by this substance.

The alkylation of a phenol, whereby hydroxylic hydrogen is replaced by the alkyl group, is accompanied in every case by an increase of 15 in the value of X . As in the case of the polysaccharides, this increase is attributable to the presence of oxygen forming a bond between carbon atoms. Data relating to some aromatic ethers and aldehydes are contained in Table IX.

TABLE IX.

Substance.	Formula.	X .	Q (calc.).	Q (obs.).
Anisole	C_7H_8O	30	902.0	901.8
Phenetole	$C_8H_{10}O$	30	1059.0	1057.9
Tolyl methyl ether	$C_8H_{10}O$	30	1059.0	1058.0
Phenyl propyl ether	$C_9H_{12}O$	30	1216.0	1214.3
Xylyl methyl ether	$C_9H_{12}O$	30	1216.0	1214.6
Resorcinol dimethyl ether.	$C_8H_{10}O_2$	45	1025.2	1023.6
<i>iso</i> Eugenol	$C_{10}H_{12}O_2$	45	1279.8	1278.8
<i>iso</i> Safrole	$C_{10}H_{10}O_2$	60	1235.2	1235.1
Asarone	$C_{11}H_{12}O_2$	75	1575.0	1577.7
Benzaldehyde	C_7H_6O	30	842.6	842.1
Hydroxybenzaldehyde ...	$C_7H_6O_2$	30	793.8	793.7
Cinnamaldehyde	$C_9H_8O_2$	45	1112.7	1113.4
Vanillin	$C_8H_8O_3$	45	917.0	915.0
Piperonal	$C_8H_8O_3$	60	872.8	870.9

Here again it is seen that all values of X are simple multiples of 15. It is to be noted that whilst the presence of the hydroxyl group in hydroxybenzaldehyde, vanillin, and *isoeugenol* does not affect the value of X appreciably, a double bond, as in the case of the hydrocarbons, increases the value by 15, provided such double bond occurs adjacent to the benzene ring. For eugenol and safrole, in which the double bond is situated at the end of the side chain, the respective calorific values are greater by about 10 than the values for the corresponding *iso*-compounds given in Table IX. In contradistinction to the case of the aliphatic compounds, the double bond of the carbonyl group in aromatic aldehydes produces an increase of 15, and not 12, in the value of X . This same increase of 15 is occasioned by the presence of double carbonyl bonds in the case of the aromatic ketones, as is seen from the data given in Table X.

It is seen that the respective thermal characteristics of the aromatic ketones are of the customary additive nature, the greatest value, 60, characterising benzil, which is constituted of two benzene nuclei and two carbonyl groups. The case of the quinones is different.

TABLE X.

Substance.	Formula.	X.	Q (calc.).	Q (obs.).
Acetophenone	C_8H_8O	30	999.6	1001.9
Benzophenone	$C_{12}H_{10}O$	45	1562.0	1558.8
Benzoin	$C_{14}H_{12}O$	45	1670.2	1673.1
Anthraquinone	$C_{14}H_8O_2$	45	1551.4	1549.0
Alizarin	$C_{14}H_8O_4$	45	1453.8	1453.1
Benzil	$C_{14}H_{10}O_2$	60	1626.8	1626.2
Phenanthraquinone	$C_{14}H_6O_2$	75	1581.4	1578.5

Here, practically no change in the value of X accompanies the transition from anthracene to anthraquinone, for according to Berthelot and Vieille, for anthracene $Q = 1708.4$, corresponding exactly with the value $X = 45$. This is attributable to the fact that no material structural alteration accompanies the transition, as two benzene nuclei are unaffected and become merely interconnected by a similar nucleus containing two carbonyl groups. The latter do not increase X by 30, as in the case of benzil, but by 15 only. The transition from benzene to benzoquinone, however, occasions a complete reconstruction of the molecule, involving the introduction of two double bonds, accompanied by an increase in the value of X from 15 to 48. The two hydroxyl groups present in alizarin are without appreciable effect on the value of X . Anthraquinone and phenanthraquinone are examples of isomerides differing considerably in calorific value, the difference in the present instance amounting almost to 30. The value of X in the case of the former is 15 units less than the value corresponding to a diketone, whilst it is correspondingly greater by this amount in the case of phenanthraquinone. In the former case, the ring interconnecting the outer benzene nuclei is symmetrical; in the latter, there is no such symmetry of molecular structure.

Examples of compounds of comparatively simple molecular composition, but nevertheless characterised by large values of X are to be found, as seen from Table XI, among the aromatic derivatives of hydrazine and of di-imine.

TABLE XI.

Substance.	Formula.	X.	Q (calc.).	Q (obs.).
Phenylhydrazine	$C_6H_8N_2$	60	883.2	880.4
Hydrazobenzene	$C_{12}H_{12}N_2$	75	1602.2	1600.2
Azobenzene	$C_{12}H_{10}N_2$	90	1558.2	1556.7
Aminoazobenzene	$C_{12}H_{11}N_3$	90	1587.9	1582.6
Benzeneazophenol	$C_{12}H_{10}ON_3$	90	1509.4	1509.8
Azoanisole	$C_{14}H_{14}O_2N_2$	120	1804.6	1806.3

Here again, the values of X are multiples of 15, commencing with the value $X = 60$ for the simplest representative, hydrazine. Subtracting from this value the number 15 appropriate to the

phenyl group, and similarly subtracting from the value 75 for hydrazobenzene the number 30 associated with the two phenyl groups, one finds the value 45 representing the effect of the $\text{NH}\cdot\text{NH}$ group in these compounds. In like manner, calculated from the values of X for the azo-derivatives given in the table, the value 60 represents the increment in the value of X attributable to the presence of the $\text{N}\cdot\text{N}$ group. This value corresponds with the value of X for acetylene, but whereas the addition of two hydrogen atoms to the latter decreases the value of X by 30, here the corresponding decrease is 15 only. From the table, it is again seen that the hydroxyl and the amino-group do not affect the value of X appreciably.

As is the case with aliphatic acids, so also with aromatic acids the value of X is decreased owing to the presence of the carboxyl group, with this difference, however, that negative values are not found in the latter case. Thus, experimental and calculated values of Q for the monobasic acids (benzoic, phenylacetic, phenylpropionic, toluic, and mesitylenic), for the dibasic acids (*o*- and *p*-phthalic and uvitic), and for tetrabasic pyromellitic acid are in close agreement on the assumption that for these acids $X = 15 - 6 = 9$. For tribasic trimesic acid, $X = 15 - 12 = 3$, and for hexabasic mellitic acid, $X = 30 - 6 = 24$.

These values for the acids can be used to calculate the respective values of X for the corresponding esters, the esterification, like the etherification of a phenol, being accompanied by an increase of 15 in the value of X . Thus for benzoic acid, $X = 9$, for the ester, $X = 9 + 15 = 24$. Using this value of X , one finds, for the ester, Q (calc.) = 944.8, compared with the experimental value, Q (obs.) = 944.4; equally close agreement between experimental and calculated values is found throughout the series of benzoic esters. For the dimethyl esters of the phthalic acids, for which $X = 9 + 30 = 39$, calculation gives $Q = 1116.8$, in close agreement with the experimental values of Q ranging from 1113.2 to 1120.8. Owing to the decrease in the value of X attributable to the carboxyl group, the values of X for the aromatic esters are of the same order of magnitude as for the aliphatic ethers.

It is of interest to note that for dihydrophthalic acid, $X = 18$, as in the case of aliphatic acids having two double bonds. For hexahydrophthalic acid, $X = -12$, as for homologues of malonic acid. Similarly, the values of the thermal characteristic of mellitic acid ($X = 24$) and hexahydromellitic acid ($X = -18$) correspond respectively to the values of X for succinic acid and its homologues. In the case of hexahydromellitic acid, Q (calc.) = 924.0, and Q (obs.) = 924.1.

V. Conclusion.

The application of the method developed in the present work to other series of compounds is at present impossible owing, in some cases, to insufficient agreement among the experimental values of Q in the case of individual compounds; these discrepancies are due partly to the use of materials of different degrees of purity in the several investigations. In other cases, the calculated values of the deviations of the thermal characteristic from the normal level ($X = 0$) are of the order of magnitude of the experimental error, and data relating to these cases have not been examined in the light of the theory developed. Thus for the calculation of the thermal characteristics of ethers and esters use has been made only of data referring to the aromatic series. In the case of aliphatic ethers, sufficiently accurate data are available only for gaseous methyl ether and liquid ethyl ether. In the latter case, assuming $X = 15$, it is found that Q (calc.) = 653.6, which agrees closely with the experimental value, Q (obs.) = 652.3 kg.-cals. Data relating to aliphatic esters are scanty and in many cases have been obtained by methods which would not be regarded as satisfactory nowadays. Assuming the value $X = -6$ for acetic acid, the corresponding value of X for ethyl acetate would be $X = 15 - 6 = 9$. This gives a value of Q (calc.) = 539.5, which agrees fairly well with the experimental value, Q (obs.) = 537.4. For oxalic acid, $X = 0$. For its dimethyl ester, therefore, $X = 30$, and Q (calc.) = 403.4, whereas the value of Q (obs.) is 402.3. In like manner, for maleic acid $X = 12$; the value of X for the corresponding dimethyl ester is therefore $30 + 12 = 42$. Using this value of X , calculation gives for the latter substance, $Q = 670.0$, which agrees very closely with the experimental value 669.9.

With the possible exception of data relating to the series of carbylamines, it appears that in all other cases the appropriate value of X in equation (2) is a multiple of 3. The equation may therefore be written in the form

$$P = 48.8n \pm 3S \quad . \quad . \quad . \quad (3)$$

where n and S are both whole numbers. The experimental results are best interpreted, however, by regarding the values of X for aliphatic compounds as multiples of 6, whilst in the case of aromatic compounds they are multiples of 15. The common factor 3 represents the value of the thermal characteristic of compounds containing in the molecule only a single atom of carbon. The constants 48.8 and 3 in equation (3) may now be interpreted as follows: the former represents the calorific value of amorphous carbon; the latter is very approximately equal to the heat of transformation

of amorphous carbon to the crystalline state. In the case of transformation into graphite, the corresponding experimental value is 2.8, whilst in the case of transformation into diamond, the corresponding value is 3.3.

A discontinuity in the value of X accompanies the transition from the first to the second member of a homologous series. This is attributable to a change in the strength of the linking in the two cases. When the alkyl group is substituted for hydrogen linked with carbon in groups containing oxygen, the value of the thermal characteristic is decreased by an amount equal to three times the number of valencies of the carbon atom in question satisfied by oxygen and not directly affected by the substitution. The same rule applies in the case of nitrogen linkings. In other cases, changes in the value of the thermal characteristic accompany the production or destruction of linkings between multivalent atoms. Nitrogen linkings in azobenzene have the same thermal characteristic as carbon linkings in acetylene. In the formation of unsaturated aldehydes and ketones by the condensation of the corresponding saturated compounds, the value of the thermal characteristic is increased owing to the replacement of carbonyl bonds by double bonds. Oxygen, linking together carbon atoms, increases the thermal characteristic by 15. The same is probably true of nitrogen. Thus, when nitrogen is substituted for one CH group in benzene, the value of X increases from 15 to 30, the latter value giving for pyridine the value Q (calc.) 666.5 compared with the experimental value Q (obs.) 665.5. Similarly for piperidine, $X = 15$, whilst for cyclohexane $X = 0$.

Heats of formation of organic substances are generally calculated from the values of the heats of combustion, carbon being assumed to be present in the form of diamond. Such calculated values, although subject to the experimental errors made in the determination of the respective heats of combustion employed in the calculation, and characterised by little physical reality, are of considerable use for purposes of calculating thermochemical data relating to reactions between organic substances. From equation (2), it is seen that the heat of formation of an organic substance from its elements, assuming carbon to be in the solid amorphous state, is given by

$$q = 4.7h + 48.8k \mp X \quad (4)$$

where h and k represent respectively the number of atoms of hydrogen and oxygen present in the molecule of the substance, and X represents, as before, the thermal characteristic of the substance. It is to be noted that, according to (4), the respective heats of formation of organic substances (1) do not depend on the

number of carbon atoms present in the molecule of the substance, (2) increase with an increase in the number of hydrogen and oxygen atoms, respectively, present, an increase of the latter producing the greater effect, (3) decrease with an increase in the value of the thermal characteristic. In the case of substances containing no oxygen and characterised by large values of X , negative values for the respective heats of formation may be afforded by (4). Thus for acetylene, $X = 60$ and $q = 9.4 - 60 = -50.6$; for azobenzene, $X = 90$ and $q = 47 - 90 = -43$.

Heats of reaction can be calculated by (2) without a knowledge of the values of q involved being available. The calculation involves only a knowledge of the values of X appropriate to the reaction. Thus, as the amino-group does not affect the value of the thermal characteristic, the heat of transformation of hydrazobenzene into benzidine is $75 - 30 = 45$ kg.-cals., 75 and 30 being the values of the thermal characteristics of hydrazobenzene and of the two phenyl groups contained in benzidine.

When compounds characterised by positive values of X are transformed into compounds of normal level ($X = 0$), the difference of the initial and the final value of the thermal characteristic is manifested as heat of transformation. Thus in the case of alcoholic fermentation of glucose, heat equivalent to 24 kg.-cals. should be evolved per gram-molecule of glucose, the value of X for glucose being 24. Carbohydrates are characterised by large values of X , and as the heat evolved during their hydrolysis is $15 - 10.6 = 4.4$ kg.-cals. per gram-molecule of liquid water, it is to be anticipated that their transformation into substances of normal level would be accompanied by considerable evolution of heat. Cellulose and other plant products would in this manner be transformed into mineral fuel by successive decreases in the value of the thermal characteristic until the normal level was attained. By means of equation (1), the calorific value, p , of such fuels per unit mass is found to be

$$p = 3.05l \quad (5)$$

where l is the amount of oxygen consumed in the combustion of unit mass of the fuel. Wood consists chiefly of cellulose, and its calorific value is about 7 per cent. greater than that calculated by (5). Experimentally determined calorific values of various coals frequently agree within the limit of experimental error with the corresponding value calculated by (5). The same is true of various naphthas, composed of mixtures of paraffins and naphthenes with small amounts of other substances.

CCXLIV.—*The Quinhydrone Electrode as a Comparison Electrode.*

By STIG VEIBEL.

BIILMANN has shown (*Ann. Chim.*, 1921, [ix], 15, 109) that in the measurement of the concentration of hydrogen-ions, the usual hydrogen electrode may in several cases be replaced by a quinhydrone electrode, formed by dissolving a small quantity of quinhydrone in the electrolyte under investigation, and placing a piece of blank platinum in the solution. The quinhydrone then represents a potential pressure of hydrogen, which is constant but very feeble. The quinhydrone electrode functions as a hydrogen electrode with a pressure of hydrogen of $10^{-24.40}$ atm. at 18° and $10^{-23.34}$ atm. at 25° . Against a hydrogen electrode with a pressure of hydrogen of 1 atm. it has a potential of 0.7044 volt at 18° , the electrolyte being 0.1N-hydrochloric acid; in other dilute acids, very nearly the same potential is reached.

Biilmann and Lund (*Ann. Chim.*, 1921, [ix], 16, 327) have further shown that in more concentrated solutions the simple quinhydrone electrode may be replaced by an electrode which contains quinhydrone and an excess of either quinol or quinone. These electrodes are named the hydro-quinhydrone electrode and the quino-quinhydrone electrode respectively.

The quinhydrone electrode, which has been under investigation in this laboratory during more than three years, is so simply prepared and acquires its potential so rapidly and preserves it constant for so long, that it seemed natural to try to apply it as a comparison electrode which could in a number of cases be more easily prepared and made use of than the calomel or the hydrogen electrode. One of its advantages is that freshly prepared comparison electrodes can be obtained in a few minutes.

At the suggestion of Professor Biilmann, I have examined the possibility of preparing a quinhydrone electrode which will rapidly acquire a well-defined potential, will be durable enough for most purposes, and will have none or but a very feeble liquid-junction potential.

For this purpose, either the electrodes in solutions of weak organic acids examined by Biilmann or electrodes with 0.01N-hydrochloric acid + 0.09N-potassium chloride as electrolyte might be suitable. According to the determinations of Bjerrum (*Z. Elektrochem.*, 1911, 17, 391), the liquid-junction potential of the latter mixture against 1.75N-potassium chloride is only 0.0004 volt. The concentration of hydrogen-ions, according to the measurements

of Sørensen, is $10^{-2.04}$ (*Compt. rend. Trav. Lab. Carlsberg*, 1909, 8, 24).

The Biilmann Electrode with a weak Organic Acid as Electrolyte.

$M/32$ -Fumaric acid or $M/20$ -oxalic acid was used as electrolyte. The electrodes were measured against a $3.5N$ -calomel electrode. The element was $Pt \left[\begin{array}{c} \text{Quinh. Oxalic acid } (M/20) \text{ or} \\ \text{solid fumaric acid } (M/32) \end{array} \right] KCl \left[\begin{array}{c} KCl \\ 3.5N \end{array} \right] Hg_2Cl_2 \left[\begin{array}{c} Hg \\ 3.5N \text{ solid} \end{array} \right]$

Table I shows the accuracy which may be attained in the preparation of the electrodes.

TABLE I.

I. Fumaric Acid.		Potential in volt.			
$\frac{1}{2}$ hour	0.3195	0.3199	0.3199	0.3196	
18 hours	0.3181	0.3180	0.3198	0.3187	
II. Oxalic Acid.					
$\frac{1}{2}$ hour	0.3637	0.3640	0.3633	0.3642	
18 hours	0.3617	0.3633	0.3627	0.3635	
66 "	—	—	0.3615	0.3621	

This table, compared with those in Biilmann's memoir (*loc. cit.*, p. 136), shows that the electrodes acquire their potential very rapidly and preserve it for a few hours. But the durability is not great enough to enable the electrodes to be kept from one day to another.

The potential in the fumaric acid solution is smaller than the value originally found by Biilmann. His measurements were made with a preparation of fumaric acid which had been bought as "pure." In view of the importance of the present investigation, the equivalent weight of that sample was determined, and found to be too high. The fumaric acid was therefore purified by two crystallisations from water; its equivalent was now 58.08 (calc. 58.02).

The Biilmann Electrode with 0.01N-Hydrochloric Acid + 0.09N-Potassium Chloride as Electrolyte.

The potential was measured directly against a hydrogen electrode with the same electrolyte. The rapidity of the current of hydrogen had no influence on the potential.

The element examined was :

The electrodes were so constant that in order to observe their variation, I had to determine the potentials to five decimal places. The total variations for all the electrodes, however, were larger, so that the mean value is given only to four places.

Table II shows the reproducibility and the durability of the electrodes. All potentials are corrected to dry hydrogen at a pressure of 760 mm. of mercury.

The measurements were carried out with a galvanometer and a Wolff compensator. The standard cell was compared with a recently controlled Weston standard cell. The potassium chloride solution was prepared by dissolving the calculated quantity of the freshly fused salt ("Kahlbaum") in the requisite weight of water. The hydrochloric acid was standardised against ash-free mercuric oxide (Ince, *Z. anal. Chem.*, 1917, **56**, 177; compare Billmann and Thaulow, *Bull. Soc. chim.*, 1921, [iv], **29**, 590); in three estimations, the normalities found were 0.10000, 0.09996, and 0.10000; mean 0.09999. The solution to be used was then prepared by measuring with the same pipette one part of the hydrochloric acid and nine parts of the potassium chloride solution.

TABLE II.

Electrode. Time.	A.	B.	C.	D.	E.	F.	G.	H.
	Potential in volt.							
5 min.	0.7042 ₂	0.7042 ₂	0.7041 ₄	0.7041 ₂	—	—	0.7037 ₁	0.7036 ₂
1 hour	0.7039 ₂	0.7039 ₂	—	—	—	—	—	—
1½ hours ...	—	—	0.7041 ₂	0.7041 ₂	0.7040 ₂	0.7040 ₂	0.7040	0.7039
5 "	—	—	0.7041 ₂	0.7041 ₂	0.7039 ₂	0.7039 ₂	—	—
20 "	0.7039 ₂	0.7040 ₂	0.7038 ₂	0.7038 ₂	0.7037 ₂	0.7037 ₂	0.7041	0.7041
48 "	0.7039 ₂	0.7039 ₂	—	—	—	—	0.7039	0.7039
72 "	0.7039 ₂	0.7038 ₂	—	—	0.7032 ₂	0.7032 ₂	—	—
144 "	0.7031	0.7031	0.7031	0.7031	—	—	—	—

It will be seen from the table that the reproducibility is excellent and the durability, at any rate for the first forty-eight hours, is satisfactory.

The mean value of the measurements during the first forty-eight hours, with the exception of those made with the electrodes G and I, which have at first a too feeble potential, is 0.7040 volt. The greatest deviation from this value is 0.00035 volt, and occurs in the case of the electrodes whose potentials have been disregarded in computing the average. The deviation from the mean value of the trustworthy measurements has a maximum value 0.00028 volt; as a rule, it is less than 0.0002 volt, so that for ordinary purposes the potential of the quinhydrone electrode with the foregoing electrolyte may be reckoned as 0.7040 ± 0.0002 volt.

Billmann and Lund (*loc. cit.*, p. 323) determined the potential of the quinhydrone electrode in 0.01N-hydrochloric acid + 0.09N-sodium chloride, and found the value 0.7042 volt. The concordance between their determination and mine is excellent.

If the values of the potential determined with the quinhydrone electrode are to be compared with the values obtained with a

0.1N-calomel electrode, 0.2485 volt must be subtracted from the former. This result may be calculated in the following way:

The Reproducibility of the Calomel Electrode.

As is well known, the calomel electrode is somewhat "capricious" when prepared under the usual laboratory conditions, that is, when one has not, through frequent repetition, obtained a certain method of preparation. The result of such caprice may be that, for instance, only two out of three electrodes will give concordant potential values. In order to compare this variability with the corresponding unsteadiness of the Biilmann electrode, I have prepared a number of calomel electrodes, both 0.1N and 3.5N. Since size of grain of the calomel might be of consequence (compare Sauer, *Z. physikal. Chem.*, 1904, 47, 146), the calomel, prepared by precipitation, was separated by elutriation into three fractions, fine-, medium-, and coarse-grained. The fine- and the coarse-grained samples were used for the preparation of electrodes.

In Tables III and IV, the electrodes of "fine" calomel are indicated by the letters *a, b, c, . . .* for the 0.1N-electrodes, and by *a₁, b₁, c₁, . . .* for the 3.5N-electrodes. Electrodes of "coarse" calomel are marked, respectively, *A, B, C, . . .* and *A₁, B₁, C₁, . . .*

TABLE III.

0.1N-Calomel electrodes.

All the electrodes are measured against the electrode A.

Time.	Potential in volt.						
	B.	C.	D.	E.	F.	G.	H.
1 hour	0.00000	0.00050	0.00065	0.00034	0.00027	0.00007	0.00100
24 hours	0.00000	—	—	—	—	0.00013	0.00039
	<i>a.</i>	<i>b.</i>	<i>c.</i>	<i>d.</i>	<i>e.</i>		
1 hour	0.00010	0.00000	0.00044	0.00000	0.00009		
24 hours	0.00002	0.00003	—	0.00000	0.00002		

As may be seen from this table, the electrodes of "coarse" calomel are much less reproducible than the Biilmann electrode. The reproducibility of the electrodes of "fine" calomel, on the contrary, is similar to that of this electrode.

* Koefoed; see Auerbach, "Messungen electromotorische Kräfte," 1915, *Ite Erg.*, 21.

TABLE IV.
3·5*N*-Calomel electrodes.

All the electrodes are measured against the same 0·1*N*-electrode.

	Potential in volt.						
Time.	A ₁ .	B ₁ .	C ₁ .	D ₁ .	a ₁ .	b ₁ .	c ₁ .
1 hour	0·1978	0·08376	0·08361	0·08362	0·08386	0·08381	0·08370
24 hours	0·08361	0·08358	0·08286	0·08295	0·08364	0·08367	0·08290

The reproducibility here is of the same degree as, but does not surpass, that of the Biilmann electrode.

Summary.

1. The Biilmann quinhydrone electrode with 0·1*N*-hydrochloric acid + 0·09*N*-potassium chloride as electrolyte acts excellently as a comparison electrode which rapidly acquires its potential.

2. The potential of the electrode is $0·7040 \pm 0·0002$ volt, measured against a hydrogen electrode with the same electrolyte, and $0·2485 \pm 0·0002$ volt, measured against a 0·1*N*-calomel electrode.

3. The reproducibility is the same as that of a 3·5*N*-calomel electrode and considerably greater than that of a 0·1*N*-calomel electrode. Only if the calomel is divided by washing into fine-grained and coarse-grained portions, and then only if the fine-grained portion is used as the electrode, is the reproducibility of the 0·1*N*-calomel electrode of the same order as that of the Biilmann electrode.

I thank Professor Biilmann for the interest he has taken in my experiments, and for his valuable assistance and advice.

THE CHEMICAL LABORATORY,
THE UNIVERSITY, COPENHAGEN.

[Received, June 14th, 1923.]

CCXLV.—*Bromination of Compounds containing the Carbonyl Group. (a) Pyruvic Acid. (b) Acetophenone.*

By CHARLES FREDERICK WARD.

THE bromination of pyruvic acid has been studied by several investigators (Wichelhaus, *Ber.*, 1868, **1**, 265; *Annalen*, 1869, **152**, 265; Wislicenus, *ibid.*, 1868, **148**, 218; Clermont, *Bull. Soc. chim.*, 1873, [ii], **19**, 103), but no product corresponding to a pure monobromopyruvic acid has been described. Wislicenus (*loc. cit.*), by treating pyruvic acid with bromine at 0°, prepared a crystalline

substance, $\text{CH}_2\text{Br}\cdot\text{CBr}(\text{OH})\cdot\text{CO}_2\text{H}$, which lost hydrogen bromide when exposed to moist air, giving an oily product which he called bromopyruvic acid.

As it was thought that a study of the bromination of pyruvic acid might help to elucidate the mechanism of the halogenation of compounds containing the carbonyl group, pure pyruvic acid was treated with bromine, under various conditions. What was apparently a simple reaction, giving an impure product, has been shown to be a series of complex changes resulting in the formation of pure, crystalline monobromopyruvic acid.

Ethyl pyruvate also has been brominated. Although no intermediate stages have been observed, the presence of a trace of sulphuric acid or hydrogen bromide causes a vigorous reaction to set in at the ordinary temperature, whereas the ester will react with bromine alone only at about 50° .

Although α -bromoacetophenone has long been known and may be prepared by a variety of methods, nothing appears to have been recorded as to the mechanism of the reaction.

It is here shown that pure bromine and acetophenone react under certain conditions, giving a very unstable, crystalline compound which very readily changes into a red oil and finally into bromoacetophenone and hydrogen bromide. The bromination is so rapid that up to the present it has been found impossible to show that it is accelerated by a trace of acid, as is the case in the bromination of acetic acid, pyruvic acid, and acetone.

EXPERIMENTAL.

Bromination of Pyruvic Acid.

The yield of pyruvic acid given by the method usually employed, namely, dry distillation of a mixture of tartaric acid and potassium hydrogen sulphate, can be increased considerably by carrying out the reaction in a large flask (2-litre for 300 grams of the mixture) at $220\text{--}225^\circ$ without any lowering of temperature during the experiment. There is no undue frothing and the reaction is completed in a much shorter time. The yield is 50–60 per cent. of the theoretical.

The pyruvic acid was purified by distillation under reduced pressure, and boiled at $65^\circ/12$ mm. It was further purified from traces of water by freezing, rejecting each time the portion having the higher melting point.

The experiments at 0° described by Wislicenus (*loc. cit.*) were repeated with specially purified materials. With pyruvic acid and bromine alone, no reaction was apparent until after a period which

varied from four to ten hours, even with different portions of the same mixture. At about 10° , the bromine and the pyruvic acid were miscible, but on cooling to 0° , two layers separated, the upper one consisting of pyruvic acid and the lower one of bromine. When cooled below 0° , the pyruvic acid solidified to a mass of colourless crystals surrounded by a red film of bromine. This series of changes could be reversed and repeated indefinitely.

As these results apparently contradicted those of Wislicenus, the experiment was repeated using pyruvic acid (15 grams), containing a trace of sulphuric acid or hydrogen bromide, and bromine (27 grams, dried with sulphuric acid), when the result was entirely different. The mixture solidified after a few minutes to a mass of bright red crystals resembling in appearance the product obtained from acetic acid, bromine, and hydrogen bromide under similar conditions. The crystals, still in the freezing mixture, gradually melted, and changed into a pale yellow glue and then into a hard mass of colourless crystals which fumed strongly in moist air. When this product was gently warmed, it melted between 60° and 70° , evolved much hydrogen bromide, and finally, when cooled, solidified to a colourless substance melting at $56-59^{\circ}$. This decomposition also took place if a stream of dry air or carbon dioxide were led over the product at the ordinary temperature or even in a freezing mixture, the final product in all cases being the solid of m. p. 59° . The same product was obtained when the substance, m. p. $60-70^{\circ}$, was dissolved in ether and the solvent removed by rapid evaporation. Although many attempts were made to obtain it, a pure intermediate compound could not be isolated.

The preceding decomposition product was rapidly extracted with 150–200 c.c. of hot benzene without the solution being actually boiled. On cooling, the bromo-acid separated in needle-shaped crystals, which were recrystallised from hot benzene or chloroform.

Instead of the sulphuric acid being added at the commencement of the reaction, the pyruvic acid may be caused to react with, say, 1 per cent. of the bromine at about 50° , the mixture cooled to 0° , and the experiment carried out as described above. The hydrogen bromide generated in this manner appears to activate the pyruvic acid almost as readily as a trace of sulphuric acid.

The most convenient way of preparing bromopyruvic acid in quantity is to treat pyruvic acid (1 mol.) with bromine (1 mol.) in small portions at about 50° . The hydrogen bromide is removed as completely as possible by passing a rapid current of dry air or carbon dioxide through the apparatus from the com-

mencement, and the product is then recrystallised as previously described.

Pure *bromopyruvic acid* is colourless and melts at 59° ; it is readily soluble in water, alcohol, acetone, or ether, sparingly soluble in benzene or chloroform, and almost insoluble in light petroleum or carbon tetrachloride. It is most conveniently recrystallised from hot benzene; when crystallisation is about to commence, a magnificent fluorescence will be observed which is of a brilliant violet colour with the pure acid, but may be purple or green under other conditions. The bromo-acid is usually obtained in clusters of irregular leaflets, but from benzene it may be deposited in long, thin, rectangular prisms and from chloroform in large, flat, regular hexagonal prisms; mixtures of the two forms were often observed and both forms had the same melting point.

The acid in aqueous solution reduces Fehling's solution rapidly (distinction from pyruvic acid), gives a precipitate with phenylhydrazine acetate, and does not react with silver nitrate in the cold; on warming, silver bromide is rapidly deposited [Found: Br (volumetrically) = 47.1, 47.9; equiv. (by titration with $N/10$. alkali) = 84.1. $C_3H_3O_3Br$ requires Br = 47.8 per cent.; equiv. = 84.0].

Ethyl bromopyruvate, $CH_2Br\cdot CO\cdot CO_2Et$, was prepared by treating ethyl pyruvate (b. p. $46^{\circ}/13$ mm.) with bromine (1 mol.) at about 70° . The product was a pale yellow oil which on fractionation gave some ethyl pyruvate, a large proportion of ethyl bromopyruvate, b. p. $98-100^{\circ}/10$ mm., and a residue which probably consisted of condensation products of the ester.

Ethyl bromopyruvate, which is heavier than, but is rapidly hydrolysed by, water, gives all the reactions of bromopyruvic acid and yields with aniline a variety of products. It also appears to undergo some condensation when warmed with zinc or magnesium, either alone or in suspension in ether.

Colour Reactions of Pyruvic Acid and of Bromopyruvic Acid with Sodium Nitroprusside in Alkaline Solution.—It is well known that pyruvic acid reacts with sodium nitroprusside in alkaline media with the production of intensely coloured solutions, but the great variety and complexity of these colour reactions do not seem to have been recognised. The following observations were made on solutions prepared by dissolving about four drops of pyruvic acid or a few crystals of bromopyruvic acid in about 1 c.c. of water, adding 4 c.c. of the alkali (5 per cent.), and then 2 c.c. of a 0.5 per cent. solution of sodium nitroprusside. Where dilution is indicated, the solution was added to about 250 c.c. of water. Slight variations in conditions may produce quite different colour changes.

Acid.	Alkali.	Colour.	Colour on	Colour after
Pyruvic	NaOH	Dark crimson.	dilution. Indigo.	addition of acetic acid. Yellow, finally green.
"	Na ₂ CO ₃	Pink after 2 mins.	Pale pink.	Colourless.
"	NH ₄ OH	Bright blue after 1 min., then violet.	Blue.	"
Bromopyruvic	NaOH	Brown.	Emerald green, then blue.	Pale yellow.
"	Na ₂ CO ₃	Pale pink.	Paler pink.	Colourless.
"	NH ₄ OH	Brown.	No characteristic changes.	

It is possible to detect the presence of a very small quantity of pyruvic acid in aqueous solution; the concentration of the alkali, however, must be about 5 per cent. The colours given by pyruvic acid are much more marked than those given by the bromo-acid, and therefore it is possible to detect traces of unchanged pyruvic acid in the brominated product.

Bromination of Acetophenone.

(a) *In Absence of a Solvent.*—Bromine (8 grams) and acetophenone (6 grams) reacted very readily at room temperature, giving a colourless glue which fumed strongly.

Owing to the rapidity of the reaction, no intermediate stages could be observed. Most of the hydrogen bromide was removed in a current of dry air, and the product recrystallised from aqueous alcohol. The yield of pure bromoacetophenone (m. p. 51°) was 75 per cent. of the theoretical. The substance has a pungent odour and a very irritating action on the eyes and nose. It boils at about 133–135°/12 mm. with some decomposition.

(b) *Bromination in Carbon Tetrachloride Solution.*—Bromine (8 grams), dissolved in carbon tetrachloride (20 c.c.), was gradually added to a solution of acetophenone (6 grams) in the same solvent (20 c.c.). After about five minutes, the red solution deposited a mass of bright red crystals, leaving a colourless mother-liquor. The red crystals immediately began to decompose and finally a clear, colourless solution was obtained. The hydrogen bromide was removed in a current of dry air, the carbon tetrachloride distilled off, and the bromoacetophenone recrystallised from aqueous alcohol. The yield was 18 grams (90 per cent. of the theoretical). If the reaction is carried out at about 25°, the addition of each portion of bromine will cause a temporary bright red turbidity without separation of solid, whilst if the temperature of reaction exceeds 45°, the bromine may be added in a slow continuous stream and no additive compound will be apparent, the substances reacting immediately to give a clear, colourless solution. This was found to be the most convenient method for preparing bromoacetophenone.

Conclusions.

It is now known that in many cases the bromination of ketones and acids is preceded by the activation of the substance through the action of a trace of an acid, which may be either sulphuric acid or one of the halogen acids (hydrochloric or hydrobromic). This is particularly noticeable in the case of acetic acid, pyruvic acid, and ethyl pyruvate, less so in the case of acetone and ethyl malonate.

The next stage is a direct combination with bromine either after activation by the catalyst, or without any apparent preliminary change, as in the case of acetophenone, where no catalyst is required. The additive compounds, which are bright red, vary in stability. It is necessary to apply heat to decompose the compound derived from acetic acid into bromoacetic acid and hydrogen bromide. With pyruvic acid, the red additive compound slowly decomposes at the ordinary temperature, whilst with acetophenone the compound is only stable for a few seconds at the ordinary temperature.

The third stage is the least well-defined and has only been studied in the case of pyruvic acid, where the red additive compound slowly decomposes, giving a hard, colourless mass which is apparently an additive compound of bromopyruvic acid and hydrogen bromide.

The fourth stage also is very indefinite except in the case of pyruvic acid, where the white compound obtained in the third stage gradually decomposes into free hydrogen bromide and bromopyruvic acid. In many cases, the third stage cannot be distinguished, as the red additive compound decomposes directly, giving the bromo-acid or ketone and hydrogen bromide.

In many cases some of the stages are not observable and in others, notably with ethyl pyruvate and ethyl malonate, the reaction proceeds with almost explosive violence when it has once been started.

Compounds which are known to enolise are very readily brominated compared with those which are not usually regarded as being able to exist in an enolic form, and it is always the α -hydrogen atom which is substituted. These facts have been used as evidence in support of the theory of bromination which assumes the enolisation of the carbonyl group:

The results described above agree very well with this view, as

the stages observed in some of the reactions are precisely those to be expected. The theory, however, fails to explain the existence of the red additive compound, since there is no reason to suppose that the compounds formed by the addition of bromine to the enol form of a ketone or an acid should be highly coloured. Further, the theory demands the existence of an enolic form of compounds such as acetic acid, which form is never met in any other reactions of these compounds.

Whether a satisfactory explanation of the facts will be found in this theory or in some form of the theory of "molecular phases" of different energy content as put forward by Baly (*Phil. Mag.*, 1920, [vi], 40, 15; T., 1922, 121, 1014; *Brit. Assoc. Rep.*, 1922, 294) can only be determined by further experiment.

In conclusion, the author desires to thank Prof. F. S. Kipping, D.Sc., F.R.S., for his continued interest in this work.

CCXLVI.—*The Isomorphism of the Amides and Substituted Amides of Dichloro- and Chlorobromo-acetic Acids.*

By PHYLLIS V. MCKIE.

AN examination of the aryl dichloro- and chlorobromo-acetates from $\alpha\beta$ -dichlorovinyl ethyl ether (Crompton and Triffitt, T., 1921, 119, 1874) showed that corresponding pairs of these compounds had almost identical melting points, and appeared to be isomorphous, forming mixed crystals with one another in all proportions. It was of interest, therefore, to determine whether this property of isomorphism extended to the dichloro- and chlorobromo-acetamides and their *N*-substituted derivatives. A number of these compounds have been prepared and the fusion curves of mixtures of the corresponding dichloro- and chlorobromo-derivatives determined. Identity, or approximate identity, of melting point of each member of the pair holds in some cases—the dichloro- and chlorobromo-acetethylamides, the dichloro- and chlorobromo-acetanilides, and the dichloro- and chlorobromo-acetethylanilides, which resemble the corresponding aryl esters in this respect; whilst in others—the dichloro- and chlorobromo-acetamides, the dichloro- and chlorobromo-acetomethylamides, the dichloro- and chlorobromo-acetobenzylamides, and the dichloro- and chlorobromo-acetomethylanilides—the two melting points lie some distance apart, a distance

amounting in the case of the acetamides to as much as 26.3° . But in every case isomorphism of the corresponding dichloro- and chlorobromo-derivatives and the formation of mixed crystals with one another in all proportions appear to hold. Two types of curve have been obtained, however: (1) the melting points of all mixtures lie on a straight line between, or are identical with, the melting points of the two components, and (2) the melting points of mixtures fall slightly to a minimum value which is lower than the melting point of either of the constituents, pointing to the formation of mixed crystals in which the composition of the solid crystals is slightly different from that of the liquid. That this fall is not due to slight decomposition is shown by the identity of melting point obtained on remelting. Decomposition and hence fall of melting point, however, will inevitably occur if the heating is unduly prolonged. To the former type belong dichloro- and chlorobromo-acetamides, -acetoethylamides, -acetomethylanilides, and -acetobenzylamides; whilst the dichloro- and chlorobromo-acetanilides, the -acetoethylanilides, and the -acetomethylanilides conform to the second type.

EXPERIMENTAL.

Preparation of Material.—The ordinary methods of preparation of acid amides from the corresponding acid halides was applicable to the simple ammonia derivatives. The acid chloride obtained by the interaction of $\alpha\beta$ -dichlorovinyl ethyl ether with chlorine or bromine, and careful fractionation, yields, under these conditions, dichloroacetamide, m. p. 98.5° (96° , Geuther, *J.*, 1864, 317; 98° , Pinner and Fuchs, *Ber.*, 1877, 10, 1066) (Found: N = 10.93. Calc. for $\text{CHCl}_2\text{-CO-NH}_2$, N = 10.95 per cent.), and chlorobromoacetamide, m. p. 124.8° (117° , Conrad and Bruchner, *Ber.*, 1891, 24, 2995; $125\text{--}126^{\circ}$, Wolff and Fertig, *Annalen*, 1900, 312, 168) (Found: N = 8.13. Calc. for CHClBr-CO-NH_2 , N = 8.13 per cent.), respectively, both of which crystallise readily from 60 per cent. aqueous alcohol (with slight loss) or benzene.

Dichloro- and Chlorobromo-acetomethylamides, -acetoethylamides, and -acetobenzylamides.—Excess of the amine, or its hydrochloride, in strong caustic soda solution, is treated drop by drop at -5° to -10° , with vigorous shaking, with the acid halide in ethereal solution, and the mixture is poured on to ice and acidified with hydrochloric acid; the product crystallises after the solution has been kept at -5° to 0° for some time. *Dichloroacetomethylamide*, m. p. 79° (Found: N = 9.85. $\text{CHCl}_2\text{-CO-NH-CH}_3$ requires N = 9.87 per cent.). *Chlorobromoacetomethylamide*, m. p. 90.3° (Found:

$N = 7.49$. $\text{CHClBr}\cdot\text{CO}\cdot\text{NH}\cdot\text{CH}_3$ requires $N = 7.51$ per cent.).

Dichloroacetoethylamide, m. p. 67.8° (Found: $N = 8.97$.

requires $N = 8.99$ per cent.). *Chlorobromoacetoethylamide*, m. p.

67.8° (Found: $N = 7.0$. $\text{CHClBr}\cdot\text{CO}\cdot\text{NH}\cdot\text{C}_2\text{H}_5$ requires $N = 6.99$

per cent.). *Dichloroacetobenzylamide*, m. p. 96.2° (Found: $N =$

6.40 . $\text{CHCl}_2\cdot\text{CO}\cdot\text{NH}\cdot\text{CH}_2\cdot\text{C}_6\text{H}_5$ requires $N = 6.43$ per cent.).

Chlorobromoacetobenzylamide, m. p. 105° (Found: $N = 5.30$.

$\text{CHClBr}\cdot\text{CO}\cdot\text{NH}\cdot\text{CH}_2\cdot\text{C}_6\text{H}_5$ requires $N = 5.34$ per cent.).

Dichloro- and Chlorobromo-acetanilides.—Good crystals of these compounds were finally obtained by mixing the acid chloride in acetone solution with twice distilled aniline (2 mols. plus 10 per cent. excess), dissolved in acetone and used immediately after distillation. The admixture was carried out slowly at -5° to -10° , the product poured on to a small quantity of ice, acidified with hydrochloric acid, and maintained at -5° to 0° until crystals separated. *Dichloroacetanilide*, m. p. 117.7° (117 – 118° , Ceck, Ber., 1877, 10, 1265) (Found: $N = 6.88$. Calc., $N = 6.87$ per cent.). *Chlorobromoacetanilide*, m. p. 116.8° (Found: $N = 5.61$. $\text{CHClBr}\cdot\text{CO}\cdot\text{NH}\cdot\text{C}_6\text{H}_5$ requires $N = 5.64$ per cent.).

Dichloro- and Chlorobromo-acetomethyl- and -acetoethylanilides.—The above process, using dry ether instead of acetone, gave: *Dichloro-acetomethylanilide*, m. p. 69.9° (Found: $N = 6.39$. $\text{CHCl}_2\cdot\text{CO}\cdot\text{NMePh}$ requires $N = 6.43$ per cent.). *Chlorobromoacetomethylanilide*, m. p. 86.6° (Found: $N = 5.31$. $\text{CHClBr}\cdot\text{CO}\cdot\text{NMePh}$ requires $N = 5.34$ per cent.). *Dichloroacetoethylanilide*, m. p. 54.4° (Found: $N = 6.02$. $\text{CHCl}_2\cdot\text{CO}\cdot\text{NPhEt}$ requires $N = 6.04$ per cent.). *Chlorobromo-acetoethylanilide*, m. p. 56.4° (Found: $N = 4.99$. $\text{CHClBr}\cdot\text{CO}\cdot\text{NPhEt}$ requires $N = 5.07$ per cent.).

Determination of the Melting Point.—Weighed quantities (about 1.5–2 grams in total) of the components were fused together at the lowest possible temperature on a watch-glass, and the mixture was stirred thoroughly while cooling. The mass was finely ground and the melting points were determined on successive small quantities by the capillary-tube method. Melting points determined after a second similar fusion were identical with the first, showing that this method involved no decomposition. Determination of the melting point of a quantity sufficiently large to allow of the thermometer being immersed in the material was, however, found impossible, as the long period involved led to definite decomposition.

In the following tables the observed melting points of mixtures of corresponding pairs of compounds are given, together with the melting points calculated on the assumption that the melting points lie on a straight line between those of the constituents.

The two acetomethylamides being omitted, the maximum depression from the straight-line curve joining the melting points of the two components is caused by the presence of the phenyl group. The acetoalkylanilides show less depression than the simple acetoanilides, the acetoalkylamides less than the acetoalkylanilides, and the unsubstituted acetamides least of all in the following order: $-\text{NHPh}$, $-\text{NHMe}$, $-\text{NPhEt}$, $-\text{NPhMe}$, $-\text{NH}\cdot\text{CH}_2\text{Ph}$, $-\text{NHEt}$, $-\text{NH}_2$. The curve of the melting points of the dichloro- and chlorobromo-acetomethylamides is out of order in this arrangement in showing a greater depression than that of either of the substituted anilides.

I wish to express my indebtedness to Mr. Holland Crompton for much help and criticism.

CCXLVII.—*The Hydrates of Potassium and Lithium Platinocyanides and the System Potassium Platinocyanide–Lithium Platinocyanide–Water.*

By HENRY TERREY and VICTOR GEORGE JOLLY.

EMERSON REYNOLDS (*Proc. Roy. Soc.*, 1909, [A], 82, 380) describes some experiments on the effects of cooling lithium platinocyanide in liquid air and ascribes the colour changes produced by the change of temperature to the loss of water, the colourless trihydrate on heating or cooling breaking down and giving the red dihydrate.

A specimen of the dihydrate given to us by Professor Reynolds proved on analysis to be lithium platinocyanide contaminated with a little of the potassium salt. Before attempting to elucidate the Reynolds phenomenon, it was necessary to investigate the hydrates

of the lithium and potassium salts and the system potassium platinocyanide-lithium platinocyanide-water, since the colour changes observed by Reynolds occur when the lithium salt contains potassium salt. Moreover, considerable divergence exists in the literature with regard to the nature of the hydrates of these two salts. The degree of hydration of the potassium salt varies from 3 to 12 molecules of water.

The lithium salt is described by Martius (*Inaug. Diss.*, Göttingen, 1860) as a milk-white, crystalline material with a blue surface

shimmer, by Haidinger (*Ber. Wien Akad.*, 1852, **8**, 109) as rose-red crystals, and by Baumhauer (*Z. Kryst. Min.*, 1911, **49**, 118) as light-green, prismatic crystals with a sky-blue fluorescence. The present authors find that a number of hydrates of both salts are capable of existence, the commonest of which is the trihydrate in the case of the potassium salt and the pentahydrate in that of the lithium salt, and that at 24.1° a double salt dihydrate is formed within certain limits when the two salts are mixed.

EXPERIMENTAL.

The Hydrates of Potassium and Lithium Platinocyanides.

The potassium and lithium salts were prepared by the decomposition of the pure barium platinocyanide by means of the requisite

amount of the corresponding pure alkali sulphate, and recrystallisation of the product. The barium salt, owing to its slight solubility in water, can be readily purified. The lithium salt, being very soluble in cold water, is slightly more easily recrystallised from aqueous alcohol, in which it is readily soluble. It is very difficult to get the lithium salt free from traces of other alkalis which are always present in the starting product, their presence being easily detected in that they give rise to red-coloured double salts which may be readily picked out under the microscope from the characteristic yellowish-green lithium salts.

In the solubility determinations, the apparatus used was similar to that described in the authors' paper on the use of radioactive materials for the determination of water of hydration (this vol., p. 1979). It consisted of a glass tube provided with a ground-glass stopper in which the solution was agitated by means of a mechanical stirrer until equilibrium was attained, usually in twelve to twenty-four hours. By releasing the stopper, the contents filtered through the Gooch crucible and the solid and liquid phases were thus separated, the whole apparatus being immersed in a thermostat. The values obtained are given in the subjoined tables and are plotted in Fig. 1.

TABLE I.

Solubility of Potassium Platinocyanide.

39-75	78-23	12-3	95-00	210-9	—

The theoretical amounts of water in the hydrates are as follows :
 $1\text{H}_2\text{O} = 4.56$; $2\text{H}_2\text{O} = 8.90$; $3\text{H}_2\text{O} = 12.54$; $5\text{H}_2\text{O} = 19.27$ per cent.

By using the dilatometric method, the transition temperatures observed were: 13.35° , 52.4° , and 74.4° , which are practically identical with those obtained on plotting the solubility against the temperature (Fig. 1, curve I).

31.5	152.0	45.0	196.0	88.2	229.0
				89.8	238.7

* Grams of anhydrous salt in 100 grams of water.

In this case, dilatometric measurements gave transition points at 26°, 38°, 46°, and 69°, whereas the solubility curve (Fig. 1, curve II) shows transition points at 29.5°, 39.5°, 49°, and 72°. For this salt, however, the determination of the degree of hydration of the solid phase presented considerable difficulty. The separated crystals retained large quantities of mother-liquor which could not be removed by draining or centrifuging, and the values obtained, especially at higher temperatures, were untrustworthy and are not recorded. Although attempts to overcome this by using dyes and radioactive materials as indicators of the amount of mother-liquor present in the solid phase were made, the question whether the breaks in the solubility and dilatometric curves represent definite hydrates is thus left undecided. There is no marked colour change of the solid phase separating through the range investigated. At the ordinary temperature, lithium platinocyanide separates with approximately 5 molecules of water, although the values obtained on dehydration of specimens dried in the air or between filter-paper gave values slightly under this amount, the mean value being 21.4 per cent., whereas the pentahydrate requires 22.3 per cent. We may compare this with the magnesium salt, which shows a similar divergence (Tammann, *Z. anorg. Chem.*, 1897, 15, 319). If the moist crystals are dehydrated at constant temperature in a current of dry air, and the loss of weight is plotted against time, the curve indicates that the rate of loss of water changes abruptly at points corresponding with the penta- and tetra-hydrates, so that at least these hydrates are capable of existence. If Wilm's method for the determination of the degree of hydration of these salts (*Ber.*, 1886, 19, 950) be used (that is, allow-

ing the dehydrated salt to rehydrate in the air), it is found that 3 molecules are quickly taken up and then more slowly full rehydration takes place.

The System Lithium Platinocyanide-Potassium Platinocyanide-Water at 24.1°.

Various proportions of the two salts were mixed with water and stirred continuously for one to two days. The solid separating was filtered in the Gooch crucible and the solid and liquid phases were analysed. The method of analysis used was to dehydrate the two phases and then dissolve the weighed solids in a known volume of water. In an aliquot portion, the platinocyanide was precipitated with silver nitrate and the excess of silver removed with hydrochloric acid. The amount of potassium in the filtrate was determined as perchlorate and the lithium by difference. This method of procedure gave good results when tested on known mixtures and is preferable to the more usual method of decomposing the platinocyanide with ammonium chloride, loss of alkali always occurring when this method was attempted. The results of the analysis are appended.

These results are plotted in Fig. 2. As is evident from this figure, starting from the lithium salt end, a double salt of the composition $\text{LiKPt}(\text{CN})_4 \cdot 2\text{H}_2\text{O}$ separates until the concentration of the potassium salt in the liquid reaches 38 per cent., when the

trihydrate of the potassium salt separates. Near the transition point, equilibrium is very slowly attained, and consequently the analysis of three of the solid phases indicates that their composition lies between that of the potassium salt and the double salt. The latter is of a ruby-red colour, with a characteristic blue shimmer, and gives on dehydration a yellow solid which very rapidly rehydrates on exposure with re-formation of the dihydrate.

FIG. 2.
 $K_2Pt(CN)_4$

The fact that a double salt separates from the extreme lithium salt end and that a small amount of the double salt gives a red colour to a mass of the lithium salt, explains some of the discrepancies in the description of the lithium salt and why the double salt was earlier mistaken for the lithium salt (compare Martius, *loc. cit.*).

This research was undertaken at the suggestion of Professor F. G. Donnan, to whom our best thanks are due.

CCXLVIII.—*The System Ferric Oxide-Phosphoric Acid-Water. A New Phosphate.*By SYDNEY RAYMOND CARTER and NORMAN HOLT
HARTSHORNE.

THIS work was originally undertaken to throw some light on the interaction between sulphur dioxide and ferrous phosphate. In strong solutions of phosphoric acid, ferrous phosphate is oxidised to a considerable extent by sulphur dioxide, but, on the other hand, sulphur dioxide is unable to reduce ferric phosphate (Wardlaw, Carter, and Clews, T., 1920, 117, 1241). Further, the oxidation potential of ferrous-ferric mixtures is appreciably lowered by the presence of phosphoric acid (Carter and Clews, unpublished work).

It was thought that a probable explanation of this was to be found in the relative stabilities of the compounds which phosphoric acid forms in solution with ferric phosphate and with ferrous phosphate, respectively, and therefore it was proposed to study both the system with which the paper deals and also its ferrous analogue.

The ferric system has, however, shown so many points of interest and, further, has offered so many experimental difficulties that up to the present we have been unable to complete the second part of our programme and therefore we publish the present work more as an addition to chemical knowledge of the ferric phosphates than as having a bearing on the above problem. We hope to communicate the results of the corresponding ferrous system at a later date.

Cameron and Bell (*J. Physical Chem.*, 1907, 11, 363) investigated the system between the concentrations 0.942 and 4.706 per cent. of P_2O_5 at 25°. Their results show a continuous change in the composition of the solid phase and would appear to indicate increasing adsorption of phosphoric acid by a compound

Erlenmeyer (*Annalen*, 1878, 194, 187) prepared three well-defined ferric phosphates to which he assigned the formulæ $Fe_2O_3.P_2O_5.4H_2O$, $Fe_2O_3.2P_2O_5.8H_2O$, and $Fe_2O_3.3P_2O_5.6H_2O$.

He also obtained a series of amorphous products in which the ratio $Fe_2O_3 : P_2O_5$ varied from 8 : 9 to 8 : 11. To these he assigned definite formulæ, but the present work and that of Cameron and Bell led us to the conclusion that they merely represent stages in the adsorption process mentioned above.

Weinland and Engraber (*Z. anorg. Chem.*, 1913, 84, 349) prepared a neutral phosphate by heating ferric chloride with phosphoric acid or with primary potassium phosphate on the water-bath.

This is evidently the same compound as that obtained by Erlenmeyer, who prepared it by boiling either of the acid compounds with water or by heating ferric oxide or hydroxide with phosphoric acid on the water-bath. These workers, however, attribute 5 and not 4 molecules of water to the salt. It is a pink, microcrystalline powder and is not easily dissolved by dilute acids.

Further, they observed a marked difference between this and the product obtained by precipitating ferric salt solutions with alkali phosphates in the cold. This is a yellowish-green, amorphous powder, variable in composition, always containing more acid radicle than is required for a neutral compound, and usually associated with some alkali. It is easily soluble in dilute acids.

Evidence is also produced to show that the so-called acid phosphates are in reality ferriphosphoric acids and that the crystalline neutral phosphate is a ferric salt of one of these. The formulae they propose are:

They suggest that the precipitated phosphates are phosphates of aquo-ferric bases.

The System at 25°.

Preliminary experiments were made at this temperature by stirring excess of commercial "pure" ferric phosphate with different strengths of phosphoric acid. The mixtures were made up by grinding the components together in a mortar, filtering the resulting cream through glass wool to remove lumps, and then transferring the filtrates to solubility tubes, in which they were stirred first for one hour at 100° to hasten any chemical change necessary for the attainment of equilibrium and then from three to seven days at 25°. The stirrers were fitted with ground glass bearings in place of the usual mercury seal, and in practice they proved sufficiently air-tight.

When it was thought that equilibrium had been reached, stirring was stopped and the solid phase allowed to settle. By means of an inverted asbestos filter, the liquid phase was drawn off into a weighing bottle and a portion of the moist solid remaining was transferred as quickly as possible to another weighing bottle. The two samples were analysed and the composition of the dry solid determined graphically by the well-known method of Schreinemakers (*Z. physikal. Chem.*, 1893, **11**, 76). Microscopic examinations were also made. The analysis was carried out by dissolving the sample in hydrochloric acid and estimating the iron by titration with potassium dichromate after reduction with stannous chloride.

The phosphate was estimated by titration with uranium acetate after removing the iron by ammonium sulphide. The method of carrying out this latter separation was as follows. The ammonium sulphide was freshly prepared by saturating 5*N*-ammonia with hydrogen sulphide. This was then added in slight excess to the solution to be analysed, and after a few moments' stirring with a rubber-tipped glass rod the whole of the ferrous sulphide aggregated as small flocks. This was filtered off and washed with *N*-2*N*-ammonium sulphide. The whole operation was conducted in the cold. The filtrate was boiled to expel excess of hydrogen sulphide and ammonia. This process usually caused the precipitation of sulphur, but as this passed off with the steam or aggregated to small lumps it did not interfere with the succeeding operations of the analysis. The resulting solution, which thus contained ammonium phosphate and chloride, was then titrated as above.

The results obtained proved to be of little value as an indication of the course of the solubility curve, since it was found later that the ferric phosphate used was contaminated with alkali phosphate and had evidently been prepared by precipitation with this reagent: indeed it appears that the only ferric phosphate obtainable is prepared in this way and therefore is untrustworthy for such work as the present (*vide* Weinland and Ensgraber, *loc. cit.*). The results of Cameron and Bell (*loc. cit.*) may be open to the same criticism, since they state that they used a ferric phosphate which they did not analyse.

At the lowest acid concentrations, however, it has been considered quite permissible to accept the information obtained in regard to the solid phases, since the nature of these would be unaffected by the presence of a soluble impurity such as sodium phosphate. This portion of the work therefore has been combined with that of Cameron and Bell, and the two sets of results are given in Table I below and are plotted in Fig. 1.

TABLE I.
Ferric phosphate mixtures at 25°.

Mixture.	Liquid phase.		Moist solid phase.		
	% Fe ₂ O ₃ .	% P ₂ O ₅ .	% Fe ₂ O ₃ .	% P ₂ O ₅ .	
A	0.0105	0.942	15.11	13.81	Cameron and Bell
B	0.0205	1.984	19.35	17.90	
C	0.0384	2.838	23.11	22.54	
D	0.0611	3.770	15.13	17.73	
E	0.0849	4.706	20.43	23.37	
1	Trace	5.93	9.57	14.3	
2	0.23	10.1	11.35	17.5	
3	1.40	14.1	24.40	27.1	
4	2.43	19.8	21.49	27.7	
5	4.42	21.7	21.36	28.3	

It will be seen that, as previously stated, Cameron and Bell's results (broken lines in Fig. 1) show a continuous change in the composition of the solid phase and would appear to indicate adsorption of acid by a compound of the formula $\text{Fe}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot x\text{H}_2\text{O}$ since the left-hand conjugation line (A) almost coincides with the imaginary line drawn from the H_2O corner through the point $\text{Fe}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$. In the present work, mixture 1 gives a line in conformity with this. Mixture 2, however, shows a complete

change, the line passing very close to the compound $\text{Fe}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$, and mixtures 3, 4, and 5 produce lines actually converging on this point.

Thus it appears that at the lowest acid concentrations there exists a neutral compound which adsorbs more or less acid, according to the concentration in the liquid phase, and that the phosphates of variable composition described by Weinland and Engraber (*loc. cit.*) and also the precipitates of Erlenmeyer (*loc. cit.*) are merely different stages in this adsorption process.

At higher acid concentrations, we have a definite compound which is clearly the $\text{Fe}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot 4$ (or 5) H_2O described by the above workers. It will be seen that the present results support the contention of Weinland and Engraber that there are 5 and not 4 molecules of water as proposed by Erlenmeyer. In this connexion, it is interesting to note that the latter's figures would have fitted equally well a compound having 4.5 H_2O . His theory certainly finds support in the composition of the mineral strengite,

$\text{FePO}_4 \cdot 2\text{H}_2\text{O}$, but this was probably formed under very different conditions.

The difference in behaviour evinced by the two forms of neutral phosphate is evidently to be explained by a fundamental difference in constitution. It will have been seen in the early part of this paper that Weinland and Engraber have already indicated as much, and in the light of the present results we may advance the still more definite view that the one compound is a true ferri

phosphate capable of adsorbing phosphoric acid, whilst the other is a ferric ferriphosphate, $\text{Fe}[\text{Fe}(\text{PO}_4)_2]_2 \cdot 5\text{H}_2\text{O}$.

Microscopic examination of the two forms failed to reveal any great difference. Both appeared to be amorphous, although $\text{Fe}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$ was certainly the more granular. It did not, however, exhibit a definite crystalline form as described by Weinland and Ensgraber. Probably this was on account of its method of preparation; Erlenmeyer too describes it as a granular powder.

Returning now to the determination of the solubility curve and the solid phases stable at the higher acid concentrations, it has been seen that the use of commercial ferric phosphate is not to be recommended. During an examination of the possibilities of new starting points, a phosphate was prepared from an oxidised solution of pure iron wire in concentrated phosphoric acid by precipitation with a large volume of water. The product, which was a pinkish-white, amorphous powder, gave the following results on analysis: $\text{Fe}_2\text{O}_3 = 32.0$; $\text{P}_2\text{O}_5 = 34.8$; $\text{H}_2\text{O} = 33.1$ per cent., in which the molecular ratio $\text{Fe}_2\text{O}_3 : \text{P}_2\text{O}_5 = 1 : 1.23$.

On being stirred with phosphoric acid, however, it was found to set up metastable equilibria not easily disturbed and therefore its use was abandoned.

Attention was next directed to the possibilities of ferric hydroxide. Since at 25° this dissolves in phosphoric acid with extreme reluctance, about one month's very rapid stirring being found necessary, experiments were made in which it was stirred first at 100° until all the red colour had disappeared and then at 25° . The results, however, at the higher acid concentrations, particularly where the liquid was more viscous, proved to be most irregular and led us to conclude that a true equilibrium was not being attained. It appears that the only sure way of avoiding the formation of metastable phases is to stir the mixtures solely at the temperature of the isotherm required and this consideration led us to abandon the work at 25° and select a higher temperature. 70° was chosen, since this is the lowest temperature, expressed in round numbers, at which ferric hydroxide dissolves in phosphoric acid in the space of a few hours.

The System at 70° .

Experimental difficulties in the collection of samples of liquid and moist solid phases increase at the higher temperatures, particularly when, as in the present case, many of the mixtures are extremely viscous, difficult to filter, and possess solid phases which are hygroscopic. To combat these difficulties, special apparatus was devised the description of which is given in the next section.

The general experimental procedure for the study of the 70°

isotherm was as follows. The mixtures were prepared by grinding together the necessary quantities of ferric hydroxide, phosphoric acid, and water in a glass mortar and then stirring in a solubility bottle in a thermostat. The latter was fitted with a glass window to enable the contents of the bottle to be observed without having to withdraw it from the bath. It was well lagged with asbestos and a small Bunsen flame (controlled by the ordinary type of regulator) was found to be sufficient to keep it at 70°. Undue evaporation was prevented by covering the surface of the water with a layer of paraffin wax.

The attainment of equilibrium was determined by withdrawing samples of the liquid phase from day to day and estimating the iron by titration with potassium dichromate solution until constant values were obtained. In most cases it was found that four to five days were required, but the mixtures were usually stirred for considerably longer periods than this.

The ferric hydroxide used was prepared by precipitating with ammonia a nearly boiling solution of 40—50 grams of ferric chloride in 2 litres of water. The mixture was meanwhile stirred mechanically and after about half an hour was allowed to settle. The hydroxide was then washed by decantation, being reheated and stirred after every fresh addition of water, until it showed signs of becoming colloidal, after which it was filtered and washed until it gave only a very faint chloride reaction. It was not found possible to wash it quite free from electrolyte. It was then either dried at 100° and finely powdered or, in the case of mixtures weak in acid, used without further treatment. The acid, which was the same as that used at 25°, was a perfectly clear and colourless liquid described as Syrupy Phosphoric Acid, sp. gr. 1.75. It was found to be free from meta- and pyro-phosphates, phosphites, nitrates, metals, and silica, but contained traces of sulphates, chlorides, and arsenic.

On equilibrium being attained, samples of both liquid and moist solid phases were withdrawn and analysed for Fe_2O_3 and P_2O_5 by the methods used at 25°, with the exception that in the latter case the magnesium pyrophosphate determination (Schmitz's method, Treadwell and Hall's "Analytical Chemistry," Vol. II, p. 434) was substituted for the uranium acetate titration as being more accurate. The solids were examined microscopically as before. In addition, rough density determinations of most of the liquid phases were made by weighing about 1.5 c.c. in a calibrated pycnometer.

After the removal of the samples from the solubility bottle, water or acid was added, the mixture again stirred, and fresh

eterminations were made. In this way, it was possible to investigate a considerable portion of the isotherm with one original solution. The breaks in the curve were approached from both sides, and by appropriate seeding it was ensured that the equilibria examined were not metastable. The results obtained are plotted in Fig. 2 and are tabulated below. Photomicrographs of the crystalline solid phases are shown in Figs. 4—7.

Owing to the experimental difficulties, the direction of the conjugation lines has not proved to be as accurate as is desirable. However, by taking into consideration the work at 25° and the composition of the already known compounds, we have been able

FIG. 2.

to arrive at the formulæ given in Table II for the solid phases. The breaks have not been determined experimentally, but their approximate positions are evident from the shape of the curve or the direction of the conjugation lines as the case may be. The lines drawn parallel to the $\text{H}_2\text{O}-\text{Fe}_2\text{O}_3$ side of the triangle in Fig. 2 indicate that they occur near 5, 40, 53, and 57 per cent. of Fe_2O_3 , and these concentrations correspond to 2.1, 26, 41, and 43 N-(gram equivalent)-solutions of phosphoric acid, respectively.

Dealing now with the solid phases in detail, we see that mixture 1 shows far less associated acid than a corresponding mixture at 25°. This decrease with rise of temperature bears out the contention that the change in solid phase composition in this area is due to adsorption.

9	—	3.46	60.47	8.46	60.73	

Comparison with the few experiments made with ferric hydroxide at 25° shows that the compound Fe₂O₃.P₂O₅.5H₂O has a much greater range of existence and is also *less* soluble at the higher temperature. The latter fact really explains the former, because the next compound, Fe₂O₃.2P₂O₅.8H₂O, appears to have an almost negligible temperature coefficient, so that in the solid figure its saturation surface remains practically parallel to the side of the prism, whilst that of Fe₂O₃.P₂O₅.5H₂O must slope towards it and so spread over its neighbour with rise of temperature.

As at 25°, both the neutral phosphates failed to reveal any definite crystalline form when examined under the microscope.

The diacid compound, Fe₂O₃.2P₂O₅.8H₂O, which has just been mentioned requires little further comment except that whereas Erlenmeyer described it as crystallising in four-sided prisms, our product invariably appeared as needles with pointed ends (Fig. 4), which, of course, may have been merely a distorted form.

The most interesting feature of the results is that they reveal the existence of a compound which, so far as is known, has not been described before, and to which we have assigned the formula Fe₂O₃.3P₂O₅.10H₂O. This composition is only tentatively advanced at present, since it is based solely on the three conjugation lines

13, 14, and 15, which are not very definite as regards their destination. It is, however, the only formula which can be reconciled with them, having regard to what is to be expected in this region of the isotherm, namely, a higher hydrate of $\text{Fe}_2\text{O}_3 \cdot 3\text{P}_2\text{O}_5 \cdot 6\text{H}_2\text{O}$. If we accept Weinland and Ensgraber's co-ordination formula for the latter, the new compound merely becomes its dihydrate, $[\text{Fe}(\text{PO})_3]\text{H}_4 \cdot 2\text{H}_2\text{O}$.

It crystallises in hexagonal plates, perfect specimens bearing a striking resemblance to the conventional benzene ring (Fig. 5). It was at first thought that they were another form of the elongated hexagonal plates of $\text{Fe}_2\text{O}_3 \cdot 3\text{P}_2\text{O}_5 \cdot 6\text{H}_2\text{O}$ (Fig. 6), but in addition to the evidence furnished by the conjugation lines we have actually allowed under the microscope the transition from the "benzene ring" type to the elongated type brought about by raising the acid concentration, so that there is no doubt that they are different compounds. Furthermore, the interfacial angles of the crystals are not the same.

Erlenmeyer describes $\text{Fe}_2\text{O}_3 \cdot 3\text{P}_2\text{O}_5 \cdot 6\text{H}_2\text{O}$ as crystallising in rhombic plates, and on subjecting a suitable liquid phase to the isothermal removal of water at 70° (without stirring) we too obtained it in this form (Fig. 7). The identity of the two forms was proved by drying specimens of each with absolute ether after the manner used by Erlenmeyer (*loc. cit.*) and submitting them to analysis, the results of which are given below.

	Rhombic plates. Found.	Elongated hexagonal plates. Found.	Required for $\text{Fe}_2\text{O}_3 \cdot 3\text{P}_2\text{O}_5 \cdot 6\text{H}_2\text{O}$.	Required for $\text{Fe}_2\text{O}_3 \cdot 3\text{P}_2\text{O}_5 \cdot 10\text{H}_2\text{O}$.
Fe_2O_3	22.9	23.0	23.0	20.9
P_2O_5	60.0	59.0	61.4	55.7
H_2O (by difference)	17.1	18.0	15.6	23.5

We have not been able to apply such a confirmatory test to the constitution of the new compound, since up to the present we have been unsuccessful in obtaining a sufficient quantity to manipulate in the drying apparatus.

All the solid phases were pinkish-white, whilst the colour of the liquid phase varied from colourless to deep rose-pink with increasing acid concentration up to mixture 13, after which it became decidedly brown. This latter colour therefore appears to be a property of $\text{Fe}_2\text{O}_3 \cdot 3\text{P}_2\text{O}_5 \cdot 6\text{H}_2\text{O}$ when in solution, although in the solid state it is pinkish-white, as already stated.

From the dotted lines joining the H_2O corner of the triangle with the points representing the three acid compounds, it will be seen that each of these is decomposed by water with formation of the

neutral compound which in the case of two of them is in conformity with Erlenmeyer's work.

Method of Collecting Phase Samples at 70°.

The apparatus is shown in Fig. 3. To collect a sample of moist solid the pulley on the axis of the stirrer (shown dotted) was replaced by the air-tight tube *E*, and after the solid had subsided dry compressed air was admitted at *C* so as to force the sludge into the weighed collector, *L*, the base of which was formed of a perforated filter-plate covered with asbestos. In this operation, the tube *O* acted as an overflow trap, whilst the clip, *N*, regulated the admission

FIG. 3.

of the sludge to *L*. By raising the tube *K* and closing *N* the compressed air was made to express liquid from the sample in *L*, which was then removed, closed with ground stoppers, and weighed. The sample was subsequently dissolved out and examined. The filtration was thus carried out at the temperature of the thermostat, a precaution which was necessary on account of the length of time required by some of the more viscous mixtures.

For the collection of liquid samples a separate apparatus, *A*, was employed, since this operation was of frequent occurrence and something more simple to manipulate was desirable. It was connected to the solubility bottle through the tube *D* in place of the moist solid collector by means of the sliding connexion, *Z*, and, after suitable adjustment, the specimen was blown over into the weighing bottle, *X*, through the filter, *Y*.

It is probable that these methods will prove useful in other

$\text{Fe}_2\text{O}_3 \cdot 3\text{P}_2\text{O}_5 \cdot 10\text{H}_2\text{O}$, X 75.

Fig. 7.

$\text{Fe}_2\text{O}_3 \cdot 2\text{P}_2\text{O}_5 \cdot 8\text{H}_2\text{O}$, Magnification $\times 75$.

equilibria investigations, particularly those involving viscous acids at high temperatures.

Summary.

The system ferric oxide-phosphoric acid-water has been studied at 25° and 70°.

At 25°, we have been able to co-ordinate the work of previous investigators on the neutral ferric phosphates. It appears that at the lowest acid concentrations a compound, $\text{Fe}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot x\text{H}_2\text{O}$, is formed which adsorbs phosphoric acid from the mother-liquor, and is probably a true ferric phosphate. At higher concentrations, it changes to a compound, $\text{Fe}_2\text{O}_3 \cdot \text{P}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$, which has no sorptive power and is probably a ferric ferriphosphate.

At 70°, we have shown the existence of the above solid phases, the compounds $\text{Fe}_2\text{O}_3 \cdot 2\text{P}_2\text{O}_5 \cdot 8\text{H}_2\text{O}$ and $\text{Fe}_2\text{O}_3 \cdot 3\text{P}_2\text{O}_5 \cdot 6\text{H}_2\text{O}$ which are already known, and also that of a new compound to which we have assigned the formula $\text{Fe}_2\text{O}_3 \cdot 3\text{P}_2\text{O}_5 \cdot 10\text{H}_2\text{O}$.

In conclusion, one of us (N. H. H.) desires to thank the Department of Scientific and Industrial Research for a grant which enabled this work to be carried out.

[Received, May 29th, 1923.]

CXLIX.—*Bromination of Aliphatic Acids.*

By BRIAN DUNCAN SHAW.

The work described in this paper was undertaken with the object of testing the suggestion put forward by Lapworth (T., 1904, 85, 41) that the action of halogens on carboxylic acids in presence of red phosphorus is the result of an enolic change which is catalysed by phosphorus halide produced by the action of phosphorus halide on water present, and on the acid itself.

The view does not take into account the acid bromide and other substances which must be formed when more phosphorus is present than is needed to react with the trace of phosphorus present in the acid. Moreover, the time required for complete bromination when the dry acid, saturated with hydrogen chloride, is much longer than when phosphorus is employed. Thus

Lapworth (*loc. cit.*) found that a sample of acetic acid, dried and treated with hydrogen chloride in one operation, by heating with a slight excess of acetyl chloride, required six hours for bromination. On the other hand, Ward (T., 1922, **121**, 1163), using 2 per cent. of red phosphorus, obtained an 80 per cent. yield of bromoacetic acid after one hour's heating.

According to Lapworth's scheme, the velocity of reaction between acetic acid and bromine should be independent of the bromine concentration. To test this deduction, a series of experiments was made on the velocity of bromination of acetic acid containing hydrogen chloride, phosphorus tribromide, acetyl chloride, or acetic anhydride. In each case, the acetic acid was in large excess. When hydrogen chloride alone was used, the bromine disappeared slowly at a constant rate, independent of its concentration, so that in this case Lapworth's view received confirmation. When any one of the other reagents was used, the reaction was initially very much more rapid, but the velocity fell off quickly as the bromine concentration diminished. Only when acetic anhydride was used, however, was the velocity proportional to the bromine concentration. Moreover, when acetic acid containing acetic anhydride was saturated with hydrogen chloride, and then heated with bromine, the reaction proceeded at approximately the same slow rate as when hydrogen chloride alone was used. This result is easy to understand only if the anhydride plays an important part in the rapid reaction, since a high concentration of hydrogen chloride will diminish the amount of acetic anhydride present by driving the reversible reaction to the right:

Two distinct series of reactions are therefore indicated, namely, that involving the enolic form of the acid, and that in which the anhydride appears to play the principal part. The latter is by far the more rapid of the two.

The reaction cycle in the rapid bromination of acetic acid in presence of red phosphorus appears therefore to be

The first reaction is reversible, but it will proceed to completion because the anhydride is removed by the second reaction, which is very rapid under the conditions of experiment. This scheme was proposed by Hentschel (*Ber.*, 1884, **17**, 1286) and by others. According to this view, the velocity of reaction between equivalent quantities of acetic acid and bromine in presence of acetic anhydride

should be proportional to the concentration of the latter. A series of experiments with acetic acid containing varying quantities of acetic anhydride showed this to be approximately the case. Quantitative proportionality, however, cannot be expected owing to the fact that part of the bromine is reacting with the enolic form of the acid.

A more crucial test consists in studying the effect of hydrogen chloride on the reaction velocity. According to Lapworth's scheme, hydrogen chloride should quicken the reaction; according to Henschel, the velocity should be decreased. It is shown in the experimental part of this paper that the latter is the case.

It seems, then, that when acetic acid is brominated in presence of red phosphorus the reaction at first proceeds entirely through the anhydride, but as the concentration of bromine diminishes, and that of hydrogen bromide increases, this reaction will be checked whilst the reaction through the enolic form of the acid will be quickened; until at the end, the reaction proceeds entirely in this way.

As a result of these experiments it was found that the use of a trace of acetic anhydride as carrier constitutes the best method for the preparation of bromoacetic acid. The product is clean, and contains no foreign material as it does when phosphorus is employed; indeed, if sufficient bromine be used, the only impurity is a trace of bromoacetyl bromide, so that for many purposes further purification is unnecessary. If the product be distilled, a yield of pure bromoacetic acid exceeding 95 per cent. of the theoretical can be obtained. The method, moreover, is general, and acetic anhydride may be used as a carrier for the bromination of acids other than acetic acid. In many cases, however, it is difficult to remove the traces of bromoacetic acid and bromoacetyl bromide from the product.

The reaction between acetic anhydride and bromine is complete in a few seconds at 100° if a catalyst such as a trace of hydrogen chloride be present. It is probable that this reaction involves an enolic change, since Orton and Jones (T., 1912, 101, 1723) found the reaction between a large excess of acetic anhydride and bromine to be independent of the bromine concentration. The mechanism therefore is probably :

Aschan (Ber., 1912, 45, 1913; 1913, 46, 2162) supported the enolic theory of the bromination of acids by a series of experiments on the bromination of acid chlorides. A mixture of bromo-acid

chloride and bromo-acid bromide was produced. He represented the reaction thus :

A precisely similar result is obtained, however, when *o*-toluoyl chloride is brominated (Davies and Perkin, T., 1922, **121**, 2203). This compound contains no α -hydrogen atom, and therefore cannot exist in an enolic modification, yet the chlorine was almost entirely replaced by bromine. The explanation offered by these authors is that the hydrogen bromide formed during the bromination of the methyl group reacts with the group $-\text{COCl}$. In this connexion, it is of interest that Staudinger and Anthes (*Ber.*, 1913, **46**, 1417) obtained theoretical yields of acid bromides by passing hydrogen bromide through the heated acid chlorides.

To obtain further evidence on this matter, the velocity of bromination of acetyl chloride has been measured. The results were not in agreement with Aschan's view, but no simple interpretation can be placed on them. It is apparent that more than one reaction is involved.

EXPERIMENTAL.

The measurements of the reaction velocities were carried out as follows. Equal portions of the mixture of prepared acid and bromine, sealed in small bulbs, were heated in a thermostat, and bulbs were withdrawn and broken under potassium iodide solution as required. The liberated iodine was titrated with thiosulphate. Absolute values for the velocity constants were not aimed at, but precautions were taken to render the results comparable.

The acetic acid was purified by freezing and by fractionation over potassium permanganate (Bousfield and Lowry, T., 1911, **99**, 1432). A specimen purified by the method of Orton, Edwards, and King (T., 1911, **99**, 78), using phosphoric oxide, was found to react readily with bromine without further treatment, showing that it contained acetic anhydride. The bromine was purified by Scott's method (T., 1913, **103**, 847). It was subsequently dried under pure sulphuric acid and distilled.

When pure acetic acid containing only a few tenths of 1 per cent. of water was heated with dry bromine at 100° in sealed bulbs, the reaction was at first very slow, but as the concentration of hydrogen bromide increased the bromine disappeared more and more rapidly. According to Lapworth (*loc. cit.*), bromoacetic acid can be prepared

by saturating 99 per cent. acetic acid with dry hydrogen chloride, and heating with bromine for nine hours on the water-bath. The author was unable to confirm this result in detail, but a good yield of bromoacetic acid was obtained by using a stronger acid (99.6 per cent.) and taking special precautions to exclude moisture throughout the experiment. Even in these circumstances, it was necessary to heat the mixture on the water-bath for thirty-five hours.

In order to obtain quantitative evidence of the influence of hydrogen chloride on the bromination of acetic acid, two portions of the same sample of 99.6 per cent. acid, one of which had been

FIG. 1.

A. 99.6% Acetic acid and bromine.

B. 99.6% Acetic acid saturated with hydrogen chloride and bromine.

saturated with dry hydrogen chloride, were heated with pure dry bromine in sealed bulbs in the manner already described. The results are represented graphically in Fig. 1.

In the experiments in which acetyl chloride or acetic anhydride was used as carrier, enough bromine was added to combine with this reagent and leave an excess of approximately 1 mol. of bromine per 100 mols. of acid. The reaction between the carrier and bromine was very rapid, so that the measurements were not complicated by this reaction.

The curves shown in Fig. 2 were obtained with different portions of a sample of acetic acid containing 1 per cent. of acetic anhydride. The considerable increase in velocity shown in curve B disappeared

completely when the acid was saturated with hydrogen chloride (curve A); the latter curve shows also that the velocity was independent of the bromine concentration. It seems, therefore, that the concentration of the acetic anhydride had been reduced to a negligible quantity. On the other hand, when the system originally contained no hydrogen chloride, the velocity varied approximately as the bromine concentration (B). There is no *a priori* reason why any simple relation between bromine concentration and velocity should hold, since three distinct factors are involved: (a) Fall in bromine concentration due to reaction with the anhydride. (b) Fall in anhydride

FIG. 2.

A. Acetic acid, anhydride, bromine, and hydrogen chloride.
B. Acetic acid, anhydride, and bromine.

concentration owing to increase in concentration of hydrogen bromide. (c) Fall in bromine concentration due to reaction with the enolic form of the acid.

The side reactions (b) and (c) affect the apparent velocity in opposite directions; (a) diminishes whilst (b) increases it.

In practice, these opposing factors appear to balance, since the values of k obtained from the equation $k = 1/t \cdot \log a/a - x$ are approximately constant.

Time (mins.).	C.c. (N/50-Thio.).	k .	Time (mins.).	C.c. (N/50-Thio.).	k .
0	115		34.45	18.2	0.00232
8.45	74	0.00227	38.45	14.9	0.00230
21.25	35.5	0.00240	45.75	8.3	0.00250
24.25	29.0	0.00247			

The results obtained with acetyl chloride were not as definite as those with acetic acid. The form of the curve obtained (Fig. 3) indicates that more than one reaction is involved. As a further test, measurements were made using equivalent quantities of pure acetyl chloride and bromine, but no constant could be obtained.

Preparation of Bromoacetic Acid.—The yield of bromoacetic acid obtained by the Hell-Volhard reaction is variable and the handling of the bromoacetyl bromide is troublesome. Better results are obtained by Ward's method (*loc. cit.*), but the substitution of a trace of acetic anhydride for red phosphorus gives an improved yield and a much cleaner product.

FIG. 3.

Acetyl chloride and bromine. Temp. 57°.

In the first experiments on the preparation of bromoacetic acid the bromine was dried under sulphuric acid and separated with a funnel. It was observed that the reaction was sluggish at first and more acetic anhydride was required than would have been expected according to the amount of water in the acid. This was due to the presence of sulphuric acid in the bromine (compare Orton and Jones, *loc. cit.*). Even when the reaction is in progress the addition of a trace of sulphuric acid is sufficient to check it. Bromine dried by this method should therefore be distilled before use.

The following experiment is typical. One hundred grams of acetic acid (99.5 per cent.) were treated with acetic anhydride (4 grams). Thirty grams of the mixture were placed in a distillation flask fitted with a reflux condenser and bromine (10 grams) was

added through the side tube, which was then closed. After the mixture had been heated for a few minutes on the water-bath, a vigorous reaction set in. When this had subsided, the remainder of the theoretical quantity of bromine (70 grams) was added through the side tube. When the bromine had entirely disappeared (one hour), a pale yellow liquid remained. More bromine was then added to make up for that carried away by the hydrogen bromide, until a faint colour persisted. On distillation, 67 grams of bromoacetic acid, b.p. 203—207°, were obtained (96 per cent. of the theoretical). If the bromine be added in small quantities at a time, the condenser will become nearly filled with the bright red, crystalline compound, $(\text{CH}_3\text{CO}_2\text{H}\cdot\text{Br}_2)_n\cdot\text{HBr}$, described by Hell (Ber., 1878, 11, 244) and loss of substance will occur owing to the volatility of this compound. The addition of all the bromine in the early stages of the reaction serves to wash this compound back into the flask. A glycerol bath may with advantage be substituted for the water-bath.

Bromoacetic Ester.—The reaction product contains sufficient hydrogen bromide to allow esterification by the ordinary method.

Acetic acid (12 grams) was brominated as described above, absolute alcohol (27 grams) added to the product, and the mixture heated on the water-bath for two hours. The product was poured into twice its volume of cold water. The lower layer was separated, washed, dried over calcium chloride, and distilled. The yield was 27 grams (82 per cent. of the theoretical); b.p. 159°.

Bromination of Acids other than Acetic Acid.—Experiments were also made with butyric, isobutyric, valeric, and stearic acids. The reaction proceeded smoothly in each case, but only in the case of stearic acid was it possible easily to free the product from traces of bromoacetic acid and bromoacetyl bromide.

Summary.

The bromination of acetic acid is shown to occur in two distinct ways, one of which appears to be through the enolic form of the acid, the other through the anhydride.

An improved method for the preparation of bromoacetic acid and its ester is described.

The author wishes to express his thanks to Professor F. S. Kipping, F.R.S., for his kind interest in this research, and to the Department of Scientific and Industrial Research for a grant which has enabled the work to be carried out.

OCL.—*The Reaction between Phosphorous Acid and Iodine.*

By ALEC DUNCAN MITCHELL.

THE reactions in which phosphorous acid takes part have formed the subject of many kinetic studies and the results are almost invariably inconclusive. The reason for this appears to be that the process of integration is applied to experimental results which do not justify its use. Integration is only permissible as a means of smoothing experimental error in order to obtain a constant, and should not be applied until an examination of actual experimental differential velocities indicates that the reaction is of the order assumed. Towards the later stages of a time-reaction there may be large deviations from the supposed order of the reaction, and these are almost completely obliterated in the "smoothing" process of integration. Also, a case has previously been investigated (Mitchell, T., 1920, 117, 1322) in which, owing to approximate mathematical equalities which obtain over small ranges, integration gives extremely concordant "constants" although based on an assumption which is entirely erroneous. Conversely, a very small "drift" in the value of an integrated constant may correspond to a large deviation from the hypothesis on which the integration is based.

The reaction between mercuric chloride and phosphorous acid has been studied repeatedly (Montemartini and Egidi, *Gazzetta*, 1902, [ii], 32, 182; Garner, Foglesong, and Wilson, *Amer. Chem. J.*, 1911, 46, 361, 648; Linhart, *Amer. J. Sci.*, 1913, [iv], 35, 353; * Linhart and Adams, *J. Amer. Chem. Soc.*, 1917, 39, 948) and the results obtained are discordant. Dhar (*Z. anorg. Chem.*, 1922, 121, 156), without referring to any of the previous workers, found it necessary to use the square root of the concentration of the mercuric chloride (as had been done by Linhart), and in the reaction between chromic and phosphorous acids (*Ann. Chim.*, 1919, [ix], 11, 130) he utilises the 1.5 power of the phosphorous acid concentration. It is believed that many of the anomalies formerly encountered, especially the use of irrational powers, may receive an explanation on the lines of the reaction now discussed.

Federlin (*Z. physikal. Chem.*, 1902, 41, 565) studied the reaction between phosphorous acid and iodine as a subsidiary research when investigating the effect of iodine in accelerating the reaction

* I am indebted to Prof. Linhart for a very courteous letter giving his views on this reaction.

between phosphorous acid and potassium persulphate. He found it to be unimolecular with regard to each reactant, but only carried out a few experiments within narrow limits of concentration. Steele (T., 1908, 93, 2203) extended this research, and concluded that, when reaction takes place in the presence of mineral acid, which may be provided by the reaction itself or may be added initially, the iodine functions in proportion to the square root of its concentration, and therefore it was supposed to act in virtue of the atoms formed by dissociation of the molecule. This conclusion was based on integrated results, and the velocity coefficients quoted in support of this statement showed a considerable deviation in each experiment, and, moreover, fell regularly with increasing concentration of iodine, other conditions being the same: for iodine solutions 0.0093, 0.0190, 0.0285, and 0.0382 molar, the constant fell as follows—0.00212, 0.00205, 0.00186, and 0.00169. On repeating a few experiments, it was soon noticed that the velocity was largely dependent on the amount of potassium iodide present—a fact which Steele had noted, but stated to be slight, and ignored. This dependence was so marked that in several cases solutions with less “available” iodine had a higher velocity than those with more “available” iodine solely owing to this cause. This fact obviously invalidated the above conclusions, since the progress of the reaction automatically increased the amount of iodide-ion present: $\text{H}_3\text{PO}_3 + \text{I}_2 + \text{H}_2\text{O} = \text{H}_3\text{PO}_4 + 2\text{HI}$.

Steele also concluded that hydrogen-ions accelerated the reaction, but, as the velocity coefficient was not quite proportional to the hydrogen-ion concentration, he used the function $(k + k'c)$ to express the relationship, c being the concentration of hydrogen-ions, k' the coefficient due to them, and k a coefficient to represent the supposedly slight reaction in their absence. He found k' to be of the order 13×10^{-3} and k to range from 0.54×10^{-3} to 0.96×10^{-3} , the method used being such as to throw most of the error on the second constant. In experiments with initially added acid, k' was lower, its range being 9.7×10^{-3} to 6.7×10^{-3} . In the second part of his communication, however, he shows that the velocity in presence of acetic acid and sodium acetate is much greater at 0° than the former velocity at 35° ; in fact, using the temperature-coefficient of 4.7 for 10 degrees (p. 2253), the velocity in the first case is of the order $60 \times 4.7^{3.5}$, that is, 13,500 times greater than in the second case—a point which it is difficult to reconcile with his assumption that k is much smaller than k' .

On carrying out a few more experiments, several cases were encountered in which additional hydrogen-ions had little or no

accelerating effect, and as they must have altered the concentration of both undissociated phosphorous acid and its ion, it was anticipated that it should be possible to find instances in which additional hydrogen-ions actually depressed the reaction velocity. Such instances were subsequently discovered in experiments in which molecular iodine, as distinct from tri-iodide iodine, was in relatively large proportion, and in which, at the same time, additional extraneous hydrogen-ions caused a relatively large increase in the hydrogen-ion concentration. Steele's conclusion that the ion was the active part of the phosphorous acid is therefore based on false premises.

In view of the new facts thus discovered, it was decided to undertake a more detailed examination of the reaction, especially as the reactions of hypophosphorous acid have been found to be explicable only on the assumption of its tautomerism (Mitchell, T., 1920, 117, 1322; 1921, 119, 1266; 1922, 121, 1626; this vol., p. 629). It may be stated at once that, although the reaction is very complicated, there is strong evidence for such tautomerism in the case of phosphorous acid. Moreover, the molecular iodine formed by the equilibrium $KI_3 \rightleftharpoons KI + I_2$ is an important factor in the reaction; it reacts directly with the normal form of phosphorous acid and this reaction is repressed by hydrogen-ions. Simultaneously, the phosphorous acid changes into another form with which the I_3' -ion reacts. This second reaction is accelerated by hydrogen-ions either directly, or, more probably, because they accelerate the tautomeric change (as in the case of hypophosphorous acid). For reasons which will appear subsequently, it is impossible to say definitely whether it is the phosphorous acid ion or molecule which takes part in either of the reactions, but the first reaction appears to be more sensitive to the depressing effect of hydrogen-ions than would be the case if it were due to a direct reaction of the acid ion. This hypothesis does, however, give an indication as to why the reaction should be very rapid in sodium acetate-acetic acid solution, whereas Steele's explanation gives only indications to the contrary. The mechanism of the reaction in these circumstances has not yet been reinvestigated, but the data now brought forward are expected to aid in its study.

The reactions outlined above may be represented by the scheme

which, although indefinite, is believed to mark a distinct advance in the treatment of the subject.

The evidence on which the above deductions are based is submitted in the discussion of results, but the development of the velocity equations may now be shown.

Let l represent the initial total concentration of phosphorous acid, and l' that of the second form, which is negligibly small but in equilibrium with the normal form; i is the concentration of molecular iodine, a that of the tri-iodide iodine, and $A = a + i$, the total "available" iodine; h is the concentration of hydrogen-ions, p that of the total potassium iodide, and f that of the free iodide (that is, not combined as tri-iodide). After a time t , all the foregoing have suffix t added, and s represents the molar concentration of available iodine reduced or phosphorous acid oxidised. Then $l_t = l - s$, $A_t = A - s$, $p_t = p + 2s$, and the hydriodic acid produced $= 2s$. Also, from the work of Jakowkin (*Z. physikal. Chem.*, 1896, 20, 19), the following relation holds: $[KI][I_2] = 0.00135[KI_3]$ or $f_t i_t = 0.00135 a_t$, the constant being later designated as k .

The oxidation of phosphorous acid according to the first reaction is given by

$$- dl/dt = k_1 l i \quad . \quad . \quad . \quad . \quad . \quad (1)$$

The reversible formation of the second form is given by

$$+ dl'/dt = k_2 l - k_3 l' \quad . \quad . \quad . \quad . \quad . \quad (2)$$

and its oxidation by

$$- dl'/dt = k_4 l' a \quad . \quad . \quad . \quad . \quad . \quad (3)$$

The total change of the normal form, from (1) and (2), is

$$- dl/dt = k_1 l i + k_2 l - k_3 l' \quad . \quad . \quad . \quad . \quad . \quad (4)$$

and that of the second form, from (2) and (3), is

$$dl'/dt = k_2 l - k_3 l' - k_4 l' a \quad . \quad . \quad . \quad . \quad . \quad (5)$$

and, finally, the decrease in iodine, from (1) and (3), is

$$- dA/dt = ds/dt = k_1 l i + k_4 l' a \quad . \quad . \quad . \quad . \quad . \quad (6)$$

The significance of the constants k_1 , k_2 , k_3 , and k_4 is obvious. In order to eliminate l' conveniently, dl'/dt is assumed $= 0$, since it is small compared with the other terms in equation (5), and the second form is assumed to react nearly as rapidly as it is produced, whence $l'(k_3 + k_4 a) = k_2 l$, and

$$ds/dt = l\{k_1 i + k_2 k_4 a / (k_3 + k_4 a)\} = l\{k_1 i + k_2 a / (a + k_3/k_4)\}$$

or, putting $k_3/k_4 = k_5$,

$$ds/dt = l\{k_1 i + k_2 / (1 + k_5/a)\} \quad . \quad . \quad . \quad . \quad . \quad (7)$$

The same result is obtained by eliminating l' and dl'/dt in the usual way and ignoring differentials of the second order and second degree, which are small and opposite in effect.

The above result has been obtained by ignoring the concentration of hydrogen-ions and therefore is only applicable to experiments in which that concentration is uniform. The experiments are arranged into several groups to fulfil this condition, and the constants for each group naturally differ: they are discussed later.

Expression (7) agrees with what was at first thought to be an anomaly, namely, that, for any particular experiment, when ds/dt was plotted against A , from experimental velocity data, the resulting smoothed curve was frequently sinuous and had a point of inflexion, whereas, on any simple hypothesis, such as that of Steele, it should be a curve of simpler type and concave to the A -axis. Such a sinuous curve could be represented in any one experiment by an expression, such as the above, which contains three arbitrary constants, and this expression might fit other similar experiments within a narrow range of conditions; but the fact that, for any particular hydrogen-ion concentration, this expression agrees with all experiments, covering a wide range of conditions, without any variation of the constants is very strong evidence in favour of its validity. This evidence is still stronger when it is realised that there are two independent variables, a and i , to be taken into account. As will be seen, for experiments in the course of which there is only slight variation of the hydrogen-ion concentration, it covers the whole range of each experiment, and for others it applies to the only portion which can be used to test it, namely, the initial velocity.

It will be noticed that the term $k_1 i$ falls off relatively rapidly at first and then more slowly, whereas the term $k_2/(1 + k_3/a)$ falls off slowly in the early stages of a reaction and then more rapidly. For concentrated iodine solutions the latter term tends towards k_2 as a limit, that is, the I_3' -ion cannot utilise the second form of the acid any more quickly than the latter is formed.

Examination of the experimental results having traced the reaction to both molecular and tri-iodide iodine, no simple function of these other than that developed here was found to agree with the results, a simply additive one of the type $ds/dt = l(k_1 i + k_2 a)$, for instance, being quite inadequate, and one connecting molecular iodine with the second form of the acid, such as $ds/dt = l\{k_1 a + k_2/(1 + k_3/i)\}$, being totally inappropriate.

There is little doubt but that one of the reactions involves the formation of an intermediate complex, although it has not been possible to demonstrate this from the available velocity data. A

few experiments were repeated in the presence of 1.65*N*-potassium chloride, in view of the work of Brönsted (*Z. physikal. Chem.*, 1922, 103, 307), who redetermined the iodine-iodide-tri-iodide equilibrium in presence of this strong saline solution, with the idea of minimising the well-established variation of activity-coefficients with total ion concentration. These experiments showed a very pronounced "lag" during the early stages, but subsequently the iodine consumption overtook that in the parallel experiment in the ordinary series. Such behaviour is typical of the formation of intermediate compounds.

Since the ratio $[I_2]/[KI_3]$ is equal to $k/[KI]$, the molecular iodine (*i*) in equation (7) could be replaced by ka/f , and such an expression would result from the assumption that an equilibrium $H_3PO_3 + I_3' = H_3PO_3 \cdot I_2 + I'$ is rapidly attained and that the complex is formed in small proportion and decomposes slowly; the assumption is therefore plausible. It is probably in this direction that the repressing effect of hydrogen-ions can be explained if a similar equilibrium results in the production of hydrogen-ions, but the adequate treatment of such complicated cases would introduce so many more arbitrary constants that any better agreement which might be obtained would be more likely to be due to the wider application of such an expression on a purely empirical basis. This line of argument is therefore not developed here, but it certainly seems that the iodine (*i*) function is capable of improvement, since it usually requires slightly too high velocities for high values of *i* and slightly too low velocities for low values of *i*, a fact which is perceptible in all the series, and especially so in Series C, where it is responsible for a large proportion of the velocity.

No alternative hypothesis can be found, however, which does not involve the assumption of the existence of a second form of phosphorous acid.

All calculations are based on velocities derived from a smoothed velocity-total iodine curve, since integration gives an extremely cumbersome expression and is a far less rigid test of accuracy. The experimental error on the velocities is of the order of 2 per cent. through the greater part of each experiment, although actual titrations were usually accurate to within about one-tenth of this, but the initial velocities, being extrapolated graphically from a curve which is often changing rapidly, are not necessarily so accurate, and may sometimes be as much as 4 per cent. in error. The agreement between calculated and observed velocities is usually closer proportionately after the initial velocity than at that point. Although the deviations are often slightly outside the limits of experimental error, yet, in view of the necessarily approximate

nature of the theory and of various data utilised, the hypothesis developed, with the reservations discussed above, must be regarded as a close approach to the actual mechanism of the reaction.

EXPERIMENTAL.

The phosphorous acid used was found, by iodine consumption (in the presence of sodium acetate) and by the potassium dichromate method (Cocking and Kettle, *Pharm. J.*, 1913, **91**, 132), to contain 93.7 per cent. of phosphorous acid. The latter method was preferable, since it is not open to possible error arising from slight loss of iodine vapour as is the former method. Titration with standard baryta gave a value which showed that the remainder of the solid was phosphoric acid, and neither water nor other impurities were appreciable. A stock solution containing 413.2 grams per litre was used throughout, and was 4.72 molar and 0.28 molar with regard to phosphorous and phosphoric acids respectively. It was checked from time to time and replaced if it showed any sign of further oxidation.

All except two of the experiments (Nos. 6 and 23) were carried out with one of two solutions of iodine. The stock solutions were $N/2$ with regard to iodine, and contained 148.8 or 84.0 grams of potassium iodide per litre, respectively, the latter being the minimum that was necessary to retain the iodine in solution on dilution: dilute solutions prepared from this solution readily lost iodine vapour. These two solutions corresponded to 3.585 and 2.024 molecules of potassium iodide per molecule of iodine, respectively.

All experiments, except that required to ascertain the temperature coefficient, were carried out at 25°. The other experimental details do not call for any special description.

Some of the experiments extended over several weeks and were vitiated in their later stages by atmospheric oxidation of the hydriodic acid produced. A large number of blank experiments, with potassium iodide and hydrochloric acid, showed that (except in Nos. 23 and 26) the oxidation was within the limits of experimental error over the range which it has been possible to deal with owing to the limitations of the theory—that is, the initial stages of the relatively slow (concentrated) experiments, and the whole of the more rapid (dilute) experiments.

Concentrations of hydrogen- and phosphite(H_2PO_3')-ions are obtained by application of the methods used previously (*loc. cit.*) and the data from which the necessary detail is obtained are: for phosphorous acid, Ostwald ("Allgemeine Chemie," Leipzig, 1893); for phosphoric acid, Ostwald (*op. cit.*) and Abbott and Bray (*J. Amer. Chem. Soc.*, 1909, **31**, 729); and for hydrochloric acid, Bray

* In experiments marked thus, there is a relatively rapid decrease in phosphorous acid concentration, and calculations are not taken beyond the stage at which this decrease becomes 5 per cent., as the ratio is consequently rising. This would account for a rise from 1.00 to 1.05 in the ratio, so that the range given is not unduly large. In Expts. 22, 30, 21, and 28, nearly half the whole range of iodine concentration is covered, and in the others, nearly the whole range.

and Hunt (*J. Amer. Chem. Soc.*, 1911, **33**, 781). Hydriodic acid is reckoned as hydrochloric acid for the purpose of obtaining the hydrogen-ion concentration, but no data involving the latter are utilised except in so far as it is necessary to know when the change in hydrogen-ion concentration exceeds certain limits. The second stage ionisation of both the polybasic acids is ignored as being negligibly small under the conditions of experiment.

The results are shown in detail for two typical experiments (Nos. 14 and 39, the former being chosen to exemplify the sinuous nature of the velocity-iodine curve), and are summarised in Table I for initial velocities and in Table II for the remainder of each experiment, except those for which only the initial values can be utilised owing to the large change in hydrogen-ion concentration. Table II shows the extreme range and also the mean values of the ratio calculated/found velocities. Each experiment in Table II is based on at least eight and frequently as many as twenty velocity determinations. The velocities are obtained from smoothed curves, but the other details are from actual readings and are not smoothed. For brevity, ds/dt is replaced by v , and the calculated velocity is subdivided into $v_1 = k_1 i$ and $v_2 = k_2/(1 + k_3/a)$ to illustrate the separate effects of molecular iodine and the I_3^- ion.

Time is given in hours throughout, and all concentrations are in molecules per litre. The hydrogen-ions due to the phosphoric acid are taken into account.

The experiments are grouped according to hydrogen-ion and

phosphorous acid concentrations, and the formula used for obtaining the calculated value is shown for each series, ignoring l and h until the discussion of results. The series are :

Series A. $\text{H}_3\text{PO}_3 = 0.0925$, $\text{HCl} = \text{---}$, $\alpha_{\text{H}_3\text{PO}_3} = 0.530$, $h = 0.0502$,
 $ds/dt \times 10^6 = i \times 10^6 \times 0.275 + 175/(1 + 0.0025/a)$.

Series B. $\text{H}_3\text{PO}_3 = 0.0925$, $\text{HCl} = 0.0980$, $\alpha_{\text{H}_3\text{PO}_3} = 0.383$, $h = 0.1255$,
 $ds/dt \times 10^6 = i \times 10^6 \times 0.185 + 430/(1 + 0.0048/a)$.

Series C. $\text{H}_3\text{PO}_3 = 0.0374$, $\text{HCl} = \text{---}$, $\alpha_{\text{H}_3\text{PO}_3} = 0.648$, $h = 0.0248$,
 $ds/dt \times 10^6 = i \times 10^6 \times 0.21 + 60/(1 + 0.0075/a)$.

Series D. $\text{H}_3\text{PO}_3 = 0.0374$, $\text{HCl} = 0.0992$, $\alpha_{\text{H}_3\text{PO}_3} = 0.403$, $h = 0.1063$,
 $ds/dt \times 10^6 = i \times 10^6 \times 0.075 + 110/(1 + 0.0025/a)$.

Series E. $\text{H}_3\text{PO}_3 = 0.1815$, $\text{HCl} = \text{---}$, $\alpha_{\text{H}_3\text{PO}_3} = 0.445$, $h = 0.0829$,
 $ds/dt \times 10^6 = i \times 10^6 \times 0.35 + 700/(1 + 0.004/a)$.

Series F. $\text{H}_3\text{PO}_3 = 0.1815$, $\text{HCl} = 0.0961$, $\alpha_{\text{H}_3\text{PO}_3} = 0.359$, $h = 0.1533$,
 $ds/dt \times 10^6 = i \times 10^6 \times 0.30 + 1250/(1 + 0.006/a)$.

Discussion of Results.

The conclusions on which the theory is based are drawn chiefly from the following considerations :

(a) Expts. 26, 1, 3, 7, 8, 14, and 19 show that as the molecular iodine tends to a limit, the velocity also tends to a limit in spite of the great increases in the I_3' -ion; therefore, if the latter reacts at all (and Expt. 23 tends to show that it does), its reaction is limited by some other factor—the maximum rate of formation of the second form of phosphorous acid from the normal form.

(b) In series which have approximately the same hydrogen-ion concentration (for example, D and E), the velocities of otherwise comparable experiments are approximately in the ratio of the phosphorous acid, the function of which is therefore unimolecular.

(c) The effect of potassium iodide in decreasing the molecular iodine and also the velocity is obvious with many pairs of experiments, for example, 14 and 16, 18 and 19, 20 and 29, 37 and 38; these show that a considerable proportion of the velocity is due to molecular iodine.

(d) The small effect of the I_3' -ion compared with that of molecular iodine is apparent in 14, 16, and 23.

(e) The fact that total ("available") iodine is of no significance is illustrated by many pairs of experiments, for example, 14 and 18, where the solution richer in iodine has a lower velocity.

(f) The effect of additional acid may be seen from many experiments, of which three pairs are typical : 1 and 9 exhibit considerable acceleration, 16 and 15 practically no effect, and 30 and 31 considerable depression.

(g) The accelerating effect is less in experiments with high molecular iodine content than in those in which this is low, other conditions being the same; and the depression is most noticeable in comparing Series C and D, in which additional acid causes a relatively large increase in the hydrogen-ion content. Hence these ions depress the reaction in which molecular iodine is concerned, and accelerate that concerning the I_3' -ion; but the depressing effect only preponderates in the total observed velocity in those cases in which molecular iodine originally contributed a large proportion of the velocity, that is, in cases where the hydrogen-ion concentration is originally small.

Similar deductions were drawn from a number of curves in which one of the variables v , i , a , and f was plotted against a second for constant values of a third, the last three being connected by $ka = if$.

The slow decrease in velocity in the series 1, 3, 7, 8, 14, and 19 was at first thought to be due to one of two causes : either a pre-

liminary rapid reaction involving only phosphorous acid in which iodine took no part, as in the parallel reaction with hypophosphorous acid; or to the fact that in using one and the same solution of iodine and potassium iodide, the concentration of molecular iodine is almost independent of dilution until the solution becomes very weak, as is seen for its values in those experiments, and would not greatly affect the velocity if the iodine functioned only in this form. [The slight effect of dilution follows from the fact that, since k is small (p. 2244), $i = kA/(p - A)$ approximately, and A/p is constant under the prescribed conditions.] Actually neither of these hypotheses was found to be tenable.

It is obvious that the initial velocities do not vary as the square root of the total iodine concentration, as Steele supposed. The fact that they approach somewhat more nearly to this value during the course of any one experiment is due entirely to the effect of the increasing iodide concentration, which decreases that of molecular iodine more rapidly than "available" iodine decreases.

The high calculated initial velocity in cases where molecular iodine is high initially has already been discussed (p. 2246). The question as to whether it may be due to the possible failure of the theory beyond these limits cannot be tested, because one has nearly reached the limit of the solubility of the molecular iodine. Brönsted (*loc. cit.*) obtained the value 0.00611 for the iodide-iodine equilibrium constant in strongly saline solution, which differs widely from that of 0.00135 obtained by Jakowkin (*loc. cit.*); the latter worker's value has been used throughout this work, however, as the conditions are more comparable with his than with Brönsted's. The higher value gives figures for the molecular iodine which are relatively less high for high concentrations of molecular iodine, and which operate in the direction of eliminating the difference under discussion and even introduce differences in the opposite direction.

When the values of k_1 and k_2 are corrected for the different amounts of phosphorous acid present, they can be considered in relation to the hydrogen-ion concentrations to which they correspond. One has then :

Series.	h .	$a_{H_2PO_3}$.	k_1 .	k_2 .	$k_2 = k_3/k_4$.
A	0.0502	0.530	2.98	0.00189	0.0025
B	0.1255	0.383	2.00	0.00465	0.0048
C	0.0248	0.648	5.62	(0.00180)	(0.0075)
D	0.1063	0.403	2.01	0.00294	0.0025
E	0.0829	0.445	1.93	0.00385	0.0040
F	0.1533	0.359	1.65	0.00682	0.0060

(The values for Series C are of little significance, since the molecular iodine, corresponding to k_1 , contributes such a large proportion

to the total velocity that k_2 and k_5 can be varied over a large range with only very little alteration in the calculated velocity.) k_1 can be regarded as a fair approximation, k_2 is less certain, and k_5 is only a very rough estimate, owing to the nature of the expression (7).

The chief deductions that can be drawn are: (a) decrease of hydrogen-ion (h) increases k_1 more rapidly than can be accounted for on the assumption that phosphorous acid functions as its ion; (b) k_2 increases roughly in proportion to the hydrogen-ion, which may therefore be supposed to catalyse the intramolecular change, as in the similar case of hypophosphorous acid; (c) k_3/k_4 appears to increase with increasing hydrogen-ion concentration and, if deduction (b) is correct, k_3 should alter in this way, since the reverse intramolecular change would be catalysed as well as the direct one corresponding to k_2 : in these circumstances, k_4 must be regarded as unaffected by hydrogen-ions.

Experiments over a larger range of acid concentration are restricted, on the one hand, by the extreme slowness of the reaction, and, on the other, by lack of trustworthy data as to ionisation at higher concentrations.

Throughout this work the possibility of the intermediate production of hypophosphoric acid has been borne in mind, but there seems to be no evidence pointing to its occurrence.

Temperature Coefficient.—Experiment 30 was carried out also at 17° and was found to be 3.55 times as slow as at 25°. This corresponds to a temperature coefficient of 4.7 for 10° in this particular case, but as it is the nett result of several others, it is doubtful whether any significance can be attached to its rather high magnitude.

Summary.

1. The reaction is shown to be much more complicated than was supposed by previous workers. It involves iodine both as the molecule I_2 and as the tri-iodide-ion I_3' , and also a second form of phosphorous acid formed reversibly from the normal form. It may be represented as:

2. Hydrogen-ions repress the left-hand reaction and accelerate the right-hand one, but this acceleration is probably only indirect and due to the acceleration of the equilibrium between the two forms of the acid, as in the case of hypophosphorous acid. The mechanism of the repressing effect has not been elucidated.

3. The above hypothesis is believed to be sound in its outline,

but no finality is claimed as to details, and directions are indicated in which these may have to be modified and amplified.

4. It seems certain that, whatever modifications may subsequently be found to be necessary, any explanation must rely ultimately on the existence of a second form (probably tautomeric) of phosphorous acid formed reversibly from the normal form.

UNIVERSITY OF LONDON,
SOUTH KENSINGTON, S.W.

[Received, June 26th, 1923.]

CCCL.—*The Colloidal Electrolyte extracted from Carrageen (Chondrus crispus).*

By FRANK COURTNEY HARWOOD.

THE mucilaginous substance extracted from carrageen or "Irish moss," with cold water (Haas and Hill, *Ann. appl. Biol.*, 1921, 7, 352; Haas, *Biochem. J.*, 1921, 15, 469; Russell Wells, *ibid.*, 1922, 16, 578) has been subjected to a physicochemical examination, with the view of throwing light on its constitution. The formula which these authors suggest for this substance is $R \begin{smallmatrix} \text{O} \cdot \text{SO}_2 \cdot \text{O} \\ \text{O} \cdot \text{SO}_2 \cdot \text{O} \end{smallmatrix} \text{Ca}$ (I).

The presence of the ester grouping in carrageen has been established and the nature of the complex radicle R partly elucidated by these investigators.

The molecular weight, calculated from the calcium content, is about 1,000; but from its colloidal behaviour, its complexity in aqueous solution must be much greater than that indicated by this low value.

The substance possesses considerable interest for the physical chemist, for if its constitution is expressed by the above formula, it should be strongly ionised in solution, giving rise to ionic micelles of a character much simpler than those of the proteins. Measurements of the conductivity of its solutions over a range of dilutions have confirmed this view, a 1.5 per cent. solution being 59 per cent. ionised, which is somewhat remarkable for a liquid of such high viscosity.

The conductivity at infinite dilution is found to be of the same order as that of calcium sulphate, and therefore it would appear that the colloidal ion of carrageen extract possesses a mobility very similar to that of the sulphate-ion. This high mobility is not in any way unusual, for McBain (T., 1919, 115, 1293) found it necessary to ascribe the high value of 64.7 to the mobility of the palmitate micelle.

The solution of the carrageen extract ionises to the same extent as a salt of a bivalent acid radicle with a bivalent negative radicle:

and if the basicity of the acid radicle in carrageen extract be calculated from the equivalent conductivities at $V = 1024$ and 32 , the value 1.925 is obtained. It is uncertain, however, whether Ostwald's rule applies to the calcium salts of organic acids; and until the sodium salt has been prepared, and its conductivity determined at $V = 1024$ and 32 , it is not possible definitely to decide between formula (I) and the alternative formula $\text{Ca}(\text{O}\cdot\text{SO}_2\cdot\text{O}\cdot\text{R})_2$ (II).

The conductivities for a number of magnesium salts of organic acids are given in Kohlrausch and Holborn's Tables (1898, p. 171) and from these it would appear that $\Lambda_{1024} - \Lambda_{32}$ for salts of monobasic organic acids is about 17.8 , and for salts of dibasic acids about 40.2 . The value 19.25 obtained for the calcium salt occurring in carrageen is close to that given by the former class of salts, and hence this evidence supports the alternative formula (II). The physical evidence as to the basicity of the acid radicle in carrageen extract is thus contradictory.

It is possible that the conductivity is due to calcium sulphate adsorbed on the colloidal micelle, and in order to test this question, the solution of carrageen extract (1.5 per cent.) was placed in an osmotic cell, with a parchment paper membrane, and the cell surrounded by an approximately equivalent concentration of calcium chloride. If the calcium sulphate were merely adsorbed on the surface of the colloidal particles, and the resulting complex gave sulphate-ions to the solution, it would be anticipated that these ions would interchange across the membrane, until the concentrations of the two ions were equal in the two compartments. On the other hand, if the sulphate complex is united to the organic radicle in the form of a sulphuric ester, only the calcium-ions would be free to move across the membrane, and a Donnan equilibrium should be established on the two sides of the cell. In the latter case, the ions on the two sides of the cell are :

and at equilibrium,

$$[\text{Ca}^{++}]_I / [\text{Ca}^{++}]_{II} = [\text{Cl}']_{II}^2 / [\text{Cl}']_I^2.$$

It was found that no sulphate-ion diffused through the membrane, and that equilibrium was established when unequal concentrations of calcium chloride were on the two sides of the membrane. The Donnan equilibrium was established within the error of the experiment.

These experimental results therefore provide strong support for the conclusion that carrageen extract is a calcium salt of an organic

acid in which the sulphate group is contained in the complex negative radicle X. The physical evidence is thus in general agreement with the view expressed by Haas, that carrageen extract is a calcium salt of a sulphuric ester.

EXPERIMENTAL.

(a) *Conductivity Measurements.*—These measurements were made in an enclosed cell of Jena glass, with a Whetham commutator as the source of the alternating current. A 1.5 per cent. solution of the carrageen extract was prepared by allowing the gel to swell for a few minutes in cold conductivity water, and then gently heating the mixture on the water-bath. A viscous, yellow solution was obtained. This was successively diluted with water to obtain the less concentrated solutions.

Several series of determinations were made on two different samples of carrageen extract, some on the day of preparation, and others after keeping the solutions for several days in resistance glass tubes. The conductivities did not change appreciably during this time. The conductivity of the water ranged from 3 to 3.5×10^{-6} mho.

The values for one series are given in the table, and the equivalent conductivities are calculated on the assumption that the molecular weight is 1,000 (the value deduced by Haas from a determination of the calcium content of the anhydrous material). Unfortunately, through an accident, the moisture content of the sample of the extract used was not estimated, and the values for the equivalent conductivity are only relative. The average value for the moisture content of several carrageen extracts prepared by Haas and Russell Wells is 4.6 per cent. Therefore the absolute values of Λ are uncertain to this extent.

Conductivity of Carrageen Extract at 25°.

Normality (V).	$\kappa \times 10^3$.	Λ .	Normality (V).	$\kappa \times 10^3$.	Λ .
0.03	1.953	65.1	0.001875	0.1506	80.32
0.015	1.001	66.73	0.0009375	0.07968	84.99
0.0075	0.5365	71.53	0.000469	0.0414	88.32
0.00375	0.2825	75.33	0.000235	0.02179	92.97

By plotting Λ against \sqrt{V} , the equivalent conductivity at infinite dilution was found to be 110 mhos, as the mean of three series. The degree of ionisation of a 0.01N-solution at 25° is calculated to be 63.4 per cent. This is, of course, independent of any assumption as to molecular weight or moisture content, except in so far as it affects the normality of the solution for which the ionisation is calculated. The degree of ionisation of calcium sulphate (0.01N) at 18° is 64.7 per cent., and a very slight change in this value with temperature would be anticipated. The carrageen

extract thus ionises in aqueous solution to an extent which is normal for a salt of a bivalent anion with a bivalent cation: the similarity between the degrees of ionisation of the two salts indicates that the carrageen extract is a calcium salt of a dibasic acid.

(b) *Osmosis Experiments*.—A small osmometer consisting of a piece of cylindrical hard glass tubing, 1.5 inches in diameter, with a side tube attached to a manometer, was used in these experiments. The parchment membrane was clamped in position, and supported against internal pressures by means of perforated ebonite disks. A solution of carrageen extract, 0.03*N*, was placed inside the cell, and this placed in a solution of calcium chloride of an equivalent concentration, contained in a large beaker, covered with a wooden plate, waxed to prevent evaporation.

The osmotic pressure rose to a maximum of 3.9 cm. in 46.5 hours, and after 161 hours, had fallen to 1.7 cm. At the end of this time, the outside solution contained no detectable amount of sulphate-ion. This solution was titrated periodically for chloride-ion, and as equilibrium had not been attained in 161 hours, a new cell was set up in which the inner liquid was stirred through a mercury seal. This precaution reduced bacterial action to a minimum. After three days, the concentration of the calcium chloride inside the cell reached a constant value, and then underwent no appreciable change after eight days. Osmosis occurred to the extent of about 1.5 c.c. in 28 c.c., and the loss by evaporation was less than 0.1 c.c. on 300 c.c. in the outer vessel. The external solution showed a very slight change in the concentration of hydroxyl-ions ($p_H = 6.5$ to $p_H = 7.0$).

The degrees of ionisation of the two calcium salts in solution I (below) were calculated on the assumption made by Arrhenius, and confirmed by MacGregor, McIntosh, Archibald, and McKay (*Trans. N.S. Inst. Sci.*, 1895—1899), according to which, in aqueous solutions of electrolytes containing a common ion, the concentration of the common ion determines the degree of ionisation. The degree of ionisation of any one of the salts in solution I is the same as that occurring in a solution containing that salt alone, whose calcium-ion concentration is the same as the total calcium-ion concentration in the solution of the mixed electrolytes.

The following values were obtained:

	I.	II.
CaX	0.0296 <i>N</i>	
CaCl ₂	0.0266 <i>N</i>	0.0314 <i>N</i>
Ca ⁺⁺	0.03828 <i>N</i>	0.02595 <i>N</i>
Cl ⁻	0.04336 <i>N</i>	0.0519 <i>N</i>

Whence $[Ca^{++}]_I/[Ca^{++}]_{II} = 1.475$ and $[Cl']_I^2/[Cl']_{II}^2 = 1.483$.

If the carrageen extract contains 4 per cent. of water, the first ratio will be about 2 per cent. lower.

It is proposed to make further use of this material for an investigation of the Donnan equilibrium, and the Procter-Wilson theory of swelling.

In conclusion, I should like to express my acknowledgments to Dr. Paul Haas, at whose suggestion the investigation was undertaken; and to Mr. W. E. Garner for helpful advice and criticism.

CCLII.—*Triazole Compounds. Part I. Some Substituted Hydroxybenzotriazoles and their Methylation Products.*

By OSCAR LISLE BRADY and JAMES NELSON EDMUND DAY.

THE parent substance of this group, 1-hydroxy-1:2:3-benzotriazole, was first isolated by Nietzki and Braunschweig (*Ber.*, 1894, 27, 3381) and also by Zincke and Schwarz (*Annalen*, 1900, 311, 332) by the action of alkalis on *o*-nitrophenylhydrazine, the reaction being supposed to proceed thus:

Curtius and Mayer (*J. pr. Chem.*, 1907, [ii], 76, 369) prepared 6-nitro-1-hydroxy-1:2:3-benzotriazole (I) from 2:4-dinitrophenylhydrazine, using hydrazine hydrate as the catalysing alkali. Borsche and Rantschew (*Annalen*, 1911, 379, 152) prepared 7-nitro-1-hydroxy-1:2:3-benzotriazole from 2:6-dinitrophenylhydrazine, whilst Borsche and Fiedler (*Ber.*, 1913, 46, 2117) obtained a compound which they claimed to be 4-nitro-1-hydroxy-5-methyl-1:2:3-benzotriazole; Morgan and Glover (*T.*, 1921, 119, 1700) have also described 4-chloro-1-hydroxy-5-methyl-1:2:3-benzotriazole. Bowman and one of us (*T.*, 1921, 119, 894) have prepared 4-nitro-1-hydroxy-5(or 7)-methyl- and 4-nitro-1-hydroxy-6-methyl-1:2:3-benzotriazoles (III and VIII), and have suggested that the compound that Borsche and Fiedler designated 4-nitro-1-hydroxy-5-methyl- was probably 6-nitro-1-hydroxy-7-methyl-1:2:3-benzotriazole.

Since the work of Curtius and Mayer, however, scarcely any investigations have been made of the properties and reactions of the hydroxybenzotriazoles. These compounds are of particular interest to us because they contain a hydroxyl group attached to nitrogen which is acidic in character, and, in this respect, are analogous to the oximes. The present paper deals with the preparation of several more of these compounds and their behaviour towards methylating agents. Those containing a nitro-group in the benzene nucleus were chosen on account of the comparative ease with which the *o*-nitrophenylhydrazines, and hence the 1-hydroxy-2:3-benzotriazoles, could be prepared by the action of hydrazine hydrate on such compounds as the unsymmetrical trinitrotoluenes or on the dinitrotolyl methyl ethers (compare Brady and Bowman, *oc. cit.*).

Curtius and Mayer attempted to prepare the acetyl derivative of 6-nitro-1-hydroxy-1:2:3-benzotriazole by the action of acetyl chloride on the sodium salt in dry ether. They obtained a white, crystalline compound, but were unable to purify it for analysis or for the determination of its melting point, owing to it being completely hydrolysed when they tried to crystallise it from alcohol. Zincke and Schwarz also experienced some difficulty in acetylating 1-hydroxy-1:2:3-benzotriazole. It has now been found, however, that the acetyl compounds can be readily prepared by the action of acetic anhydride followed by crystallisation from benzene, sometimes with the addition of a few drops of acetic anhydride; alcohol, in every case, brings about immediate hydrolysis.

Bowman and one of us found that 4-nitro-1-hydroxy-5(or 7)-methyl-1:2:3-benzotriazole (III) crystallised with a molecule of water which was lost at 100°. 4-Nitro-1-hydroxy-6-methyl-1:2:3-benzotriazole (VIII) gives a similar hydrate, which, however, is less stable, losing its water, for example, on crystallisation from dilute alcohol. On the other hand, hydrates could not be obtained from 6-nitro-1-hydroxy- (I), 6-nitro-1-hydroxy-5-methyl- (V), and 6-nitro-1-hydroxy-4-methyl-1:2:3-benzotriazoles (X). It is noteworthy that where the hydrate is formed there is a nitro-group ortho to the triazole ring.

Curtius and Mayer (*loc. cit.*) describe the preparation of the methyl, ethyl, and benzyl ethers of 6-nitro-1-hydroxy-1:2:3-benzotriazole by the action of the appropriate alkyl halide on the sodium salt of the triazole, but these workers did not investigate the reaction at all fully, confining themselves to recording the melting points, solubilities, and analyses of the compounds. We have found that certain substituted hydroxybenzotriazoles behave as tautomeric compounds and give two methyl ethers; in one the

alkyl group is attached to oxygen and in the other to nitrogen, as evidenced by their behaviour with hydriodic acid. 6-Nitro-1-hydroxy-5-methyl-1:2:3-benzotriazole gives an *O*-methyl ether melting at 135° (VI) and, in smaller quantity, a *N*-methyl ether (VII) melting and decomposing at 265°, which can be separated by the volatility of the former in steam. 6-Nitro-1-hydroxy-4-methyl-1:2:3-benzotriazole behaves in a similar manner, giving the ethers (XI) and (XII). 6-Nitro-1-hydroxy- (I), 4-nitro-1-hydroxy-6-methyl- (VIII), and 4-nitro-1-hydroxy-5(or 7)-methyl-1:2:3-benzotriazoles (III) gave *O*-ethers, but no *N*-ether could be isolated. The yields of *N*-ethers are small, and it is possible that they are invariably formed, but escape detection owing to the impracticability of using distillation in steam as a means of separation in these cases.

The various compounds prepared are summarised in the following scheme :

With reference to the constitution of the *N*-ethers three formulæ are possible :

Minor variations could, moreover, be introduced into formulæ (XIV) and (XV) by making the oxygen atom form a bridge between two nitrogen atoms. We prefer formula (XIII) on the analogy of the *N*-ethers of the oximes (compare Forster and Holmes, T., 1908, 93, 244; Angeli, Alessandri, and Aiazzi-Mancini, *Atti R. Accad. Lincei*, 1911, [v], 20, i, 546; Brady, T., 1914, 105, 2104), but further work is in hand in order to decide this point.

EXPERIMENTAL.

6-Nitro-1-hydroxy-5-methyl-1:2:3-benzotriazole (V).—This compound was prepared by the action of excess of hydrazine hydrate on the corresponding trinitrotoluene without the isolation of the intermediate dinitrotolylhydrazine. To a solution of 6.8 grams of 3:4:6-trinitrotoluene in 60 c.c. of hot alcohol were added slowly 12 c.c. of 50 per cent. hydrazine hydrate diluted with 40 c.c. of alcohol. A red, crystalline precipitate of the dinitrotolylhydrazine appeared, but this dissolved after the liquid had been boiled under reflux for six hours, being converted into the more soluble hydrazine salt of the triazole. The solution was cooled and the triazole precipitated by the addition of water and dilute hydrochloric acid. After crystallisation from dilute alcohol, it was obtained in yellow prisms melting and decomposing at 194° (Found: N = 28.9. $C_7H_6O_3N_4$ requires N = 28.9 per cent.).

No hydrate could be obtained from this compound by dissolving it in ice-cold aqueous ammonia and reprecipitating the triazole with dilute acid at a low temperature.

6-Nitro-1-acetoxy-5-methyl-1 : 2 : 3-benzotriazole.—One gram of the above triazole was treated with 5 c.c. of acetic anhydride, and one drop of concentrated sulphuric acid added. The mixture became warm and the triazole dissolved and, on cooling, the acetyl derivative crystallised out. It separated from hot benzene in faintly pink, monoclinic needles, melting and decomposing at 166° (Found: N = 23.9. $C_8H_8O_4N_4$ requires N = 23.7 per cent.).

6-Nitro-1-methoxy-5-methyl-1 : 2 : 3-benzotriazole (VI) and 6-Nitro-1 : 5-dimethyl-1 : 2 : 3-benzotriazole 1-Oxide (VII).—Four grams of 6-nitro-1-hydroxy-5-methyl-1 : 2 : 3-benzotriazole were dissolved in a solution of 4 grams of sodium hydroxide in 50 c.c. of water and treated in a stoppered bottle with 6 grams of methyl sulphate. The mixture was well shaken for ten minutes and left over-night. The solid was collected and distilled in steam, when part volatilised and crystallised out in the receiver. This crystallised from methyl alcohol in long, pale canary-yellow needles melting at 135°, and consisted of 6-nitro-1-methoxy-5-methyl-1 : 2 : 3-benzotriazole (Found: N = 27.0; OMe = 14.6. $C_8H_8O_3N_4$ requires N = 26.9; OMe = 14.9 per cent.).

The liquid in the distilling flask which contained the non-volatile portion was filtered while hot and, on cooling, a yellow, crystalline material separated, which was crystallised from methyl alcohol and obtained in canary-yellow, feathery tufts, melting and decomposing at 265°. This compound is apparently 6-nitro-1 : 5-dimethyl-1 : 2 : 3-benzotriazole 1-oxide (Found: N = 27.1. $C_8H_8O_3N_4$ requires N = 26.9 per cent.). On treatment with hydriodic acid as in the Zeisel method, no methyl iodide was evolved, showing that the methyl group was not attached to oxygen.

The methylation has also been carried out with methyl iodide. Three grams of the triazole were dissolved in methyl alcohol and a solution of 0.35 gram of sodium in methyl alcohol was added, followed by 8 grams of methyl iodide. The mixture was heated for two hours on the water-bath under reflux, then evaporated to dryness, and the residue distilled in steam. The O-ether was again obtained, but nothing crystallised from the liquid in the flask and extraction with chloroform gave only a trace of material which could not be identified.

3 : 5-Dinitro-o-tolyl Methyl Ether.—This compound was obtained by Blanksma (*Rec. trav. chim.*, 1910, 29, 411) by the removal of the amino-group from 3 : 5-dinitro-2-methoxy-p-toluidine. He established its constitution by heating it with ammonia and

obtaining 3 : 5-dinitro-*o*-toluidine, but did not publish an analysis. We have now prepared it by the nitration of *o*-tolyl methyl ether in an analogous manner to the ethyl ether (compare Stadel, *Annalen*, 1883, **217**, 154). To 500 c.c. of fuming nitric acid (*d* 1.5) cooled to 5° and mechanically stirred, 50 c.c. of *o*-tolyl methyl ether were added, drop by drop, at such a rate that the temperature of the acid did not rise above 10°. This took about one and a quarter hours. The solution was poured on to crushed ice, the solid separated, washed with cold dilute sodium carbonate solution, and then with water. The nitro-compound may be crystallised from methyl alcohol, when it is obtained in light yellow needles melting at 69° (Blanksma gives 67°). Heating with ammonia converted it into 3 : 5-dinitro-*o*-toluidine (Found : N = 13.2. Calc., N = 13.2 per cent.).

6-Nitro-1-hydroxy-4-methyl-1 : 2 : 3-benzotriazole (X).—Twenty grams of recrystallised 3 : 5-dinitro-*o*-tolyl methyl ether were dissolved in 100 c.c. of alcohol, 20 c.c. of 50 per cent. hydrazine hydrate diluted with 80 c.c. of alcohol were added and the mixture was heated on the water-bath under reflux for two hours. The hot solution was then acidified with 50 c.c. of concentrated hydrochloric acid, cooled, and the triazole which separated crystallised from dilute alcohol, when it was obtained in small, very pale yellow prisms melting and decomposing at 225° (Found : N = 29.0. $C_8H_8O_3N_4$ requires N = 28.9 per cent.).

6-Nitro-1-acetoxy-4-methyl-1 : 2 : 3-benzotriazole.—To 7 c.c. of acetic anhydride, 1.5 grams of the above triazole were added, followed by one drop of concentrated sulphuric acid. The reaction started at once, but to effect complete dissolution the mixture was heated on the water-bath. The acetyl derivative, which separated on cooling the solution, crystallised from benzene in almost colourless, cubic crystals melting at 142° (Found : N = 23.7. $C_9H_8O_4N_4$ requires N = 23.7 per cent.).

6-Nitro-1-methoxy-4-methyl-1 : 2 : 3-benzotriazole (XI) and 6-Nitro-1 : 4-dimethyl-1 : 2 : 3-benzotriazole 1-Oxide (XII).—These were prepared and separated in the same way as compounds VI and VII. The volatile *O*-methyl ether crystallised from methyl alcohol in clusters of radiating needles melting at 137° (Found : N = 27.0; OMe = 14.4. $C_8H_8O_3N_4$ requires N = 26.9; OMe = 14.9 per cent.).

The residue in the flask after the steam distillation was filtered while hot, cooled, and extracted with chloroform; the solid obtained on evaporation of the solvent was crystallised from methyl alcohol, when 6-nitro-1 : 4-dimethyl-1 : 2 : 3-benzotriazole 1-oxide was obtained in brilliant yellow needles melting and decomposing at 220° (Found : N = 27.1. $C_8H_8O_3N_4$ requires N = 26.9 per cent.). No methyl

iodide was evolved when the compound was treated with hydriodic acid in the usual way.

A solution of 5 grams of the triazole was treated with a solution of 0.65 gram of sodium in the same solvent, 15 grams of methyl iodide were added, and the mixture was heated on the water-bath for two hours under reflux and then evaporated to dryness. The residue on distillation in steam was separated into the two methyl ethers obtained above. The relative amounts were approximately the same as with methyl sulphate, only a very small amount of the *N*-ether being produced.

A solution of 2 grams of the triazole in a slight excess of dilute aqueous ammonia was boiled until neutral. A solution of 1.7 grams of silver nitrate was added, the yellow, gelatinous precipitate of silver salt collected, washed with water, then with methyl alcohol, suspended in methyl alcohol, and boiled under reflux for half an hour with 5 grams of methyl iodide. The hot solution was separated from silver iodide and, on cooling, almost pure *O*-ether crystallised out; this was removed, the solution evaporated to dryness, and the solid residue distilled in steam. A further amount of the *O*-ether was obtained, but the residual liquid in the flask gave no *N*-ether on extraction with chloroform.

4-Nitro-1-hydroxy-6-methyl-1 : 2 : 3-benzotriazole (VIII).—This compound has been described by Bowman and one of us (*loc. cit.*). It has now been obtained in larger quantity directly from 3 : 4 : 5-trinitrotoluene. Ten grams of 3 : 4 : 5-trinitrotoluene were dissolved in 100 c.c. of hot alcohol, 20 c.c. of 50 per cent. hydrazine hydrate mixed with 30 c.c. of alcohol were added, and the whole was heated under reflux on the water-bath for three hours. The solution was cooled, diluted with water, acidified with hydrochloric acid, and the precipitated triazole crystallised from 50 per cent. alcohol. The compound thus obtained formed yellow needles which melted and decomposed at 241°. When air-dried, they were anhydrous as described by Bowman and one of us, but it was found that if cold dilute hydrochloric acid were added cautiously to an ice-cold solution of the ammonium or sodium salt of the triazole, short, deep orange prisms of a *monohydrate* separated (Found: N = 26.6; H₂O = 8.6. C₇H₆O₃N₄.H₂O requires N = 26.4; H₂O = 8.5 per cent.). When the orange crystals of the hydrate are heated, they lose their water at 90–95° and are converted into the yellow, anhydrous compound, which then melts and decomposes at 241°; the yellow, anhydrous compound is always precipitated when hot solutions of the salts are acidified.

4-Nitro-1-acetoxy-6-methyl-1 : 2 : 3-benzotriazole.—One gram of the above triazole was treated with 5 c.c. of acetic anhydride and one

drop of concentrated sulphuric acid, when it was rapidly converted into the acetyl derivative. This was separated and crystallised from benzene to which a few drops of acetic anhydride had been added, when it was obtained in colourless, prismatic crystals melting and decomposing at 210° (Found: $N = 23.7$. $C_9H_8O_4N_4$ requires $N = 23.7$ per cent.).

4-Nitro-1-methoxy-6-methyl-1 : 2 : 3-benzotriazole (IX).—One gram of 4-nitro-1-hydroxy-6-methyl-1 : 2 : 3-benzotriazole was dissolved in a solution of 1 gram of sodium hydroxide in 100 c.c. of water and shaken with 1.5 grams of methyl sulphate in a stoppered bottle. It was necessary to work at this dilution, as the sodium salt is sparingly soluble in water. On leaving over-night, a small quantity of solid had separated which proved to be the *O-ether*. Extraction of the solution with ether yielded very little more of this compound, and on acidifying the mother-liquor more than half of the triazole was recovered unchanged.

Three grams of the triazole in 20 c.c. of methyl alcohol were treated with 0.35 gram of sodium dissolved in 40 c.c. of methyl alcohol, 8 grams of methyl iodide were added, and the mixture was heated on the water-bath for two hours. The solution was then evaporated to dryness, but it was found that nothing could be distilled in steam. The solid was therefore crystallised from methyl alcohol, when the *O-ether* was obtained in yellow plates melting at 183° (Found: $N = 27.2$; $OMe = 14.2$. $C_8H_7O_2N_4$ requires $N = 26.9$; $OMe = 14.9$ per cent.). No *N-ether* could be isolated from the mother-liquors from the crystallisation.

4-Nitro-1-hydroxy-5(or 7)-methyl-1 : 2 : 3-benzotriazole (III).—This compound, described by Bowman and one of us, was best prepared by boiling under reflux 10 grams of 2 : 3 : 4-trinitrotoluene in 130 c.c. of alcohol with 20 c.c. of 50 per cent. hydrazine hydrate. The solution was cooled and left over-night, when the sparingly soluble hydrazine salt of the triazole crystallised out; this was dissolved in water and the triazole precipitated with hydrochloric acid and dried at 100° .

4-Nitro-1-acetoxy-5(or 7)-methyl-1 : 2 : 3-benzotriazole.—To 10 c.c. of acetic anhydride 1.5 grams of the above triazole were added, followed by one drop of concentrated sulphuric acid. The triazole dissolved and almost immediately the acetyl derivative separated out as a colourless, crystalline powder. On crystallisation from benzene containing a few drops of acetic anhydride, it separated in almost colourless, monoclinic prisms melting and decomposing at 182° (Found: $N = 23.8$. $C_9H_8O_4N_4$ requires $N = 23.7$ per cent.).

4-Nitro-1-methoxy-5(or 7)-methyl-1 : 2 : 3-benzotriazole (IV).—Three grams of 4-nitro-1-hydroxy-5(or 7)-methyl-1 : 2 : 3-benzotriazole

were added to 50 c.c. of methyl alcohol in which 0.45 gram of sodium had been dissolved, and 3 c.c. of methyl iodide were run in. The mixture was heated under reflux for an hour, cooled, and water added gradually with constant shaking, when the *methyl ether* separated in a crystalline condition. On crystallisation from methyl alcohol, it was obtained in brownish-yellow needles melting at 152° (Found: N = 27.0; OMe = 15.1. $C_8H_8O_3N_4$ requires N = 26.9; OMe = 14.9 per cent.). Attempts at methylation with methyl sulphate proved to be very unsatisfactory, only a very small amount of ether being formed. Decomposition of the triazole apparently took place, as the solution rapidly became very dark coloured; moreover, acids no longer precipitated from it the triazole but a brown, amorphous substance, which could not be purified and resembled the compounds obtained by the action of alkalis on the trinitrotoluenes.

The *O*-ether obtained by methylation with methyl iodide is not appreciably volatile in steam, and no *N*-ether could be isolated from the mother-liquors from its preparation.

6-Nitro-1-hydroxy-1:2:3-benzotriazole (I).—This compound was best prepared by adding to a hot solution of 7.5 grams of 2:4-dinitrochlorobenzene in 100 c.c. of alcohol, 15 c.c. of 50 per cent. hydrazine hydrate diluted with 45 c.c. of alcohol, and boiling under reflux for six hours. The sparingly soluble 2:4-dinitrophenylhydrazine separated almost at once from the hot solution, but slowly disappeared until a clear, dark red solution of the hydrazine salt of the triazole was obtained; on cooling, the latter separated out. It was collected and dissolved in the minimum amount of water and the free triazole precipitated with hydrochloric acid. A further, but less pure, crop of triazole was obtained by diluting and acidifying the mother-liquor from the preparation. The product, on crystallisation from alcohol, deflagrated at 206° without melting. The yield of crystallised triazole was between 50 and 60 per cent. of the theoretical; a considerable amount was lost owing to its being somewhat soluble in cold water and more so in aqueous alcohol.

6-Nitro-1-acetoxy-1:2:3-benzotriazole.—Two grams of the triazole were mixed with 10 c.c. of acetic anhydride, two drops of concentrated sulphuric acid added, and the mixture was heated on the water-bath until solution took place. On cooling, the acetyl compound separated. It crystallised from benzene containing a few drops of acetic anhydride in colourless prisms melting at 154° (Found: N = 25.5. $C_8H_6O_4N_4$ requires N = 25.2 per cent.).

6-Nitro-1-methoxy-1:2:3-benzotriazole (II).—Two grams of 6-nitro-1-hydroxy-1:2:3-benzotriazole were dissolved in methyl

alcohol in which had been dissolved 0.26 gram of sodium, 5 grams of methyl iodide were added, and the mixture was boiled under reflux for four hours. The alcohol was evaporated off and the residue distilled in steam; after a prolonged treatment, a small quantity of material volatilised, but afterwards no more seemed to distill. The solid in the receiver was collected and crystallised from methyl alcohol, when the methyl ether (m. p. 130°) described by Curtius and Mayer (*loc. cit.*) was obtained. These workers assumed that it was an *O*-ether, and this has now been proved by a methoxyl determination (Found: OMe = 15.6. Calc., OMe = 16.0 per cent.). The clear solution in the distilling flask from the steam distillation was filtered while hot and, on cooling, deposited a compound which was found to be identical with the above methyl ether. This was also obtained by the action of methyl sulphate on an alkaline solution of the triazole, and no *N*-ether could be detected in any case.

THE RALPH FORSTER LABORATORY OF ORGANIC CHEMISTRY,

CCLIII.—*Piperitone. Part V. The Characterisation and Racemisation of l-Piperitone.*

By JOHN READ and HENRY GEORGE SMITH.

OWING to the fact that optically active piperitone undergoes partial or complete racemisation during the formation of most of the common derivatives, and also when distilled under atmospheric pressure, the only process at present available for isolating preparations of high optical rotatory power consists in submitting a suitable essential oil to fractional distillation under diminished pressure (Smith and Penfold, *J. Proc. Roy. Soc. N.S. Wales*, 1920, **54**, 40; Simonsen, T., 1921, **119**, 1644; Read and Smith, *J. Soc. Chem. Ind.*, 1923, **42**, 339r.). The physical characteristics recorded below refer to specimens of *d*- and *l*-piperitone isolated by a careful application of this method and possessing the highest optical rotations yet observed for this ketone.

Although specimens obtained in the manner indicated are probably contaminated with small amounts of impurities, the agreement now noticed between the optical rotatory powers of *d*- and *l*-piperitone indicates that probably no marked racemisation has occurred during the processes involved. Further, the appended summary illustrates the remarkably close physical correspondence between these optically active preparations, which appear to be

the purest yet described, and *dl*-piperitone regenerated from the pure *dl*- α -semicarbazone (T., 1922, **121**, 1871):

	Boiling point.	d_4^{20} (vac.).	n_D^{20} .	$[\alpha]_D^{20}$.
<i>d</i> -Piperitone ex <i>Andropogon Suarancusa</i> ...	116—118.5°/20 mm.	0.9344	1.4848	+49.13°
<i>l</i> -Piperitone ex <i>Eucalyptus dives</i>	109.5—110.5°/15 mm.	0.9324	1.4848	—51.53°
<i>dl</i> -Piperitone ex <i>E. dives</i>	113°/18 mm.	0.9331	1.4846	±0.00°

As recorded below, the racemisation of the optically active ketone is most readily effected by means of heat or alkaline reagents, whereas the racemising action of acid reagents is much less marked. This point, which is of primary importance in connexion with the chemical characterisation of the optically active forms of the ketone, may be illustrated by referring to a study of the interaction of *l*-piperitone with hydroxylamine; in acid solution a highly dextrorotatory oxime appears to be the main product, whilst in alkaline solution under appropriate conditions (T., 1922, **121**, 586) an 80 per cent. yield of optically inactive hydroxylamino-oxime may be produced. Incidentally, the last-named product has been shown to consist of at least two isomeric substances, each possessing a higher melting point than the value previously recorded (T., 1921, **119**, 783, 1653).

Notwithstanding the unusual ease of racemisation thus exhibited by the optically active forms of piperitone, it has proved possible, with proper precautions, to utilise these substances as sources of optically active derivatives. The various possibilities of the kind are under consideration, and we hope shortly to communicate details of certain preliminary investigations of this nature which have been directed towards the conversion of *d*- and *l*-piperitone into optically active menthones and related derivatives (compare *J. Proc. Roy. Soc. N.S. Wales*, 1922, **56**, 170).

EXPERIMENTAL.

Physical Properties of l-Piperitone from the Essential Oil of Eucalyptus dives.

A sample of the "eight-hour oil" (1363 grams) was distilled under diminished pressure, in portions of about 500 c.c., from a Claisen flask immersed in an oil-bath (this vol., p. 1661). After three systematic redistillations under 18 mm. pressure, the bulk of the piperitone was concentrated into the three fractions denoted below:

Fraction.	Boiling point.	Bath temperature (limit).	Weight (grams).
5	100—108°	130°	160
6	108—120	140	494
7	120—130	160	20

After three further redistillations, fraction 6 was augmented to 610 grams (b. p. 108—120°/18 mm.); two further redistillations yielded 290 grams distilling over a range of 4° (108—112°/15 mm.); and a final redistillation gave 155 grams collected over 1° (109·5—110·5°/15 mm.), at a bath temperature of 140°. This fraction, which amounted to 11·4 per cent. of the crude oil used, was assumed to consist of pure *l*-piperitone, and the following physical constants were observed: d_4^{20} 0·9324 (vac.), n_D^{20} 1·4848, α_D^{20} — 48·05°, * $[\alpha]_D^{20}$ — 51·53°; d_4^{25} 0·9285 (vac.), n_D^{25} 1·4827. The specimen remained colourless after keeping for several months in diffused daylight.

Another preparation, which had not been subjected to such exhaustive purification, had d_4^{20} 0·9317 (vac.), n_D^{20} 1·4841, α_D^{20} — 46·57°, $[\alpha]_D^{20}$ — 49·98°; 1·1936 grams of this specimen, when dissolved in benzene and made up to 30·0 c.c. at 20°, gave α_D^{20} — 2·37°, whence $[\alpha]_D^{20}$ = — 59·57°.

Physical Properties of d-Piperitone from the Essential Oil of Andropogon Jwarancusa.

A sample of this oil, which was kindly placed at our disposal by Dr. Simonsen, had d_4^{20} 0·9286 (vac.), n_D^{20} 1·4848, α_D^{20} + 51·65°, $[\alpha]_D^{20}$ + 55·62°. A specimen of the extracted ketone, which we also received from Dr. Simonsen, had d_4^{20} 0·9351 (vac.), n_D^{20} 1·4854, α_D^{20} + 45·19°, $[\alpha]_D^{20}$ + 48·33°. Upon carefully redistilling a portion (75 grams) of this specimen under diminished pressure, and rejecting the distillate which passed over below 116°/20 mm., two fractions were collected possessing the following characteristics:

Fraction.	Boiling point.	d_4^{20} .	n_D^{20} .	Weight (grams).
1	116—118·5°/20 mm.	+ 45·91°	1·4848	43·0
2	118·5—121°/20 mm.	+ 47·03	1·4857	23·0

The fractions were pale yellow, and their odour was quite distinct from that of the *l*-piperitone from *E. dives*, owing apparently to the presence of traces of a highly odoriferous impurity. Fraction 1 had d_4^{20} 0·9344 (vac.), whence $[\alpha]_D^{20}$ = + 49·13°.

The Racemisation of l-Piperitone.

When maintained at 180° in a nickel crucible for two hours, a specimen of purified piperitone having α_D^{20} — 32·08° yielded an active piperitone with α_D^{20} — 26·78°. On heating a fresh quantity of the same specimen in a quartz flask at 200° for three hours, a product was obtained which gave no measurable optical rotation

* All the values of α_D in this paper are recorded for a 1-dm. tube.

when examined in a 1-dm. tube in sodium light at 20°. The optically active ketone may thus be racemised without difficulty by the action of heat alone.

Observations of partial racemisation made during a series of extractions with normal sodium sulphite solution suggested the application of alcoholic alkali as a racemising agent. Accordingly, *l*-piperitone (30 grams, 1 mol., $\alpha_D^{20} - 25.42^\circ$) was mixed with a solution of potassium hydroxide (13.2 grams, 1.2 mols.) in alcohol (190 c.c.). After heating under reflux for forty minutes, the ketone was recovered in 70 per cent. yield (21 grams) by steam distillation, and found to be optically inactive.

As partial resinification was observed during the above process, a less vigorous racemising agent was sought, and eventually the following process proved to be the most convenient for the rapid preparation of optically inactive piperitone in quantity. The chemically pure, active ketone (110 grams, $\alpha_D^{20} - 32.08^\circ$) was mixed with a cold solution obtained by dissolving metallic sodium (1.2 grams) in absolute alcohol (80 c.c.), and kept for twenty-four hours at the ordinary temperature. The mixture was poured into a slight excess of very dilute sulphuric acid, the resulting ketone being washed with water and dried over calcium chloride. By subsequent distillation under diminished pressure, the optically inactive substance was obtained in more than 90 per cent. yield (100 grams).

Specimens of piperitone extracted from the oil of *E. dives* by fractional distillation under atmospheric pressure invariably retained a slight laevorotation after such treatment with alcoholic sodium ethoxide, whereas all specimens obtained from the purified crystalline bisulphite compound became optically inactive. Complete loss of optical activity in the presence of alcoholic sodium ethoxide may thus be regarded as a criterion of the chemical purity of preparations of this kind (compare T., 1922, 121, 1871).

A characteristic feature of the addition of quite small amounts of alcoholic sodium ethoxide to piperitone, even after scrupulous purification, is the deep red colour which appears within a few seconds. On acidification, the red colour is discharged, but it returns again upon the addition of a slight excess of alcoholic sodium ethoxide or sodium hydroxide. The colour change would thus appear to attend a process of enolisation, involving in turn a loss of the original molecular asymmetry and the consequent racemisation of the ketone.

In view of cognate investigations, which will form the subject of a later paper, the process described by Beckmann (*Annalen*, 1888, 250, 334) for inverting *l*-menthone was applied to *l*-piperitone. A

specimen of the purified ketone having $\alpha_D^{20} = 32.08^\circ$ was dissolved in melting 90 per cent. sulphuric acid, and eventually maintained at $30-40^\circ$ for an hour. The recovered piperitone, however, had $\alpha_D^{20} = 28.79^\circ$, and had thus undergone only slight racemisation.

A much more complete racemisation was effected by shaking *L*-piperitone ($\alpha_D^{20} = 25.42^\circ$) with a saturated aqueous solution of sulphur dioxide at the ordinary temperature, until the attainment of complete solution: the ketone recovered by boiling the solution under reflux for an hour was only slightly active ($\alpha_D^{20} = 0.09^\circ$).

The Interaction of l-Piperitone and Hydroxylamine.

1. *l*-Piperitone (10 grams, $\alpha_D^{20} = 46.57^\circ$) was mixed with a 10 per cent. excess of hydroxylamine hydrochloride (5 grams) dissolved in water (10 c.c.), and hot methylated spirit was added in just sufficient quantity to give a homogeneous solution. Four successive quantities of sodium acetate crystals (3.4 grams) were added at regular intervals (0, 1, 2, and 3 hours) to the hot solution, which was kept on the water-bath for six hours. The bulk of the alcohol was then removed by evaporation, and the residual liquid neutralised with sodium bicarbonate solution and extracted with ether. The pale yellow oil (10.1 grams) isolated in this way formed a viscous mass on cooling: 0.2383 gram dissolved in benzene and made up to 30.0 c.c. gave $[\alpha]_D^{20} + 180.7^\circ$.

The product was freed from unchanged ketone by extracting with dilute sulphuric acid in ethereal solution (T., 1922, **121**, 587). By neutralising the acid extract, a pale yellow liquid was obtained, which became viscid on cooling and evidently consisted of somewhat impure *l*-piperitoneoxime: 0.2142 gram dissolved in benzene and made up to 30.0 c.c. gave $[\alpha]_D^{20} + 238.1^\circ$.

2. *l*-Piperitone (5 grams, 1 mol., $\alpha_D^{20} = 17.10^\circ$) was added to a solution of somewhat more than a molecular proportion of hydroxylamine hydrochloride (2.5 grams) in water (20 c.c.). The mixture was then made slightly alkaline with sodium hydroxide solution and shaken thoroughly at intervals in a stoppered flask. On the following day, crystalline material had started to separate; a second quantity of hydroxylamine hydrochloride (2.5 grams) was then added, the solution being again rendered slightly alkaline. After shaking the alkaline solution vigorously at intervals for about a week, the whole of the piperitone had disappeared, with the production of a bulky, crystalline precipitate. The latter, after being washed successively with water, alcohol, and ether, melted, when dry (4.1 grams), at $148-150^\circ$. A saturated acetone solution of the product, when examined polarimetrically in a 2-dcm. tube at 20° in sodium light, showed no measurable optical activity, and

a similar result attended the use of more highly active specimens of piperitone in this reaction.

By prolonged fractional crystallisation from boiling acetone, in which it was sparingly soluble, material of this kind (40 grams) was shown to consist of a mixture of substances, the melting points of the various fractions obtained varying from about 130° to 186°. The main component deposited from the acetone solution melted when pure at 176°, and by recrystallisation from hot alcohol, in which it dissolved with moderate ease, was obtained in aggregates of minute, colourless needles, or sometimes in opaque, crystalline nodules, melting at the same temperature (176°). As the main product of the reaction and the first component to be recognised (compare T., 1921, 119, 783), this substance may be designated as *dl-piperitone- α -hydroxylamino-oxime* (Found: C = 59.9; H = 10.1. $C_{10}H_{20}O_2N_2$ requires C = 60.0; H = 10.0 per cent.). In the course of the fractionation, a small quantity of a somewhat less soluble *dl-piperitone- β -hydroxylamino-oxime* was isolated; this substance formed minute, colourless needles, melting at 185–186° (Found: C = 59.4; H = 10.0 per cent.). Both these compounds gave the colour reactions already described (*loc. cit.*). The mother-liquors appeared to contain small amounts of more soluble substances, which were not separated in a state of purity.

dl-Piperitone- α -hydroxylamino-oxime was insoluble in hot or cold water, or in cold sodium hydroxide solution, but it dissolved readily in dilute acids. When mixed in ethereal solution with *p*-nitrobenzoyl chloride and kept over-night, it yielded a *di-p-nitrobenzoyl* derivative, crystallising from boiling alcohol in small, feathery needles, melting at 165–166° (Found: C = 57.7, 57.9; H = 5.9, 5.7. $C_{24}H_{26}O_8N_4$ requires C = 57.8; H = 5.3 per cent.). The derivative was insoluble in dilute acid or alkali, and did not give the colour reactions yielded by the parent substance.

Our acknowledgments are due to Mr. R. S. Hughesdon, B.Sc., for assistance rendered in the course of the work now described. We are indebted to the McCaughey Research Fund of the University of Sydney for a grant in aid of the investigation, which is being continued.

CCLIV.—*Studies in Phototropy. The Reversed Phototropy of Cinnamaldehydesemicarbazone and its Methoxy-derivatives.*

By ISIDOR MORRIS HEILBRON, HERBERT EDWARD HUDSON, and
DORIS MABEL HUISH.

It has previously been shown (Heilbron and Wilson, T., 1914, 105, 2892) that cinnamaldehydesemicarbazone exhibits a type of phototropy which is the converse of that ordinarily observed. When first prepared, it is colourless, and, if immediately placed in the dark, undergoes no change of colour. If, however, the semicarbazone is exposed to diffused sunlight for some hours, although no visible effect is noticeable, on now placing it in the dark, a yellow colour develops on the exposed surfaces, which again disappears on re-exposure to light. In the present communication, the study of this phenomenon, which we suggest designating as *reversed* phototropy, has been extended to the methoxy-derivatives of the parent cinnamaldehydesemicarbazone, and also to the closely related phenyl- and thio-semicarbazones.

The methoxycinnamaldehyde-semicarbazones and -phenylsemicarbazones all crystallise from solution as colourless substances and, with the exception of *m*-methoxycinnamaldehydephenylsemicarbazone, which is insensitive to either sunlight or ultra-violet light, all exhibit reversed phototropic properties. On the other hand, the thiosemicarbazone derivatives, which we expected to find quite similar in character, exhibit only *direct* phototropy, becoming yellow in diffused sunlight and not reverting to the colourless modification on removal from the source of light. A series of experiments has been carried out with the view of obtaining evidence of phototropic change in solution, and for this purpose solutions of the intensely phototropic *o*-methoxycinnamaldehyde-thiosemicarbazone in various solvents were exposed for lengthy periods to sunlight. In no case, however, was there the slightest indication of the production of any colour in the solution and it may thus be reasonably concluded that phototropy is essentially a characteristic of the solid state.

Thermotropy.—This phenomenon is very strikingly manifested by the semicarbazones exhibiting reversed phototropy. So long as any of these remain unactivated by light, rise in temperature produces no colour change. On the other hand, after exposure to sunlight, in certain cases even for so short a period as five minutes, the colourless activated substance becomes yellow almost immediately when placed in a steam-oven.

On reviewing the evidence brought out by the above experiments, it will be seen that in a reversed phototropic change the first effect must be one involving the absorption of a certain number of energy quanta, whereby the molecule is transformed from its inactive, colourless phase (*A*) into an *active* colourless variety (*A'*). This latter form is in turn transformed into the coloured modification (*B*), phototropic equilibrium being established between the latter two phases :

With the idea of possibly gaining some further insight into the mechanism of phototropic change, the absorption spectra of the inactive, active, and coloured modifications of individual semicarbazones in various solvents were investigated, but these threw no new light on the problem, other than confirming that, in solution and independent of the solvent employed, all the forms are identical. Stobbe has shown that in the case of the fulgides (*Annalen*, 1908, 359, 1) the active wave-lengths involved in the bringing about of *direct* phototropic change are those which the substance itself absorbs. We have now been able to prove, as indicated below, that this applies equally in the present series. An ordinary photographic plate was fixed, washed, and when almost dry dusted over with colourless, inactive cinnamaldehydesemicarbazone. The plate was then placed in the spectrograph and exposed for about two hours, an iron arc being used as source of light. On examining the semicarbazone, no visible change was detected, but after leaving the plate over-night, a narrow, yellow band was clearly indicated at $\lambda = 2800\mu\mu$, this being the characteristic ultra-violet frequency of the substance.

In order to determine whether energy is emitted during the transformation in the dark of the active colourless into the coloured form, a photographic plate covered with cinnamaldehydephenylsemicarbazone was activated in strong light and then placed in the dark in contact with an undeveloped plate. After being left over-night, during which time the phenylsemicarbazone had become yellow, the upper plate was developed, but no mark whatsoever could be detected on it.

Although from the evidence before us we do not feel that a

complete explanation of phototropic phenomena can be arrived at, especially as regards the factors determining *direct* or *reversed* phototropy, we suggest that, as the phenomenon is a property of the solid state alone and is primarily induced by electro-magnetic influences, it must be essentially a process connected with the displacement of valency electrons within the molecule. In this connexion, G. N. Lewis has pointed out (*J. Amer. Chem. Soc.*, 1916, **38**, 762) that an accumulation of doubly-linked atoms in a molecule necessarily causes a remarkable increase in the mobility of the electrons of such atoms, owing to diminution in the constraints acting upon them. As a natural consequence, a decrease in the frequency of individual electrons is brought about, so that, in the case of a colourless substance, its absorption bands may be shifted out of the ultra-violet into the short-wave visible spectrum. It seems to us that phototropic change simply represents a concrete example of this generalisation, for despite the fact that the phenomenon is associated with widely varying classes of organic compounds, in all cases conjugated linkings are present, and consequently the conditions necessary for electronic rearrangements obtain. The fact now established that phototropic change occurs in distinct phases would appear to support this assumption, the first effect of light doubtless being the displacement of one or more electrons from a particular unsaturated centre, thus producing the primary active phase. This may then pass, owing to a further regrouping of the mobile electrons within the molecule, into other configurations involving the conjugated system as a whole (compare Kernack and Robinson, T., 1922, **121**, 427).

Viewed in this light, a phototropic change would simply represent an intermediate stage of an irreversible chemical reaction. The active phases of higher energy content, which are similar to Baly's activated molecules (*Phil. Mag.*, 1920, [vi], **40**, 15), would tend either to lose energy and again pass into the inactive phase (recrystallisation effect), or, on the other hand, to undergo complete chemical change with formation of a new substance. Thus Stobbe (*loc. cit.*) has found with the fulgides that, when the phototropic change is frequently repeated, the difference of colour between the two forms becomes gradually less, the phototropic process giving place to a non-reversible chemical reaction in which a substance of different constitution is produced. Similarly, Halban and Geigel (*Z. physikal. Chem.*, 1920, **96**, 233) have shown that, in the case of tetrabenzoylethylene, an irreversible chemical change rapidly follows the primary phototropic process.

The acceleration of phototropic action by rise of temperature, on a molecule which has been activated by light, readily becomes

explicable on this electronic basis, as it simply involves change of equilibrium between particular active phases.

EXPERIMENTAL.

Cinnamaldehydethiosemicarbazone, prepared by Freund and Schander's method (*Ber.*, 1902, 35, 2602), and twice recrystallised from aqueous alcohol, was obtained in colourless needles melting at 123°. From the results of a nitrogen estimation, the above authors considered this semicarbazone to be anhydrous [Found: (F. and S.) N = 20.07. Calc. (anhydrous) N = 20.48 per cent.]. We have now ascertained that it is actually a hydrated substance, containing one molecule of water. This may be removed either by heating for some hours in a steam-oven or by keeping in an exsiccator over concentrated sulphuric acid for several days. Like the above investigators, we invariably obtained high values for nitrogen when the analysis was carried out by the ordinary Dumas method. If, however, the procedure employed by Haas be adopted (T., 1906, 59, 570), and the copper oxide be completely replaced by freshly fused granular lead chromate, normal results will be given. It is necessary even here to carry out the combustion exceedingly slowly and to employ as high a temperature as possible.

The anhydrous thiosemicarbazone, after crystallisation from chloroform, melts sharply at 139°. Curiously enough, with this substance no difficulty was experienced in obtaining normal nitrogen values by the Dumas method.

On exposure to sunlight for several hours, both substances assume a bright canary-yellow colour which persists on removal from the source of light. Recrystallisation of the anhydrous yellow modification from aqueous alcohol again produces the colourless thiosemicarbazone hydrate, whereas, recrystallised from chloroform, it separates out in the colourless, anhydrous form.

Compound melting at 123°. Found: C = 53.6; H = 5.9; N = 19.1; H₂O = 8.2, 8.1. C₁₀H₁₁N₃S.H₂O requires C = 53.8; H = 5.8; N = 18.8; H₂O = 8.1 per cent. *Compound melting at 139°.* Found: C = 58.2; H = 5.2; N = 20.4. C₁₀H₁₁N₃S requires C = 58.3; H = 5.4; N = 20.5 per cent.

o-Methoxycinnamaldehydesemicarbazone.—Twenty grams of *o*-methoxycinnamaldehyde, dissolved in alcohol, were treated with an aqueous solution of semicarbazide acetate. The semicarbazone was gradually precipitated, and was purified by crystallisation from absolute alcohol. It forms colourless crystals melting at 200°, and exhibits the phenomenon of reversed phototropy in a very pronounced degree. An attempt to obtain an isomeric form was made by exposing an alcoholic solution of the semicarbazone for

thirty hours to the light of a quartz mercury lamp, but the original semicarbazone alone was recovered (Found : $N = 19.1$. $C_{11}H_{13}O_2N_3$ requires $N = 19.2$ per cent.).

o-Methoxycinnamaldehydephenylsemicarbazone was prepared by mixing an alcoholic solution containing 20 grams of *o*-methoxycinnamaldehyde with 24 grams of phenylsemicarbazide hydrochloride, dissolved in the minimum quantity of water. The orange-coloured precipitate which was immediately thrown out of solution was filtered off and, after twice crystallising from alcohol, the phenylsemicarbazone was obtained in colourless leaflets melting at 175° . It is interesting to note that, in general, semicarbazones exhibiting pronounced phototropic properties are first precipitated in coloured forms, and must thus be in the form of activated molecules. This same compound was readily produced by boiling cinnamaldehydesemicarbazone with aniline for five minutes. On pouring the hot reaction mixture into dilute acetic acid, a semi-solid mass separated out, which became hard on standing. After crystallisation, first from benzene and finally from alcohol, the phenylsemicarbazone was obtained pure. This substance is highly phototropic and, after six hours' exposure to sunlight, develops, on the excited surface, a deep orange-yellow colour on placing in the dark. This colour again disappears on re-exposure to sunlight for two hours. Freshly prepared *o*-methoxycinnamaldehydephenylsemicarbazone, if immediately placed in the dark, remains colourless, proving definitely that activation by light is first necessary to promote the phototropic properties. The effect of heat in accelerating phototropic change is very evident with this compound. Exposure to bright light for about half-an-hour is sufficient to cause the development of a strong yellow colour at the temperature of a closed steam-oven, whereas, in the dark, at the ordinary temperature, colour is only very slowly developed. As in the case of certain stilbene derivatives phototropy was found to be dependent on the presence of oxygen in the enveloping gas (Stobbe and Mallison, *Ber.*, 1913, **46**, 1226), experiments were carried out with this phenylsemicarbazone in such a manner that activation by light was effected in an oxygen-free atmosphere, carbon dioxide and hydrogen, respectively, being employed for this purpose. The reversed phototropic effects were, however, found to be unimpaired (Found : $N = 14.3$. $C_{17}H_{17}O_2N_3$ requires $N = 14.2$ per cent.).

o-Methoxycinnamaldehydethiosemicarbazone is rapidly precipitated, on addition of a hot aqueous solution of thiosemicarbazide to an alcoholic solution of the aldehyde, as a yellow powder which, after two crystallisations from ethyl alcohol, yields colourless needles

melting at 185° . It is sparingly soluble in hot chloroform, more readily soluble in ethyl acetate or alcohol. This thiosemicarbazone is intensely phototropic, becoming bright canary-yellow when exposed to light for a few hours. Various experiments were carried out in attempts to produce an isomeric form, but in every case unchanged thiosemicarbazone was regenerated (Found: $N = 17.8$, $C_{11}H_{13}ON_3S$ requires $N = 17.9$ per cent.).

m-Methoxycinnamaldehydesemicarbazone.—*m*-Methoxycinnamaldehyde, prepared by Pfeiffer's method (*Annalen*, 1917, 442, 322), was condensed with semicarbazide acetate in the usual manner. The semicarbazone crystallises from alcohol in shining leaflets melting at 197° , readily soluble in ethyl alcohol, chloroform, or ethyl acetate, and insoluble in light petroleum. It exhibits very intense reversed phototropy, assuming a bright canary-yellow colour on being placed in the dark over-night, after an exposure of half-an-hour to ordinary sunlight. The colour entirely disappears on re-exposure to light (Found: $N = 18.9$, $C_{11}H_{13}O_2N_3$ requires $N = 19.2$ per cent.).

m-Methoxycinnamaldehydephenylsemicarbazone was thrown down as an orange-yellow precipitate from a reaction mixture containing 5 grams of *m*-methoxycinnamaldehyde and 6 grams of phenylsemicarbazide hydrochloride in aqueous alcohol. After recrystallisation from alcohol, it formed colourless leaflets melting at 161° . Unlike the semicarbazone itself, it is insensitive to light, being completely devoid of phototropic properties. That this compound is a normal phenylsemicarbazone is proved, not only by the fact that the aldehyde is regenerated on hydrolysis with 20 per cent. hydrochloric acid, but also by its preparation from *m*-methoxycinnamaldehydesemicarbazone on boiling with aniline (Found: $N = 14.2$ per cent. $C_{17}H_{17}O_2N_3$ requires $N = 14.2$ per cent.).

p-Methoxycinnamaldehydesemicarbazone.—The aldehyde and its semicarbazone were prepared by Scholtz and Wiedemann's method (*Ber.*, 1903, 36, 853). The semicarbazone forms colourless leaflets melting at 202° , which even after exposure for three days to bright sunlight develop only feeble phototropic properties. The corresponding phenylsemicarbazone melts at 184° and is but feebly phototropic (Found: $N = 14.2$, $C_{17}H_{17}O_2N_3$ requires $N = 14.2$ per cent.).

The thiosemicarbazone forms canary-yellow needles melting at 194° and is devoid of phototropic properties (Found: $N = 17.8$, $C_{11}H_{13}ON_3S$ requires $N = 17.8$ per cent.).

In conclusion, we desire to express our thanks to Professor E. C. C. Baly, F.R.S., for many valuable suggestions bearing on the spectro-

graphic examination of the compounds, to Dr. J. W. C. Phillips for help in connexion with the preparation and analysis of the cinnamaldehydethiosemicarbazones, and also to the Council of the Department of Scientific and Industrial Research for grants which have enabled the work to be carried out.

CCLV.—*Studies in Mutual Solubility. Part I. Introductory. The Mutual Solubility of Glycerol and Aliphatic and Aromatic Ketones.*

By BASIL CHARLES MCEWEN.

In the course of an extensive investigation on the mutual solubility of carbon compounds a number of general principles governing the miscibility of liquids have been observed. To illustrate these principles as briefly as possible, the solubility relations between a single carbon compound, namely, glycerol, and members of several typical classes of carbon compounds have been selected for consideration.

In general, a given solvent most readily dissolves those substances which are closely allied to it chemically, since, in such cases, solvent and solute contain within their molecules certain atoms or groups which possess a mutual affinity for one another; such mutual affinity giving rise to what may be termed a "solution stress" between the solvent and the solute. Thus, water tends to dissolve hydroxylic compounds, such as the alcohols and phenols, on account of the mutual affinity between the oxygen atoms within the hydroxyl groups. In general, the more oxygen a compound contains the more readily does it dissolve in water and other hydroxylic compounds. This is especially the case when the oxygen is present in combination with hydrogen, that is, as hydroxyl groups. When, however, the hydrogen of a hydroxyl group is replaced by an aliphyl or aryl radicle, the solubility in water and other hydroxylic compounds is lessened, owing to steric hindrance.

Flaschner and McEwen have shown (T., 1908, 93, 1000) that the increase of mutual solubility between water and members in the series of alcohols, aliphatic acids, and aliphatic amines, as well as between water and members of the pyridine and piperidine series, is due to the respective oxygen and nitrogen atoms (carbon and hydrogen atoms causing a decrease in miscibility), and that, further, the larger the carbon-hydrogen group attached to the oxygen or

nitrogen, or the nearer such a group is to these atoms, the smaller is the mutual solubility. The same general rules have been found to apply to glycerol, which, on account of the three hydroxyl groups within its molecule, resembles water in many of its solubility relationships.

The introduction of an amino-group into an aliphatic or aromatic hydrocarbon increases its solubility in water and other hydroxylic compounds, on account of the mutual affinity between the oxygen in the hydroxyl group and the nitrogen in the amino-group. Thus, for example, methylamine and aniline are more readily soluble in water and glycerol than are methane and benzene in the same solvents. The introduction of aliphyl and aryl groups decreases the solubility of carbon compounds in water and other hydroxylic compounds, and increases their solubility in hydrocarbons. The higher members of the homologous series of alcohols, aldehydes, ketones, and acids, for example, are less soluble in water and glycerol than the lower members, which possess a smaller carbon content, whilst, on the other hand, as the hydrocarbon character becomes more fully developed in the higher homologues they become increasingly soluble in other hydrocarbons. Thus, the mutual solubility of two liquids is, in general, affected by the introduction of any substituent into the molecule of one of the liquids. If the substituent in the first liquid possess but little affinity for atoms or groups within the molecule of the second liquid, the mutual solubility tends to decrease, the diminution being determined, not only by the chemical nature, but also by the spatial relationships of any substituents introduced into the molecule in accordance with the general principles of steric hindrance. Glycerol, for example, is miscible with aniline in all proportions, but is soluble in *o*-toluidine only to a small extent at the ordinary temperature, although the upper critical solution temperature for *o*-toluidine and glycerol can be realised without difficulty. Glycerol is miscible with *p*-toluidine in all proportions (at temperatures above the melting point of the latter, namely, 42.8°), the mutual solubility being less affected in this case, on account of the greater remoteness of the methyl group from the amino-group.

The secondary and tertiary monoamines also show a progressive decrease in their miscibility with glycerol, with increase in the size of the alkyl groups attached to the nitrogen atom. The decrease in mutual solubility in these cases must be attributed to steric hindrance, the nitrogen atom being prevented from coming sufficiently close to a hydroxyl group of the glycerol for the mutual affinity between the oxygen and nitrogen atoms to have full play. The increased solubility in hydrocarbon solvents occasioned by the

introduction of alkyl groups into carbon compounds must be attributed to mutual affinity between the carbon atoms (and, possibly, hydrogen atoms) in solvent and solute. Thus, the mutual solubility of glycerol and aniline is partly due to the mutual affinity between the nitrogen in the amino-group of the aniline and the oxygen in one or more of the hydroxyl groups of the glycerol, and partly to the mutual affinity between the carbon atoms in the two compounds. That the former is the predominating influence is shown by the slight miscibility, at the ordinary temperature, of *o*-toluidine and glycerol.

Again, phenol is completely miscible with glycerol at all temperatures; the replacement of the hydrogen in the hydroxyl group by an alkyl group, for example, by a methyl group, considerably reduces the miscibility. Thus, the upper critical solution temperature of glycerol and anisole is 275.5° . If a hydroxyl group be now introduced into the ortho-position (guaiacol), the mutual solubility will be greatly increased; and although guaiacol and glycerol are not completely miscible at all temperatures, yet the complete solubility curve for this pair of liquids can be experimentally realised (see Part II).

Even if the substituent in an aromatic derivative possess great mutual affinity for a particular atom or group in another liquid, the mutual solubility may still be *lowered* if the substitution occur in the ortho-position to the particular group which originally determined the mutual solubility. Thus benzene is sparingly miscible with glycerol; phenol is completely miscible with glycerol at all temperatures; benzaldehyde is completely miscible with glycerol only above 160.7° (the upper critical solution temperature for glycerol and benzaldehyde). Yet the introduction of a hydroxyl group in the ortho-position to the aldehydo-group in benzaldehyde *lowers the mutual solubility*, the upper critical solution temperature for glycerol and salicylaldehyde being 176.6° .

In general, if the miscibility of a given liquid, X, with an aromatic compound containing a particular group, A, be greater than the miscibility of the same liquid, X, with the aromatic compound when the group A is replaced by a different group, B, then, if both the groups A and B are introduced into the aromatic compound in the ortho-position to one another, the miscibility with the liquid X will tend to a lower value than when only the group A was present, and may even be less than when only the group B was present. This generalisation will be considered more fully in Parts II and III.

The determinations of the solubility curves were made by Alexéev's synthetic method, the temperature at which separation into two liquid phases occurred being determined by means of standard Anschütz thermometers. A narrow tube was blown out

at one end into a small bulb, and, at the other end, drawn out into a capillary. The capillary was scratched at a point near its open end with a diamond, and the whole tube was carefully cleaned and weighed. A definite quantity of glycerol was introduced by means of a not too fine capillary pipette, and after the open end of the capillary had been sealed to prevent absorption of moisture by the glycerol the tube was again weighed. The tube was placed on a watch-glass, and the end of the capillary broken off cleanly, at the place scratched by the diamond. A definite quantity of the second liquid was then introduced by means of another capillary pipette, and the open end of the capillary tube again sealed. The tube, together with the small piece of capillary on the watch-glass, was weighed, and the weight of the second liquid introduced obtained.

FIG. 1.

I = Acetone + glycerol. II = Methyl ethyl ketone + glycerol. III = Acetophenone + glycerol.

In the case of solids with low melting points, such as thymol and *p*-toluidine, the same procedure was adopted, the solid being first melted and then introduced in the liquid state. As a large number of the solubility measurements were carried out at a temperature exceeding 38°, it was found desirable, in the case of volatile liquids, to cool both the small bulb tube and the vessel containing the liquid in ice-water before introducing the liquid into the bulb. Since, in certain cases, slight decomposition occurred when the liquid mixtures were heated to high temperatures, each mixture was only used for one determination at the upper part of any solubility curve.

Merck's "Bidistilled Extra Pure Glycerol (Ph. Brit.)" was employed in all the solubility determinations. Fresh portions were used for the determination of each solubility curve, to ensure freedom from absorbed moisture. The purest obtainable samples of the other liquids were fractionated and the fractions boiling at the temperatures specified in each case were employed in the

determination of the solubility curves. The refractive indices of the liquids were also determined as a test of their purity.

In the following tables the amounts of the respective ketones are given in percentage by weight of the solution. The results are reproduced in Fig. 1.

Acetone.	Soln. pt.	Acetone.	Soln. pt.
89.61	40.0°	48.43	95.5° *
86.93	58.5	46.31	95.3 *
76.96	81.3	45.75	95.3
67.42	91.7	44.67	95.2

55.34	95.6 *	20.44	66.6
53.07	95.7	15.77	44.8
51.28	95.6 *	10.90	9.5
Methyl ethyl ketone.	Soln. pt.	Methyl ethyl ketone.	Soln. pt.
92.14	55.5°	41.27	163.2°
86.55	118.5	36.17	162.5
74.78	150.0	26.75	155.5
67.14	161.5	13.21	128.5
60.25	164.5	10.73	116.5
53.84	164.5	4.00	37.5
Acetophenone.	Soln. pt.	Acetophenone.	Soln. pt.
97.13	90.5°	42.00	185.0° *
95.30	113.5	34.62	184.0
83.42	162.5	21.14	174.5
75.07	175.5	15.88	164.0
61.90	183.6	8.86	136.5
53.32	185.5 *	4.38	97.5
51.13	185.4 *		

Critical opalescence observed.

(Slight decomposition occurred at high temperatures in the case of methyl ethyl ketone and glycerol, the contents of the bulb tube becoming slightly brown, and a lower value for the solution point being obtained at each subsequent determination.)

Glycerol: B. p. 288.1°/715.5 mm.; $n_D^{20} = 1.4634$.

Acetone: B. p. 54.5°/715.5 mm.; $n_D^{20} = 1.3514$.

Methyl ethyl ketone: B. p. 79.0°/715.5 mm.; $n_D^{20} = 1.3800$.

Acetophenone: B. p. 200.1°/715.5 mm.; $n_D^{20} = 1.5252$.

The upper critical solution temperature for glycerol and acetone is, accordingly, 95.7°. The replacement of a methyl group in acetone by an ethyl group raises the upper critical solution temperature by nearly 70°, the upper critical solution temperature for glycerol and methyl ethyl ketone being 164.5°. The replacement of a methyl group in acetone by a phenyl group raises the upper critical solution temperature by nearly 90°, the upper critical solution temperature for glycerol and acetophenone being 185.5°.

In general, the larger the alkyl group attached to the carbonyl

group of a ketone, the smaller is the mutual solubility with glycerol. The upper parts of the curves, as is generally the case, are nearly symmetrical: the lower halves of the curves cannot be obtained, on account of the appearance of a solid phase.

CCLVI.—*Studies in Mutual Solubility. Part II. The Mutual Solubility of Glycerol and Alcohols, Aldehydes, Phenols, and their Derivatives.*

By BASIL CHARLES MCEWEN.

GLYCEROL, like water, is miscible in all proportions with the lower members in the series of monohydric saturated aliphatic alcohols.

It is also miscible with the lower members in the series of aromatic alcohols. *iso*Butyl alcohol and *sec.*-butyl alcohol have upper critical solution temperatures with water of 130° and 113.7°, respectively, but are completely miscible with glycerol. *iso*Amyl alcohol has an upper critical solution temperature with glycerol of 74.2°. In the following table the amount of *iso*amyl alcohol is given in percentage by weight of the solution; the results are reproduced in Fig. 1.

<i>iso</i> Amyl alcohol.	Soln. pt.	<i>iso</i> Amyl alcohol.	Soln. pt.	<i>iso</i> Amyl alcohol.	Soln. pt.
84.26	12.5°	46.16	73.0°	19.20	71.5°
76.21	36.8	36.79	74.1*	13.97	66.5
62.40	61.4	31.90	74.2*	10.35	58.0
54.41	69.3	27.62	73.7	5.05	21.5

* Critical opalescence observed.

*iso*Amyl alcohol: B. p. 129.3°/715.5 mm.; $n_D^{20} = 1.3990$.

Similarly, glycerol is completely miscible with the lower members in the series of monohydric phenols, but becomes less soluble with increase in the size of the carbon-hydrogen group, or groups, in the higher homologues. Thus thymol, m. p. 51°, has an upper critical solution temperature with glycerol of 218.5°.

The solubility relations between glycerol and benzaldehyde and salicylaldehyde, between glycerol and anisole, and glycerol and guaiacol are shown in the following table, and in Figs. 2, 3, and 4. The amount of the aromatic compound is, in each case, given in percentage by weight of the solution.

FIG. 2.

* Critical opalescence observed.

(Slight decomposition occurred at high temperatures in the cases of Benzaldehyde and glycerol, salicylaldehyde and glycerol, and anisole and glycerol, the contents of the bulb tube becoming slightly brown, and a lower value for the solution point being obtained at each subsequent determination. No decomposition occurred in the case of guaiacol and glycerol, on account of the lower value of the upper critical solution temperature.)

Benzaldehyde : B. p. $177.1^{\circ}/715.5$ mm.; $n_D^{25} = 1.5355$.

Salicylaldehyde : B. p. $194.1^{\circ}/715.5$ mm.; $n_D^{25} = 1.5632$.

Anisole : B. p. $150.2^{\circ}/715.5$ mm.; $n_D^{25} = 1.5080$.

Guaiacol (chem. pur. synthet.) : B. p. $202.3^{\circ}/715.1$ mm.; $n_D^{25} = 1.5341$.

It is thus evident that the replacement of the hydrogen of the hydroxyl group in phenol by a methyl group (anisole) considerably reduces the mutual solubility with glycerol. The subsequent introduction of a hydroxyl group in the ortho-position to the methoxy-group (guaiacol) raises the mutual solubility again, so that guaiacol is completely miscible with glycerol except for a small range of temperature (39.5° to 83.5°). The complete solubility curve of glycerol-guaiacol can thus be followed. It will be seen that the law of rectilinear diameters holds fairly well for the upper portion, whilst the diameter is somewhat more sharply curved for the lower part of the solubility ring.

The introduction of a hydroxyl group in the ortho-position to the aldehyde-group in benzaldehyde *lowers* the mutual solubility with glycerol, salicylaldehyde and glycerol having an upper critical solution temperature of 176.6° . In this case, as was pointed out

in Part I (preceding paper), the mutual solubility is less than for either glycerol and phenol, or glycerol and benzaldehyde.

An explanation of these solubility relationships appears to be furnished by the assumption of a mutual attraction between the oxygen atoms modified, to a greater or less extent, by the influence of steric hindrance. Thus phenol and glycerol are miscible in all proportions. *o*-Cresol and glycerol are still miscible in all proportions, the steric hindrance of the methyl group not being sufficiently great to prevent complete miscibility. If the methyl group be replaced by a methoxy-group, we find that guaiacol and glycerol are only completely miscible below 39.5° and above 83.5° , a small amount of mutual attraction being set up between the oxygen atoms in the two adjacent groups in the benzene ring, so that the remaining attraction for the oxygen atoms in the glycerol is weakened. The amount of mutual attraction between the oxygen atoms in the *ortho*-position, in this case, will not be very great, because the methyl group attached to the oxygen in the methoxy-group screens, to a large extent, the oxygen atom in that group, so that the oxygen in the adjacent hydroxyl group exerts nearly as much attraction on the oxygen in the glycerol hydroxyl groups as in the preceding case of *o*-cresol and glycerol. The steric hindrance exerted by the methyl group attached to the oxygen atom in the methoxy-group is well shown by the sparing mutual solubility of anisole and glycerol (the upper critical solution temperature for this pair of liquids being 275.5°). Again, if an aldehyde-group be introduced in the *ortho*-position to the hydroxyl group in phenol (salicylaldehyde), the miscibility with glycerol is considerably reduced (upper critical solution temperature = 176.6°). This would indicate the existence of a moderate amount of mutual attraction between the oxygen atoms in the adjacent hydroxyl and aldehyde-groups, and a corresponding weakening in the remaining attraction for the oxygen atoms in the glycerol. It should therefore follow that the mutual solubility of glycerol and benzaldehyde should be greater than that of glycerol and anisole, and such, in fact, is found to be the case. Indeed, the upper critical solution temperature of glycerol and benzaldehyde (160.7°) is even lower than that of glycerol and salicylaldehyde (176.6°).

It would be anticipated that the introduction of an aldehyde-group into, say, guaiacol, if not in the *ortho*-position to either the hydroxyl or the methoxy-group, would somewhat increase the miscibility with glycerol, and it was found that, whilst the upper critical solution temperature for glycerol and guaiacol was 83.5° , vanillin was miscible with glycerol in all proportions above its melting point, 80° . The introduction of a carbon-hydrogen side

chain into guaiacol should, on the other hand, reduce the miscibility with glycerol. Thus eugenol and glycerol were found to have a much higher upper critical solution temperature than guaiacol and glycerol.

In the case of pyrocatechol, where two hydroxyl groups are in the ortho-position in the benzene nucleus, it was found that there was complete miscibility with glycerol at temperatures above the melting point of pyrocatechol, 104°. Now, although in this case there may be assumed to be a moderate amount of mutual attraction between the oxygen atoms in the adjacent hydroxyl groups in the benzene nucleus, yet, since there are two hydroxyl groups present, the remaining attraction exerted by both groups for the oxygen atoms in the glycerol is still sufficient to determine complete miscibility.

As to the nature of the mutual affinity between the oxygen atoms in the cases considered, little evidence is available. Since an element such as oxygen may show more than one valency, it is possible that in the presence of a second oxygen atom, whether in the same or another molecule, additional valencies may come into play. Thus, if oxygen be regarded as functioning as a quadrivalent element, the two additional valencies of the oxygen atom in a molecule of one liquid may exert an attractive force on an oxygen atom in a molecule of another liquid, the oxygen atom in the second liquid also possessing two additional valencies. This attractive force may be sufficient to determine the complete miscibility of the liquids, unless reduced to a greater or less extent by either the steric hindrance of adjacent carbon-hydrogen groups within the molecule, or by the additional valencies being already exerted between adjacent oxygen atoms within the same molecule instead of being available to act on the oxygen atoms in the molecule of the second liquid.

CCLVII.—*Dyestuffs Derived from Heterocyclic Bases containing Reactive Methyl Groups.*

By JAMES LEONARD BRIERLEY SMITH.

I. *Photosensitising Dyestuffs.*—The dyestuffs obtained by condensing the alkylidides of methyl-substituted heterocyclic compounds, containing a reactive methyl group, with *p*-dimethylaminobenzaldehyde are pronounced photographic sensitisers (König, *J. p.*

Chem., 1912, [iii], **86**, 172; König and Treichel, *ibid.*, 1921, [ii], **102**, 63; Barbier, *Bull. Soc. chim.*, 1920, [iv], **27**, 427; Mills and Pope, T., 1922, **121**, 946; Mills and Smith, *ibid.*, p. 2724).

A series of dyestuffs of this type has therefore been prepared from the methiodides of various heterocyclic compounds, in order to observe the effect of various substituents on the photosensitising action of this class of dyestuffs.

The observation of Mills and Smith (*loc. cit.*) of the unusually high reactivity of the 2-methyl group in the alkiodides of the thiazole bases is confirmed by these experiments. All the methiodides of the 4- and 5-substituted derivatives of 2-methylthiazole (I) reacted exceedingly readily with *p*-dimethylaminobenzaldehyde and with nitrosodimethylaniline. The same is true of the methiodides of 2-methylbenzothiazole (II) and of the 2-methyl- α - and - β -naphthiazoles (III and IV). However, the methiodides of 2:3-dimethylbenziminazole (V) and 2:3:3-trimethylindolenine (VI) condensed less readily with *p*-dimethylaminobenzaldehyde than the 2-methylthiazole methiodides.

The resulting 2-*p*-dimethylaminostyryl derivatives all possess photosensitising properties. In the simple thiazole series, the extra sensitiveness conferred on the gelatino-silver bromide photographic plate by the dyestuff increases regularly with the complexity of the substituent groups: a comparison of the 2-*p*-dimethylaminostyryl derivatives of II, V, and VI has shown that the photosensitising property and the colour of the compound are changed very considerably by the substitution of -NMe or -CMe₂ for -S-. All the compounds described diminish the normal speed of the gelatino-bromide plate. With exception of the light yellow 2-*p*-dimethylaminostyryl-3-methylbenziminazole methiodide, they are highly coloured, lustrous, crystalline compounds, useless as dyestuffs because of the fugitive character of the shades on silk in regard to light and washing. The discharge of the colour by mineral acids, and its restoration by the addition of alkali are characteristic of all these compounds.

II. *The Anils of the 4- and 5-Substituted 2-Aldehydthiazole Methiodides.*—It was shown by Kaufmann and Vallette (*Ber.*, 1912, 45, 1737) that quinaldine alkiodides condense with nitroso-dimethylaniline in the presence of piperidine, to yield the highly coloured anils of quinoline-2-aldehyde alkiodides. Mills and Smith (*loc. cit.*) have shown that 4-phenyl-2-methylthiazole methiodide can undergo a similar condensation.

As these anils only differ from the corresponding dimethyl-aminostyryl derivatives in having the system $-\text{CH:N}-$ in place of $-\text{CH:CH}-$, a series of them was prepared for comparison with the styrylthiazole derivatives. Since these anils are highly coloured compounds, nitrosodimethylaniline in alcoholic solution in the presence of piperidine serves as a very delicate test for the reactivity of a methyl group in the methiodides of methyl-substituted heterocyclic compounds. All the methiodides of the 4- and 5-substituted derivatives of 2-methylthiazole are exceedingly reactive, giving this test in a few seconds in the cold.

These anil methiodides are more highly coloured than the corresponding styryl compounds, and differ from them in a marked degree in photosensitising properties; the anils all decrease very considerably the normal sensitiveness of the gelatino-silver bromide photographic plate. It is not improbable that this is due to the "screening" effect of the colour imparted to the plate, since these dyestuffs are very highly coloured.

These anil methiodides are useless as dyestuffs, as the red colour imparted to silk is very fugitive in daylight, and may easily be removed by washing. The colour of the anil in solution is very easily discharged by acids, but may be restored slowly by the addition of alkali.

The apparatus and method employed for taking the spectrographs of the compounds described in the present paper are substantially the same as those described by Mills and Pope (*Phot. J.*, 1920, 60, 186).

EXPERIMENTAL.

2-Methylthiazole Methiodide, $\text{C}_4\text{H}_5\text{NS}, \text{CH}_3\text{I}$.—2-Methylthiazole, prepared from thioacetamide and chloroacetal by Hantzsch's method (*Annalen*, 1888, 250, 270), was converted almost quantitatively into the methiodide by heating with methyl iodide for four hours at 60° ; the reaction also proceeds rapidly at the ordinary temperature. This methiodide, which was readily soluble in water and sparingly soluble in hot alcohol, crystallised from the former solvent in colourless needles subliming at 298° but not melting at 300° in a sealed tube (Found: $\text{I} = 52.57$. $\text{C}_5\text{H}_5\text{NS}$, requires $\text{I} = 52.70$ per cent.).

2-p-Dimethylaminostyrylthiazole Methiodide, $C_{14}H_{17}N_2IS$. — On heating a solution of 2-methylthiazole methiodide (4.0 grams) and *p*-dimethylaminobenzaldehyde (2.5 grams) in alcohol (60 c.c.) with piperidine (0.6 c.c.), a red colour developed rapidly; after boiling for four hours, red crystals (1 gram) separated from the solution on cooling. These, having been collected, washed with hot water and ether, and recrystallised from methyl alcohol, gave fine, red needles with faint blue reflex, m. p. 253° (decomp.) (Found: $I = 33.98$; $S = 8.80$. $C_{14}H_{17}N_2IS$ requires $I = 34.14$; $S = 8.61$ per cent.).

This dyestuff resembles very closely the 2-*p*-dimethylaminostyrylpyridine methiodide described by Mills and Pope (*loc. cit.*). The colour in solution is orange. The dyestuff is a photosensitiser for the gelatino-bromide plate, and confers an extra sensitiveness which extends to $\lambda 5800$, with a maximum at $\lambda 5000$.

2-p-Dimethylaminostyryl-4-methylthiazole Methiodide. — 2:4-Dimethylthiazole methiodide (8 grams), prepared by Hantzsch's method (*Annalen*, 1888, 250, 265), and *p*-dimethylaminobenzaldehyde (4.7 grams) were heated in alcohol (100 c.c.) with piperidine (1.1 c.c.), a red colour appearing immediately. The red crystals (4 grams) that had formed after one hour's boiling separated from methyl alcohol in red needles with blue reflex, m. p. 269° (decomp.) (Found: $C = 46.65$; $H = 4.95$; $I = 32.91$; $S = 8.24$. $C_{15}H_{19}N_2IS$ requires $C = 46.63$; $H = 4.92$; $I = 32.90$; $S = 8.29$ per cent.).

The colour in solution is deep orange. The extra sensitiveness conferred by the dyestuff on the gelatino-bromide plate extends to $\lambda 5950$, with a maximum at $\lambda 5500$.

4-Phenyl-2:5-dimethylthiazole, $C_{11}H_{11}NS$. — An equimolecular mixture of ω -bromopropiophenone (Pampel and Schmidt, *Ber.*, 1886, 19, 2896) and thioacetamide reacted vigorously when moistened with alcohol and warmed gently; the crystalline product was dissolved in dilute hydrochloric acid. From the solution after filtration from tar the base was set free by alkali as an oil, which was extracted with ether and dried with potassium hydroxide.

The oil remaining after evaporation of the ether was fractionated, when 4-phenyl-2:5-dimethylthiazole passed over at $296^\circ/758$ mm. as a colourless, highly refractive oil with a faint aromatic odour. The yield was 40 per cent. of the theoretical (Found: $S = 17.07$. $C_{11}H_{11}NS$ requires $S = 16.93$ per cent.). The picrate forms golden-yellow needles, m. p. 128° , and the chloroplatinate fine, yellow needles from water, m. p. 299° (decomp.) (Found: $Pt = 24.68$. $C_{22}H_{24}N_2Cl_6S_2Pt$ requires $Pt = 24.74$ per cent.).

4-Phenyl-2:5-dimethylthiazole methiodide, $C_{11}H_{11}NS, CH_3I, H_2O$, was prepared by heating the base with methyl iodide in a sealed

tube for forty-eight hours at 100°. On recrystallisation from water, in which it is very soluble, it was obtained as colourless, monohydrated needles. The anhydrous salt is a yellow, crystalline powder, m. p. 171° (Found: $\text{H}_2\text{O} = 5.03$. $\text{C}_{12}\text{H}_{14}\text{NIS}, \text{H}_2\text{O}$ requires $\text{H}_2\text{O} = 5.16$ per cent. Found: $\text{I} = 38.30$. $\text{C}_{12}\text{H}_{14}\text{NIS}$ requires $\text{I} = 38.37$ per cent.).

2-p-Dimethylaminostyryl-4-phenyl-5-methylthiazole methiodide, $\text{C}_{21}\text{H}_{23}\text{N}_2\text{IS}$, was prepared from 4-phenyl-2:5-dimethylthiazole methiodide and *p*-dimethylaminobenzaldehyde by the method described above. On recrystallisation from methyl alcohol, in which it is much more soluble than the other related compounds, it was obtained as opaque prisms with intense green reflex, m. p. 219° (decomp.) (Found: $\text{I} = 27.51$; $\text{S} = 6.90$. $\text{C}_{21}\text{H}_{23}\text{NIS}$ requires $\text{I} = 27.49$; $\text{S} = 6.93$ per cent.).

The colour in solution is purple. The dyestuff is a powerful photosensitiser for green, and the extra sensitiveness conferred on the gelatino-bromide plate extends to $\lambda 6250$, the sensitisation band being uniformly intense to $\lambda 5800$, for moderate exposures.

4:5-Diphenyl-2-methylthiazole Methiodide, $\text{C}_{16}\text{H}_{13}\text{NS}, \text{CH}_3\text{I}$.—4:5-Diphenyl-2-methylthiazole was prepared from thioacetamide and bromodeoxybenzoin (Limpricht and Schwanert, *Annalen*, 1870, 155, 68) as described by Hubacher (*ibid.*, 1890, 259, 244). The methiodide, prepared by heating the base with methyl iodide in a sealed tube for forty-eight hours at 100°, crystallises from alcohol, in which it is very soluble, in colourless needles, m. p. 197° (Found: $\text{I} = 32.16$. $\text{C}_{17}\text{H}_{16}\text{NIS}$ requires $\text{I} = 32.31$ per cent.).

2-p-Dimethylaminostyryl-4:5-diphenylthiazole methiodide (3 grams), obtained from the above methiodide (4 grams) in the manner previously described, after boiling the solution for twenty minutes, crystallises from methyl alcohol in purple needles, m. p. 234° (decomp.) (Found: $\text{I} = 24.27$; $\text{S} = 6.21$. $\text{C}_{26}\text{H}_{25}\text{N}_2\text{IS}$ requires $\text{I} = 24.24$; $\text{S} = 6.11$ per cent.).

The colour in solution is purple. The dyestuff confers extra sensitiveness on the gelatino-bromide plate extending to $\lambda 6250$, with a maximum at $\lambda 5600$, although the sensitisation band is considerably less intense than that of the previously described compound.

2-p-Dimethylaminostyrylbenzothiazole methiodide was prepared from 2-methylbenzothiazole methiodide and *p*-dimethylaminobenzaldehyde according to the method described above. On recrystallisation from methyl alcohol, the dyestuff was obtained as steel-blue needles, m. p. 250° (decomp.) (Found: $\text{I} = 30.00$. $\text{C}_{18}\text{H}_{19}\text{N}_2\text{IS}$ requires $\text{I} = 30.10$ per cent.).

The colour in solution is purple. The dyestuff confers extra

sensitiveness on the gelatino-bromide plate extending to $\lambda 6700$, with a maximum at $\lambda 5700$.

König and Treichel (*loc. cit.*) have prepared the methoperchlorate corresponding with the above methiodide, but give no details of its photosensitising action.

4- β -Naphthyl-2-methylthiazole, $C_{14}H_{11}NS$.—An equimolecular mixture of bromo- β -naphthyl methyl ketone (Müller and Pechmann, *Ber.*, 1889, 22, 2561; Pampel and Schmidt, *Ber.*, 1886, 19, 2398) and thioacetamide was moistened with alcohol and heated on the water-bath for half an hour: the resulting semi-crystalline product was extracted with 20 per cent. hydrochloric acid, and the base was set free from the filtrate by alkali as an oil, which was extracted with ether, and dried over caustic potash. The oil remaining after evaporation of the ether was distilled in a vacuum, when 4- β -naphthyl-2-methylthiazole passed over at $208^\circ/15$ mm. as a colourless, viscous oil, which may be distilled unchanged at $363^\circ/747$ mm. (Found: S = 14.35. $C_{14}H_{11}NS$ requires S = 14.22 per cent.).

It is easily soluble in alcohol or ether, but insoluble in water.

The hydrochloride forms colourless needles which are decomposed by water; the picrate, yellow needles, m. p. 179° , and the chloroplatinate, yellow prisms from hot water (Found: Pt = 22.56. $C_{25}H_{24}Cl_2N_2S_2Pt$ requires Pt = 22.67 per cent.).

4- β -Naphthyl-2-methylthiazole methiodide was obtained quantitatively by heating the base with methyl iodide in a sealed tube for thirty hours at 100° . It forms almost colourless needles from alcohol, m. p. 222° (decomp.) (Found: I = 34.50. $C_{15}H_{14}NIS$ requires I = 34.60 per cent.).

It is almost insoluble in cold alcohol or water, but fairly soluble in hot alcohol.

2-p-Dimethylaminostyryl-4- β -naphthylthiazole methiodide was prepared from the above methiodide in the manner described for the other similar compounds. On recrystallisation from methyl alcohol, the dyestuff was obtained as red crystals with green reflex, m. p. 232° (decomp.) (Found: I = 25.25; S = 6.42. $C_{24}H_{23}N_2IS$ requires I = 25.50; S = 6.43 per cent.). The colour in solution is orange. The dyestuff confers an extra sensitiveness on the gelatino-bromide plate which extends to $\lambda 6300$, with a maximum at $\lambda 5800$.

2-Methyl- α -naphthothiazole Methiodide, $C_{12}H_9NS, CH_3I$.—This methiodide was obtained, in a 60 per cent. yield, by heating 2-methyl- α -naphthothiazole (Jacobson, *Ber.*, 1887, 20, 1898) with methyl iodide in a sealed tube for fifteen hours at 100° . On recrystallisation from alcohol, the methiodide was obtained as straw-

coloured prisms, m. p. 234° (decomp.) (Found: $I = 37.01$. $C_{13}H_{12}NIS$ requires $I = 37.24$ per cent.).

The methiodide is almost insoluble in cold alcohol or water; one part dissolves in about 60 parts of boiling alcohol.

2-p-Dimethylaminostyryl- α -naphthathiazole methiodide was prepared by the general method described above. On recrystallisation from methyl alcohol, it was obtained in prisms with green reflex, m. p. 232° (decomp.) (Found: $I = 26.72$. $C_{22}H_{21}N_2IS$ requires $I = 26.91$ per cent.).

The colour in solution is magenta. The dyestuff confers an extra sensitiveness on the gelatino-bromide plate which extends to $\lambda 6800$, with a maximum at $\lambda 5900$.

2-Methyl- β -naphthathiazole Methiodide, $C_{12}H_9NS, CH_3I$.—This methiodide was obtained, almost quantitatively, by heating 2-methyl- β -naphthathiazole (Jacobson, *Ber.*, 1887, 20, 1897) with methyl iodide in a sealed tube for fifteen hours at 100° . On recrystallisation from alcohol, the salt was obtained as straw-coloured needles, m. p. 245° (decomp.) (Found: $I = 36.92$. $C_{13}H_{12}NIS$ requires $I = 37.24$ per cent.).

The methiodide is almost insoluble in cold alcohol or water, but is fairly soluble in hot alcohol.

2-p-Dimethylaminostyryl- β -naphthathiazole methiodide was prepared by the general method described above. By recrystallisation from methyl alcohol, it was obtained as lustrous blue needles, m. p. 256° (decomp.) (Found: $I = 26.72$; $S = 6.78$. $C_{22}H_{21}N_2IS$ requires $I = 26.91$; $S = 6.78$ per cent.).

The colour in solution is purple. The dyestuff confers an extra sensitiveness on the gelatino-bromide plate which extends to $\lambda 6700$ with a maximum at $\lambda 6100$.

2-p-Dimethylaminostyryl-3-methylbenzimidazole Methiodide.—A solution of 2:3-dimethylbenzimidazole methiodide (Fischer, *Ber.*, 1892, 25, 2838) (2.3 grams) and *p*-dimethylaminobenzaldehyde (1.2 grams) in alcohol (20 c.c.) was boiled with piperidine (0.8 c.c.), and light yellow crystals (1 gram) separated after three hours. Recrystallised from methyl alcohol, the dyestuff was obtained as lustrous yellow needles, which did not melt at 310° (Found: $C = 54.55$; $H = 5.25$; $I = 30.38$. $C_{19}H_{22}N_3I$ requires $C = 54.41$; $H = 5.25$; $I = 30.31$ per cent.).

The colour in solution is lemon-yellow. The dyestuff confers an extra sensitiveness on the gelatino-bromide plate which extends to $\lambda 6800$, with a maximum at $\lambda 5200$.

2-p-Dimethylaminostyryl-3:3-dimethylindolenine Methiodide.—On heating a solution of 2:3:3-trimethylindolenine methiodide (2.6 grams) (Fischer, *Annalen*, 1887, 242, 353) and *p*-dimethyl-

aminobenzaldehyde (1.3 grams) in alcohol (30 c.c.) with piperidine (0.3 c.c.), an intense purple colour developed rapidly. After boiling for eight hours, the solution was poured into 5 per cent. potassium iodide solution (300 c.c.), when an iridescent tar was precipitated, which soon crystallised. This, having been collected, washed with benzene, water, and ether, and recrystallised from methyl alcohol, gave the dyestuff (1 gram) as steel-blue needles, m. p. 238° (decomp.) (Found: I = 29.1. $C_{21}H_{25}N_2I$ requires I = 29.4 per cent.).

The colour in solution is purple, and is easily discharged by acids, but is restored a few minutes after the addition of alkali. The dyestuff depresses the normal speed of the gelatino-bromide plate, but confers an extra sensitiveness which extends to the D line.

The p-Dimethylamino-anil of 2-Aldehydo-4-methylthiazole Methiodide.—When piperidine (0.1 c.c.) was added in the cold to a mixture of 2:4-dimethylthiazole methiodide (4.5 grams) and nitrosodimethylaniline (2.7 grams) dissolved in alcohol (80 c.c.), a red colour developed in a short time. After boiling for four minutes, green crystals (2.8 grams) had separated from the hot solution: after boiling for a further two hours, a further amount (2 grams) was obtained. On recrystallisation from methyl alcohol, the dyestuff was obtained in opaque needles with dark green reflex, m. p. 234° (decomp.) (Found: C = 43.24; H = 4.80; I = 32.73; S = 8.05. $C_{14}H_{18}N_3IS$ requires C = 43.41; H = 4.65; I = 32.82; S = 8.27 per cent.).

The colour in dilute solution is a deep ruby red. The dyestuff decreases considerably the normal sensitiveness of the gelatino-bromide plate.

The p-Dimethylamino-anil of 2-Aldehydo-4-phenyl-5-methylthiazole Methiodide.—This compound was prepared from 4-phenyl-2:5-dimethylthiazole methiodide in the manner described above. On recrystallisation from methyl alcohol, in which it is much more soluble than the other similar compounds, the dyestuff was obtained as golden-green needles, m. p. 209° (decomp.) (Found: C = 52.10; H = 4.92; I = 27.34; S = 6.96. $C_{20}H_{22}N_3IS$ requires C = 51.83; H = 4.75; I = 27.43; S = 6.91 per cent.).

The colour in solution is deep purple. This dyestuff also decreases very considerably the normal sensitiveness of the gelatino-bromide plate.

The p-Dimethylamino-anil of 2-Aldehydo-4:5-diphenylthiazole Methiodide.—This compound was prepared from 4:5-diphenyl-2-methylthiazole methiodide in the manner previously described. On recrystallisation from methyl alcohol, the dyestuff was obtained

as lustrous, brassy crystals, m. p. 215° (decomp.) (Found: I = 23.98; S = 5.95. $C_{25}H_{24}N_3IS$ requires I = 24.19; S = 6.10 per cent.).

The colour in solution is deep purple. The dyestuff also decreases considerably the normal sensitiveness of the gelatino-bromide plate, although not to the same extent as the other similar compounds.

The author desires to express his gratitude to Dr. W. H. Mills for his invaluable advice and help, and also to the Royal Society and to the Department of Scientific and Industrial Research for financial assistance during a part of the time concerned.

CCLVIII.—*The Relationship of the Tautomeric Hydrogen Theory to the Theory of Induced Alternate Polarities.*

By FRED ALLSOP and JAMES KENNER.

SOME time ago (Burton and Kenner, T., 1922, 121, 489), exception was taken to the suggestion made by Macbeth and Pratt (T., 1921, 119, 1356) that "a certain parallel may be drawn between the behaviour of the polynitro-aliphatic compounds and of polynitro-aromatic substances, especially those in which the ortho-para influence of the nitro-group exists." Subsequently, this view was considerably modified by the admission that "too much stress must not be laid on this parallel, as aromatic and aliphatic substances are compounds of very different types" (Henderson and Macbeth, T., 1922, 121, 892). At the same time, an explanation of the reactivity of polynitro-aliphatic compounds was advanced, based on the theory of alternate polarity (Macbeth, *ibid.*, p. 1116), and later the view put forward by Burton and Kenner, that the reactivity in question constituted a further illustration of the tendency of such compounds to acquire a tautomeric hydrogen atom (Thole and Thorpe, T., 1911, 99, 2183),* was adversely criticised. In making their suggestion, however, Burton and Kenner expressly pointed out that "it leaves open the questions as to how and why such a change occurs," because it was hoped to

* At the time of writing the previous paper it had escaped my notice that Norris and Thorpe (T., 1921, 119, 1203) had also previously applied this consideration to the elimination of halogen from certain compounds.—J.K.

deal with the matter in more detail in connexion with a discussion of the general phenomena of tautomerism and related phenomena. The latter is supplied in an abbreviated form as an appendix to this paper. Meanwhile, further experimental evidence in favour of the tautomeric hydrogen theory has been furnished by Gupta and Thorpe (T., 1922, 121, 1896), whilst Robinson (*Ann. Reports*, 1922, 19, 102) regards both views as correct.

We would, however, suggest that the tautomeric hydrogen theory is, if anything, more comprehensive than the theory of induced alternate polarity in its application to the reactions in question. Thus, in our view, the object of the latter, when applied to a reaction in which the portions X and Y of the compound XY become associated with different atoms of another compound, is to explain why these are in the 1 : 2, 1 : 4, or, in general, the 1 : 2n position with respect to each other. This will be evident from the considerations adduced by Kermack and Robinson under the heading "Primary Conjugation" (T., 1922, 121, 432), and by Lapworth (*ibid.*, p. 416). The theory thus indicates possible preliminary stages of the interaction, but is not concerned with the conditions governing the extent to which these are surpassed in practice. Thus, the action of potassium methoxide on *o*-dinitrobenzene would, according to the theory, result in the formation of the coloured complex (I), in which the sign ——— may, and in most cases does, correspond to very slight union. If, therefore, the mixture be not heated, but worked up in the usual manner,

the original reagents will be recovered. The redistribution of valency resulting in the displacement of the nitro-group is, in general, brought about only by the supply of heat energy to the system and by utilising the effects of mass action. According to this view, therefore, the statement that the nitro-group is displaced because it is "negative" would be incomplete in that it would omit any reference to the later stages of the reaction. Similarly, in the case of the reaction between potassium methoxide and tetranitromethane, the theory predicts the formation of the complex (II), but not the further spontaneous decomposition experimentally observed. This is due to the liberation of energy resulting from the transition from the original unconjugated condition of

the double bonds in the complex to a conjugated condition in the *aci*-nitro-form, and to the formation of the potassium salt of this strong acid, and is only partly offset by the energy required for the disruption of the two reacting molecules. These are the features which, we think, are referred to when the reaction is ascribed to a tendency to acquire a tautomeric hydrogen atom. Thus we regard the tendency to conjugation as one of the determining factors of the tautomerism of β -diketones and the corresponding polynitro-derivatives of methane, whilst salt-formation is perhaps the most important indication of tautomerism in compounds like ethyl malonate, of which the free enol is very unstable.

Further, it is not permissible to employ the theory of induced alternate polarities, as is done by Macbeth, without discrimination as to the nature of the compounds involved.* On this basis, for example, it might be expected that each of the iodine atoms in tetraiodomethane (III) would be "negative." Nevertheless, one of them exhibits all the recognised "positive" properties. Iodoform is obtained from tetraiodomethane by means of alcoholic potassium hydroxide, sodium ethoxide, or potassium cyanide (Nef, *Annalen*, 1899, 308, 329), water (Gustavson, *Annalen*, 1874, 172, 173), hydrogen chloride, or hydrogen iodide (Moissan, *Compt. rend.*, 1891, 113, 22). Correspondingly, iodoform contains a "positive" hydrogen atom, and is brominated by treatment with sodium hypobromite. Similarly, bromoform may be iodinated (Dehn, *J. Amer. Chem. Soc.*, 1909, 31, 1227), or brominated, and tetra-bromomethane shows similar reactions to tetraiodomethane (Nef, *loc. cit.*). The most obvious explanation of these reactions is on steric grounds. Thus, owing to their large volumes, the positive nucleus of the fourth iodine atom in tetraiodomethane might well be prevented by those of the other three from attaining as close a proximity as it normally would do to the pair of electrons it shares with the carbon atom. It would thus be unusually "exposed," to adopt the phraseology of Conant (*J. Amer. Chem. Soc.*, 1921, 43, 705), and there would be a considerable tendency for it to unite with the negative portion of another molecule, especially if the positive portion of this, for example, hydrogen, were such that, owing to its smaller volume, it could take up a more approximately normal position in relation to the above-mentioned pair of electrons. It is in accordance with this that halogen may displace halogen in these compounds according to

* This discussion was included in a paper on "The Theories of Polarity in Organic Compounds" submitted to the Society in November last, prior to the appearance of general remarks by Robinson to a similar effect (*Ann. Reports*, 1922, p. 103).

the rule that chlorine displaces bromine, and bromine displaces iodine.

Again, both the hydrogen atoms of acetylene are pronouncedly "positive," and replaceable by metals. Similarly, di-iodoacetylene is formed by the action of iodine monochloride on calcium carbide or copper acetylide, and is converted by acid solutions of potassium iodide into acetylene (Howell and Noyes, *J. Amer. Chem. Soc.*, 1920, **42**, 991). Thus, in place of the one positive atom in these compounds (IV) which a rigid literal application of the theory of alternate polarities would predict there are two. An explanation

has been given by Stark ("Atomdynamik," III, p. 95), who points out that the position of the six electrons shared by the two carbon atoms in acetylene is such as to involve considerable dispersion of the lines of force between them and the positive carbon residues. A number of these therefore take a shorter course to the electrons shared with the hydrogen or iodine atoms, drawing these closer to the positive carbon nuclei, and away from the positive hydrogen nuclei. It may be pointed out that, even under these conditions, the positive carbon nuclei are still exposed, and therefore will show "positive" reactions, and combine with "negative" hydroxyl (compare also Kermack and Robinson, *loc. cit.*, p. 430). The potential reactivity of the acetylenes may therefore be represented by formula V, which may be considered a not inadequate expression of their well-known instability.

The structural resemblance between tetraiodomethane and tetranitromethane renders it not unreasonable to assume that the positive character of one of the nitro-groups in the latter is in part determined by the causes, whether steric or no, operative in the former. And, in fact, Chattaway and Harrison (T., 1916, **109**, 172) did attribute the reactivity of tetranitromethane to steric factors. The objection raised to this suggestion by Henderson and Macbeth (T., 1922, **121**, 894), that it does not explain why the bromine atom of bromotrinitromethane is removed in preference to the nitro-group, is easily met, since it seems clear that any reaction will follow the course which enables it at the same time to relieve the steric congestion round the carbon atom, and to comply with the condition that the most complete "chemical neutralisation" (Michael, *J. pr. Chem.*, 1899, [ii], **60**, 292) shall be attained. From their discussion of the case of dibromodinitromethane,

Henderson and Macbeth's point of view would seem to be that the halogen atom suffers displacement from bromotrinitromethane because its induced positive polarity is at variance with its "normal" electro-negative nature,⁴ whereas this is not so in the case of the nitro-group. The partial recognition thus implied of the condition of maximum "chemical neutralisation" is insufficient, because it is necessary to consider all the products of a reaction, rather than a single one. If this be not done, erroneous conclusions may result. For example, a hydroxymethyl group rather than chlorine is eliminated from β -chloro- β -nitropropane- α -diol (VI) under the influence of sodium ethoxide, although the contrast between an induced positive condition and the normal condition might be expected to be greater in the case of halogen than in the case of carbon (Wilkendorf and Trenel, *Ber.*, 1923, 56, [B], 611):

It seems the more desirable to emphasise these points early in the history of the theory of induced alternate polarities, because other theories, like Baeyer's strain theory and Thiele's theory of partial valencies, have in the past been subjected to much criticism, which would have been seen to be ill-directed if the spirit rather than the literal form of the theories had been considered.* In our

* A large proportion of the evidence which has been adduced against Thiele's theory appears to the authors either inconclusive or beside the point. Thus, the addition of HX [for example, $\text{H-CN, H-NH}_2, \text{H-CH(CO}_2\text{R)}_2$] (Harries, *Ber.*, 1897, 30, 230; Vorländer, *Ber.*, 1903, 36, 172, 2339) to $\alpha\beta$ -unsaturated ketones can be written

Again, the optical measurements of Auwers and Eisenlohr (*Annalen*, 1910, 373, 287; 1918, 415, 135), the existence of triphenylmethyl, and the resemblance of the change of, for example, safrole into isosafrole to that of $\beta\gamma$ - into $\alpha\delta$ -unsaturated acids, all indicate that the phenyl group is best represented as $\text{Ph}\text{---}$. Thus, cinnamaldehyde is Ph-CH:CH-CB:O , and there is no free partial valency, in the degree and sense considered by Thiele, on the carbon atom next the phenyl group. Hence, in the addition of HX, the point to which X attaches itself is not determinable by Thiele's theory, and the criticisms of Hinrichsen (*Chem. Ztg.*, 1901, 316, 43) and of Straus (*Ber.*, 1909, 42, 2866) and others are based on a misconception. The case of muconic acid (Chandrasena and Ingold, T., 1922, 121, 1306) is somewhat different. The formula (A) shows that free partial valencies only occur in

the 1:6-position, so that 1:4-addition is not to be expected. Reduction probably occurs by addition of hydrogen in the 1:6-position, followed by

view, a proper understanding of the various, and often apparently contradictory, facts of organic chemistry will only be gained by referring them to and grouping them round the central principle, that the attainment of stable equilibrium by any system demands that its entropy shall become a maximum. The various theories of organic chemistry, such as those just mentioned, really refer to different processes which conduce towards this end, on the assumption that only one factor, whether it be, for example, unsaturation, or "strain," or steric influence, is operative. In practice, this ideal condition is never more than approximately realised, and the explanation of apparent deviations from these specialised theories is to be found by making due allowance for the other, possibly subsidiary, factors involved. This will be found to apply as much to the theory of polarity as to any other theory, and should be remembered when it is sought to criticise a theory embodying a large mass of experimental evidence by adducing isolated apparent exceptions to it.

Since the entropy of a system is dependent on its temperature and the concentrations of the components, variations of the experimental conditions will obviously affect its equilibrium condition. In recognition of this, the law of mass action has been deduced,

rearrangement. Since bromine does not combine directly with oxygen, 1:6-addition is not possible when bromine and muconic acid interact. Hence, the intermediate carbon chain must be attacked, but as this has no free partial valencies, the reaction is outside the scope of Thiele's theory. In fact, the interest of these and certain other reactions (compare Straus, *loc. cit.*) to us is that they correspond very closely with the process of substitution in benzene, which, as Thiele considered, has no free partial valencies. In this case, again, it would seem that Hollemann is mistaken in supposing that Thiele's theory of addition can be applied ("Direkte Einführung von Substituenten in den Benzolkern," Amsterdam, 1910, p. 476). Hexatriene is very possibly to be regarded also as containing no free partial valency, so that the action of bromine on it (van Romburgh and van Dorssen, *Proc. K. Akad. Wetensch. Amsterdam*, 1906, 9, 111) cannot be referred to Thiele's theory:

Possibly the result is due to the tendency to relieve the tertiary rather than the secondary carbon atoms in the pseudo-cyclic system represented. Other apparent deviations may be attributable to the experimental conditions employed for reasons explained later in the main text of this paper. For example, although the reduction of acetaldehyde by zinc and hydrochloric acid to allyl alcohol is not in accordance with the theory, propaldehyde, the "correct" reduction product, is formed at the same time, and almost exclusively if reduction is carried out by aluminium amalgam, or catalytically in presence of nickel.

but it is an important limitation of this generalisation that it deals only with the extent to which a reaction may proceed in a given direction, and takes no account of changes in entropy to be attained by modification of the nature of the products of reaction. Clearly, such modification may be expected from a variation in the other factors which determine the entropy of a system, and is, in fact, only too well known to organic chemists in the form of "side products." Another probable limitation to the use of the theory of polarity as a formula is thus indicated, and has been observed among compounds of the type with which this paper is more specifically concerned. In the previous paper (Burton and Kenner, *loc. cit.*), reference was made to the fact that tetranitromethane is decomposed by dilute aqueous potassium hydroxide only partly in the manner above discussed, and also according to the equation

This reaction is favoured by dilution of the alkali, but the proportion of nitro-compound decomposed in this manner does not in any case exceed 30 per cent. (Schmidt, *Ber.*, 1919, 52, 400). The reaction evidently involves the replacement of nitro- by hydroxyl groups, since an analogous reaction is observed when a 20 per cent. yield of ethyl diethoxymalonate is obtained by the gradual addition of ethyl dibromomalonate to a dilute alcoholic solution of sodium ethoxide at 48–50° (Curtiss, *Amer. Chem. J.*, 1897, 19, 691; compare Conrad and Brückner, *Ber.*, 1891, 24, 3004; Staudinger and Schneider, *Helv. Chim. Acta*, 1923, 6, 310).

Similarly, mesoxalic acid is readily prepared by treatment of dibromomalononic acid with aqueous sodium hydroxide (Conrad and Reinbach, *Ber.*, 1902, 35, 1819). In these reactions, an atom or group which usually shows "positive" reactions is replaced by a "negative" hydroxyl or alkoxy-group. This, however, will not be observed in either case if concentrated potassium or sodium ethoxide is added to a cold, strong alcoholic solution of the nitro- or bromo-derivative. Again, the former type of reaction is entirely suppressed in favour of the latter when ethyl dibromomalonate and sodium phenoxide interact in alcoholic solution (Conrad and Brückner, *loc. cit.*):

It is clear, therefore, that even in the same experiment, a given atom or group may react as if endowed with both positive and negative polarity, and that the theory of alternating polarities cannot be used as a rigid formula.

In connexion with the foregoing discussion, we have investigated the behaviour of hexanitroethane, with the object of ascertaining how far it is comparable with that of tetranitromethane. The hexanitro-compound was prepared by nitration of the potassium salt of tetranitromethane by Will (*Ber.*, 1914, 47, 961), who at the same time gave a general account, without experimental details, of some of its reactions, including the formation of molecular additive compounds with aromatic hydrocarbons corresponding to those obtained from tetranitromethane. More important from the present point of view is the statement that the potassium salt of tetranitroethane, possibly accompanied by some of that of dinitromethane, is produced by the action of alcoholic potassium hydroxide:

As evidence in favour of this conclusion, it is stated that the potassium salt obtained is reconverted into hexanitroethane by nitration. When, however, we treated the hexanitro-compound with potassium ethoxide under the conditions used for the preparation of potassium *aci*-trinitromethane from tetranitromethane (Hantzsch and Rinckenberger, *Ber.*, 1899, 32, 628), the potassium salt produced, although formed in good yield, was of a much lighter yellow colour than the genuine potassium salt of tetranitroethane, furnished only a trace of hexanitroethane on nitration, and was converted by treatment with bromine water into an oil instead of the crystalline trinitrotribromoethane obtained from potassium *aci*-tetranitroethane (Scholl and Brenneisen, *Ber.*, 1898, 31, 642). It would appear, however, that this salt is an intermediate product in the above reaction, because it was readily obtained, although in somewhat poor yield owing to its solubility, when an ethereal solution of the hexanitro-compound was allowed to react at the ordinary temperature with an aqueous alcoholic solution of potassium cyanide. The salt was identified by its colour, crystalline form, temperature of explosion, and content of potassium. The result is of interest because, whilst it is clearly to be foreseen by the aid of the tautomeric hydrogen hypothesis, it is not so obvious from the point of view developed by Macbeth. Thus, the formulation of bromotrinitromethane (VII) may not unreason-

ably be extended to hexanitroethane in the form (VIII), according to which, nitro-groups in one half of the molecule induce negative

polarity in one of those of the other half. The difficulty, however, disappears when the consideration is introduced that only atoms in the $1:2n$ position relatively to each other can be involved in the formation of the preliminary complex. When, therefore, sodium ethoxide reacts with hexanitroethane, the ethoxyl group must (if $n = 2$) attach itself either to a nitro-group in the same half of the molecule, or to the carbon atom in the other half of it.

Of these alternatives, the former actually occurs, but the latter is possibly exemplified by the decomposition which takes place when potassium *aci*-tetranitroethane is treated with dilute sulphuric acid (Scholl and Brenneisen, *loc. cit.*):

Similarly, Weems (*Amer. Chem. J.*, 1894, **16**, 575) showed that ethyl ethanehexacarboxylate is converted into the potassium derivative of the tetracarboxylic ester by means of alcoholic potassium hydroxide:

In this instance, however, it is necessary to boil an alcoholic solution of the ester with 30 per cent. alcoholic potash for some hours. The difficulty with which reaction occurs is reproduced when the ester is recovered unchanged after treatment with alcoholic ammonia at 150° (Philippi, Hanusch, and von Wacek, *Ber.*, 1921, **54**, [B], 895), and is probably connected with the well-known indifference of dialkylated malonic esters towards ammonia (Fischer and Diltthey, *Ber.*, 1902, **35**, 844), and their difficult hydrolysis (compare, for example, Leuchs, *Ber.*, 1912, **45**, 194). The same inertia, as we have found, characterises ethyl dinitroethanetetracarboxylate, which Ulpiani and Gasparini prepared by electrolysis of the ammonium salt of ethyl nitromalonate in aqueous solution (*Gazzetta*, 1902, **32**, 236):

The slight reaction which occurs when this ester is treated with alcoholic potassium hydroxide probably consists in the replacement of one or more carboxyl groups, since the solution obtained is red.

The presence of "positive" nitro-groups in hexanitroethane is further illustrated by the liberation of iodine which takes place when its alcoholic solution is added to aqueous potassium iodide, and by the rapid evolution of nitrogen which occurs when an ethereal solution of the nitro-compound is treated with hydrazine hydrate and potassium hydroxide. The volume of gas liberated, however, is about 50 per cent. in excess of that demanded by the equation

Similarly, we have observed that an excessive amount of nitrogen is also evolved during the prolonged action of these reagents on tetranitromethane.

A number of other reactions of tetranitromethane, which have been described by Schmidt (*Ber.*, 1920, 53, 1529, 1537; 1921, 54, [B], 1414; 1922, 55, [B], 1751), and explained by him on the basis of the formula (IX), would also seem to depend on the "positive" properties of one of the nitro-groups. Thus, the formation of β -nitroanethole (XII) and of α -ethoxy- β -nitro- α -p-methoxyphenylpropane (XIII) from tetranitromethane and anethole in presence of pyridine and alcohol, respectively, may be ascribed to the formation of the intermediate product (X) or (XI):

Similarly, the course of the nitration of *p*-cresol by means of tetranitromethane and pyridine at 0° is probably to be expressed as follows:

This view, it may be noted, accords with the suggestion of Pfeiffer (*Annalen*, 1917, 412, 265) that the formation of molecular compounds between nitro- and benzenoid derivatives depends on the attachment of the nitro-group to the nucleus rather than to the substituent groups. We have now shown that the preparation of β -nitroanethole and of 3-nitro-*p*-cresol can also be carried out

with the aid of hexanitroethane, although the yields are not so good.

Another reaction of tetranitromethane consists in the formation of, for example, *N*-methylphenylnitrosoamine, by interaction of the nitro-compound, dimethylaniline, and pyridine at 100°:

The course of this reaction is connected by its discoverers with the formation of potassium carbonate and nitrite from tetranitromethane and potassium hydroxide above referred to. But whereas this reaction occurs to a subsidiary extent only, the yields of nitrosoamine from tertiary amines are in most cases excellent. This difference, and the simultaneous formation of nitroform in the reaction, seem to us to render the suggestion just mentioned at least doubtful. The reaction may rather take the following course:

It is also applicable to hexanitroethane, although the yield is very moderate owing to the instability of the nitro-compound at higher temperatures.

Note on Tautomerism and Related Phenomena.

Although the phenomena of tautomerism have been so extensively investigated, it may be said that our conception of their essential nature remains extremely vague, and that, as a result, very slight progress has as yet been made towards the formulation of the connexion between tautomerism and constitution.

It is clear that the cause of the phenomenon must be sought in the conditions determining the attainment of equilibrium by the composite system represented by the chemical molecule. This was recognised by Michael, who stated that "die Fähigkeit einer Verbindung . . . in desmotropen Formen aufzutreten ist vom Unterschied der Entropiezunahmen abhängig, die mit dem Gang der Umlagerung in der einen oder anderen Richtung verbunden sind. . . . Ist er relativ klein, so können mehrere Formen auftreten, und unter Umständen vermag sich ein Gleichgewicht der desmotropen Formen zu bilden, das selbst gegen sehr schwache chemische und physikalische Kräfte empfindlich sein kann" (*Annalen*, 1908, 363, 27). This statement has, however, had little, if any, influence on the course of later work on the subject, doubtless owing to the

difficulty of estimating the entropy of any system. It seems, however, that some progress may be made by adopting the simple view that tautomerism in the main represents a compromise between two factors, each tending to impose on the molecule a constitution out of accord with the other, and that according as either is accentuated or reinforced by other influences, the stability of one or the other form is favoured.*

In the case of keto-enolic tautomerism, the conversion of the enolic into the ketonic modification reproduces the instantaneous transition of vinyl alcohol into acetaldehyde, but is restrained by the tendency of the unsaturated system to pass into the conjugated and more saturated condition :

Obviously, therefore, the supply of energy to an equilibrium mixture of the two forms will cause an increase in the proportion of the less saturated ketonic form, as was shown by K. H. Meyer and Willson (*Ber.*, 1914, 47, 832). The stability of this form will also be favoured if other modes of satisfying its unsaturation be supplied. Hence, possibly, it is that the ketonic form is more stable and, consequently (compare van't Hoff, "Vorlesungen," I, 217; Dimroth, *Annalen*, 1910, 377, 134), more soluble, in presence of associated solvents such as water and the alcohols than in non-associated solvents such as hexane (compare K. H. Meyer, *Annalen*, 1911, 380, 212). This is in accordance with the view that solubility is dependent on association with the solvent (compare, for example, Ephraim, *Ber.*, 1921, 54, [B], 379).

Again, the diminished tendency to enolisation consequent upon alkylation of ethyl acetoacetate may probably be attributed to a reduction in the degree of saturation to be achieved by conjugation, since the enolic form in this case would contain a quaternary carbon atom. On the other hand, acylation of a 1 : 3-diketone provides a further carbonyl group to exert an influence in favour of conjugation

* Tautomerism is also to be expected, and has frequently been observed, when the displacement of a double bond in the constitutional formula of a compound leads to a formula representing an equally, or approximately equally, saturated molecular condition, due regard being paid to considerations of conjugation. Under this heading may be grouped not only all cases of virtual tautomerism (including, besides the well-known instances, the indenenes, the benzotriazoles, the glyoxalines, the anils of isatin, and the teocyanines), but also those of the normal and labile forms of the glutaconic acids, and the triazoles. Very probably also, a number of reactions of the pyrroles, and the identity of the 3- and 5-alkyl derivatives of pyrazole are to be attributed to the comparable degrees of saturation represented by the ordinary imino- and the less usual methylene formulae for these compounds.

by enolisation, and the result is an increased tendency to assume this state:

The presence of a phenyl group in juxtaposition to one of the carbonyl groups also favours enolisation. This effect is attributable to the unsaturated character of the phenyl group as illustrated by the similarity between the rearrangement of propenylbenzene into methylstyrene and of $\beta\gamma$ - into $\alpha\beta$ -unsaturated acids, each under the influence of alkali:

The stability of the *aci*-form of phenylnitromethane is perhaps the simplest illustration of the influence of this type of conjugation or tautomeric equilibrium:

From this point of view, the transition from the ketonic to the enolic form of benzoylacetone represents a reduction in the number of partial valencies from three to one,

as compared with a reduction in the case of acetylacetone from four to two, and corresponding with the greater tendency of the former to enolisation (K. H. Meyer, *Ber.*, 1912, 45, 2843).

Tribenzoylmethane is, however, stable in the ketonic form (Claisen, *Annalen*, 1896, 291, 25), and thus constitutes an apparent exception to these suggestions. But if the enolic formula (XIV) be considered, it will be seen to contain the grouping (XV). Now it is known that in (XVI) the hydrogen atoms are replaceable by metals, and therefore are pronouncedly "positive" in character. As V. Meyer showed (*Ber.*, 1888, 21, 1308), the same applies to phenylacetonitrile (XVII). Hence it is obviously improbable that the grouping (XV), with an oxygen atom in the "positive" position, will be spontaneously generated. Dibenzoylmethane can enolise in the form (XVIII), which does not contain (XV), but in this case one of the benzoyl groups acts only as a substituent, and so reduces the tendency to enolisation, which only becomes con-

siderable in benzoyldiacetylmethane (XIX) and triacetylmethane (XX).

In this discussion, it has so far been unnecessary to refer to the acidity of the enolic forms, because it is only slight, although it is recognised that the alkyl derivatives of ethyl acetoacetate are weaker acids than the ester itself (Goldschmidt and Oslan, *Ber.*, 1900, 33, 1152; Hantzsch, *ibid.*, 1910, 43, 3071), and some connexion between acidity and enolisation has been repeatedly affirmed (Claisen, *Annalen*, 1896, 291, 37; K. H. Meyer, *Ber.*, 1912, 45, 2843). When the enolic form is a strong acid, its dissociation in solution will evidently have a notable effect on the equilibrium, and it is probably for this reason that whereas, as already mentioned, the proportion of a 1:3-diketone existing in the enolic form in solution is increased when dissociating are replaced by non-dissociating solvents, the reverse is the case with phenylnitromethane. For this reason, K. H. Meyer's determinations of the total amount, dissociated and undissociated, of enolic or *aci*-forms of compounds, which are strongly acidic, cannot be regarded as true measures of the actual tendency towards formation of the hydroxy-form. This is very possibly determined solely by the considerations* already advanced. For example, Meyer and Wertheimer's conclusion that *o*-nitroacetophenone passes mainly into the enolic rather than into the *aci*-form agrees with the fact that the former constitutes a satisfactorily conjugated system (XXI), whereas the latter (XXII) contains the grouping the formation of which has already been indicated to be less probable.

An alternative statement of the view of tautomerism indicated above is that the desmotropic forms represent the various possible ways in which the molecular system can settle down into equilibrium. This includes Knorr's view that tautomerism is a special case of structural isomerism (*Annalen*, 1898, 303, 133; 1899, 306, 350), which has recently been illustrated in an interesting manner by the work of Thorpe and his collaborators on intramolecular and ring-chain tautomerism (T., 1922, 121, 128, 650, 1430, 1765). It also indicates that the phenomena of tautomerism are to be classed with any others which are the outcome of alternative conditions of molecular equilibrium. These include those isomeric changes for the accomplishment of which the intervention of a reagent is unnecessary, and polymorphism.

Thus, Meerwein and van Emster have pointed out that camphene hydrochloride and isobornyl chloride, in their reversible interconvertibility, behave as tautomeric compounds (*Ber.*, 1920, 53, [B], 1825):

It seems possible to resist his suggestion only on the ground that the nature of tautomeric change may differ from that of ordinary isomeric change. It would seem, however, to be equally true of both that "eine derartige unvermittelte innermolekulare Umlagerung setzt sich aus zwei Abschnitten zusammen, einer Verschiebung aus der Gleichgewichts-anordnung des ersten Isomeren unter Energieverbrauch und einem Fallen in die Gleichgewichts-anordnung des zweiten Isomeren unter Energieentbindung. Beide Vorgänge verlaufen nicht sprunghaft, sondern vielmehr stetig; sie beginnen mit der Verlängerung und Ausbauchung der Kraftlinien der teilnehmenden Valenzelektronen und setzen sich in Reissen und Neubinden von Kraftlinie um Kraftlinie fort" (Stark, "Atomdynamik, III, p. 158). The value of this conception is well illustrated by

the case of the change from isoborneol (XXIII) to camphene (XXV). As pointed out by Ruzicka (*Helv. Chim. Acta*, 1923, 6, 281), although it cannot be assumed that tricyclene (XXIV) itself is an intermediate product of the change (Meerwein and van Emster, *loc. cit.*), the assumption that it is so permits an accurate forecast of the products of the change in more complicated cases. The reason for this is probably to be found in the passage of both isoborneol and tricyclene, in the course of their conversion into camphene, through the same or approximately the same stage, not to be represented by ordinary formulæ, of the type referred to by Stark.

The above comparison between tautomeric and isomeric change suggests that the essential property of the hydrogen atom which is involved in tautomerism is not its lightness, as was originally suggested by van Laar, and is probably still conveyed to many by the term "mobility," but its adaptability or capacity, in which it is pre-eminent with the carbon atom, for combination with a great variety of other elements. If this be so, any element might be tautomeric provided that in the desmotropes it is attached to elements with which it combines equally readily. Except in the cases of carbon and hydrogen, this condition practically resolves itself, as in the above case, into one of combination with the same element in the two forms.

Polymorphism occurs when there are alternative conditions of equilibrium of the forces determining crystalline form. The modern recognition of the chemical nature of these forces therefore involves the conclusion that polymorphism differs from tautomerism and the related types of isomerism only in being inter- rather than intra-molecular.* It seems not impossible that alternative equilibrium conditions may also exist in solids due to a somewhat different intra- as well as to a different inter-molecular distribution of force, and that such conditions may be responsible for those cases of the existence of two forms of a solid compound, which have been so difficult to classify definitely as polymorphous or structurally isomeric. For example, it is usually considered to be a characteristic of polymorphs that they furnish identical solutions, and this property has been utilised by Sidgwick (*T.*, 1915, 107, 672) as the basis of a method of discriminating between polymorphs and chemical isomerides. The method is also approved by Tutton ("Crystallography," 1922, p. 1263), although he himself earlier (p. 1258) points out that in carrying out what is considered to be the most trustworthy test—that of interconvertibility of the solid

* Darx (*Rec. trav. chim.*, 1922, 41, 321) states that Smits in 1910 developed the view that polymorphism is a form of dynamic isomerism, but gives no references to the literature.

forms in presence of the liquid—no trace of solvent must be present, since under these conditions desmotropes are readily interconverted. According to Schaum (*Annalen*, 1898, 300, 205; 1899, 308, 18), however, although the colourless and yellow forms of 3-nitroacetanilide are identical in solution, they are not polymorphous, because they are not interconvertible in absence of a solvent. In other cases, the two forms may even preserve their identity, under certain conditions, in the liquid state. Thus Knoevenagel showed that the two forms of *o*-nitrotoluene may be preserved in the liquid condition for some months, and Schaum detected small but definite differences in refraction and viscosity between the two forms of benzophenone (*Chem. Ztg.*, 1910, 34, 417). In explanation, a condition of fusion, at a temperature not too far removed from the melting point, would seem quite conceivable in which the relative molecular orientation of the solid form is not entirely destroyed, so that on resolidification the original form will be recovered. The manner in which the phenomena of polymorphism and chemical isomerism may shade off into each other has also been emphasised by Pfeiffer (*Ber.*, 1915, 48, 1777, 2426; compare Schaum, *Centr.*, 1914, I, 436), who showed that a considerable number of derivatives of 2- and 4-nitrostilbenes exist in forms which, in most cases, are polymorphs in that the members of each pair are interconvertible below their melting points. But in the case of 2-nitro-4'-methoxystilbene-4-carboxylic acid, a relationship exists which is represented by the scheme

In this case, therefore, the two forms of the acid exhibit the characteristics of isomeric compounds, and yet it can scarcely be assumed that the difference between them represents any variation other than in degree of that which obtains between the two forms of any of the other compounds of similar structure.

EXPERIMENTAL.

Preparation of Hexanitroethane.—Bromopicrin was prepared by Will's method (*loc. cit.*), but the procedure recommended by him for its conversion into potassium *aci*-tetranitroethane was modified in that larger quantities of potassium cyanide and potassium nitrite (70 grams of each per 100 grams of bromopicrin) were used. In this manner, the yield was increased to 22 per cent. by weight of the bromopicrin employed, but the product was liable to contain

potassium bromide. Unless this was removed by recrystallisation, a red colour developed in the course of the subsequent preparation of hexanitroethane according to Will's directions, and the yield was negligible.

Action of Alkaline Reagents on Hexanitroethane.

Potassium Cyanide.—A solution of the nitro-compound (1.5 grams) in ether (20 c.c.) was gradually added to a solution of potassium cyanide (1.5 grams) in water (12 c.c.) and alcohol (12 c.c.). After twelve hours, the crystalline deposit (0.3 gram) was collected, washed with alcohol and ether, and purified by crystallisation from dilute aqueous potassium hydroxide solution. The yellow, hexagonal prisms so obtained exploded at 271°, and the product was further identified as potassium *aci*-tetranitroethane by analysis (Found: K = 27.0. Calc., K = 27.3 per cent.), and by nitration to hexanitroethane. The yield obtained in the last operation was less than that usually obtained in the preparation of the hexanitro-derivative, but this was attributable to the small scale of the experiment.

Potassium Ethoxide.—A solution of the nitro-compound (1.5 grams) in ether (40 c.c.) was gradually added, with cooling, to a solution of potassium (0.8 gram) in absolute alcohol (5 c.c.). A precipitate was formed at once, and collected after two hours. The product (2.1 grams) was light yellow (Found: K = 31.8 per cent.), and furnished only a trace of hexanitroethane on nitration. When brominated under the conditions prescribed by Scholl and Brenneisen (*Ber.*, 1898, **31**, 642) for the conversion of potassium *aci*-tetranitroethane into the crystalline tribromotrinitroethane, an oil with the characteristic suffocating odour of such halogenated nitro-derivatives was produced, but it could not be induced to crystallise when inoculated with the derivative just named.

Action of Hydrazine on Hexanitroethane.

This reaction could not be carried out precisely under the conditions described by Macbeth (*loc. cit.*) in other cases, owing to the sparing solubility of the hexanitro-compound in alcohol. It was therefore decomposed in a flask connected to a nitrometer, a solution of hydrazine, prepared according to the directions of Macbeth, being employed, and a little ether being added to facilitate dissolution of the nitro-compound. Decomposition readily occurred, and was accompanied by a perceptible rise in temperature. In two experiments, the volumes of nitrogen collected respectively corresponded to 1.55 and 1.58 mols. per mol. of nitro-compound. When ether was not used, a somewhat smaller volume was obtained, owing to

deposition of some solid matter on undissolved nitro-compound. Scholl and Brenneisen (*loc. cit.*) showed that potassium *aci*-tetra-nitroethane underwent profound hydrolytic decomposition on acidification, and similarly we were unable, by the method employed by Macbeth, to separate the salt which gave rise to the red solution remaining from the present experiments.

Nitration of Anethole.

A solution of anethole (3 grams) and pyridine (2 grams) in dry ether (10 c.c.) was treated at 0° with a solution of hexanitroethane (3 grams) in dry ether (40 c.c.). After some hours, when the odour of hexanitroethane was no longer perceptible, the product was diluted with water (100 c.c.) and more ether, and gradually treated with potassium hydroxide solution (10 per cent.; 25 c.c.), and shaken until the red solid disappeared. The ethereal solution was worked up in the usual manner, and the residue cooled. The crude solid (1 gram), separated by filtration from oily matter, after crystallisation from light petroleum melted at 47–48° and did not depress the melting point of β -nitroanethole.

By acidifying the alkaline liquor from the above experiment, a small quantity of a solid, m. p. 92–93° after crystallisation from light petroleum, was obtained, but it was not further investigated. It is not produced in the course of the nitration of anethole by tetranitromethane.

Nitration of p-Cresol.

An ethereal solution of hexanitroethane (4.2 grams) was gradually added at 0° to a solution of *p*-cresol (3 grams) and pyridine (2.2 grams) in alcohol (10 c.c.). A colour change occurred, and when the mixture was removed from the cooling medium, its temperature quickly rose to 26°. After half an hour, the nitro-compound formed was removed with steam, and isolated in the usual manner. The yield of *m*-nitro-*p*-cresol, identified by its m. p. 33–34° (which was not depressed by another specimen of the compound), was 60 per cent. of the theoretical. The *benzoyl* derivative (Found: C = 65.1; H = 4.5. $C_{14}H_{11}O_4N$ requires C = 65.31; H = 4.28 per cent.) was also prepared from each specimen, and obtained in prisms, m. p. 100–101°.

Nitrosomethylaniline from Dimethylaniline.

A warm solution of hexanitroethane (11.5 grams) in alcohol (175 c.c.) was added gradually to a boiling solution of dimethylaniline (8 grams) and pyridine (7.5 grams) in alcohol (10 c.c.) in a reflux apparatus. After a few minutes, the mixture was worked up in the manner indicated by Schmidt (*Ber.*, 1920, 53, [B], 1537).

The nitrosomethylaniline produced responded to Liebermann's nitroso-reaction, and its identity was further established by its conversion into *p*-nitrosomethylaniline hydrochloride, from which the base, m. p. 117–118°, was obtained.

The yield was only small owing to the partial decomposition of hexanitroethane in hot alcoholic solution, and 5 grams of dimethylaniline were recovered from the experiment.

Ethyl Dinitroethanetetracarboxylate.

This ester was prepared by electrolysis of a solution of ethyl ammonium ethylnitromalonate by Ulpiani and Gasparini's method (*loc. cit.*), but the yield was poor. It crystallised from light petroleum in crystalline masses, m. p. 74–75° (Ulpiani and Gasparini give 65–66°), and therefore it was thought that our product might be ethyl ethanetetracarboxylate, for which the melting point is 76–77°. Somewhat curiously, a mixture of the two esters shows no very decided depression of melting point, but the composition of the electrolytic product was established by analysis (Found: N = 7.1. Calc. for $C_{14}H_{20}O_{12}N_2$, N = 6.86 per cent.).

The ester was almost completely recovered after being boiled with alcoholic potassium hydroxide solution for two hours. Similarly, potassium cyanide solution had practically no action on the ester. In experiments with hydrazine hydrate and potassium hydroxide at 80°, less than 0.1 molecular proportion of nitrogen was evolved after one hour.

One of us (F. A.) expresses grateful acknowledgment of a grant from the Department of Scientific and Industrial Research, which has enabled him to participate in this work. Further, we wish to thank the Research Fund Committee of the Chemical Society for a grant towards the expenses of this investigation.

THE UNIVERSITY, SHEFFIELD.

[Received, May 29th, 1923.]

XLIX.—*Researches on Antimony. Part I. Tri-m-xylylstibine and its Derivatives.*

By ARCHIBALD EDWIN GODDARD.

ALTHOUGH arsenic and antimony show so many points of resemblance, our knowledge of the organo-metallic compounds of the latter is much the less extensive. The aim of the present research is to investigate comprehensively antimonials of the types R_3Sb , R_2SbX , $RSbX_2$, and $RSbX_3$, the derived acids, the sulphonation, nitration, reduction, and halogenation products, and

the influence of antimony on the orientation of the various substituents. The work so far carried out is indicated by the following scheme:

The initial material, 4-bromo-*m*-xylene, was prepared by the bromination of commercial xylene at 0°, iron powder being used as a catalyst; from the mixture, 3-bromo-*o*-xylene, 4-bromo-*m*-xylene, and 2-bromo-*p*-xylene were separated by fractional distillation. This method gives better yields than that in which bromination is carried out in carbon disulphide solution; moreover, the objectionable by-products which arise from partial bromination of the solvent are avoided (Stilp, *Diss.*, Rostock, 1910).

Tri-*p*-xylylstibine, recently described by the author (this vol., p. 1170), and the corresponding meta-compound (I) have been obtained in much better yields by the Fittig than by the Grignard reaction, which was previously employed. The latter compound, like most stibines, gives rise to a dichloride, dibromide, and mercurichloride.

Tri-*m*-xylylstibine dissolved readily in fuming nitric acid, yielding apparently a mixture of tri-5-nitrotri-*m*-xylylstibine oxide (IV), hydroxy-nitrate, and dinitrate (V); the last, which formed the largest proportion of the product, was isolated in the pure state by fractional crystallisation from alcohol. When it was heated in a sealed tube for six hours with phosphorus pentabromide and chloroform, 4-bromo-6-nitro-*m*-xylene was obtained, the nitro-group thus being proved to be in the meta-position to the antimony and in the para-position to a methyl group (compare Morgan and Micklethwait, T., 1911, 99, 2286). Since the same three products were obtained when tri-*m*-xylylstibine was boiled with fuming nitric acid for thirty minutes, the hydrogen atom in the position ortho to both methyl groups is efficiently protected.

Reduction of the dinitrate with hydrogen sulphide in ammoniacal alcoholic solution probably takes place in two stages: $\equiv\text{Sb}(\text{NO}_2)_2 \rightarrow \equiv\text{SbS} \rightarrow \equiv\text{Sb}$. In addition to these compounds, the final liquors contained amino-derivatives which were diazotisable, pointing to partial reduction of the nitro-groups. The chief product was tri-5-nitrotri-*m*-xylylstibine (V), the intermediate formation of the sulphide being assumed from the fact that when hydrogen sulphide is passed into an ammoniacal alcoholic solution of triphenylstibine dichloride or dibromide, triphenylstibine sulphide first results and then the free stibine (Kaufmann, D.R.-P. 223694; 240316).

The reduction of tri-5-nitrotri-*m*-xylylstibine dinitrate by zinc dust in ammoniacal alcoholic solution containing ammonium chloride led to the production of tri-5-aminotri-*m*-xylylstibine (III). This was converted into its tribenzoyl derivative by benzoyl chloride, whereas Gunther (*Diss.*, Rostock, 1904; *Annalen*, 1902, 381, 184) found that triaminotriphenylstibine lost its antimony on treatment with this reagent.

Michaelis (*Annalen*, 1902, **321**, 185) failed to isolate any derivatives of triaminotriphenylarsine by means of the diazo-reaction. The present author encountered some difficulty in working with tri-5-aminotri-*m*-xylylstibine, but nevertheless succeeded in isolating tri-5-iodotri-*m*-xylylstibine (VIII), although the diazo-reaction in this case tended to give rise to viscous products. The base forms a sparingly soluble diazonium chloride which couples with alkaline β -naphthol, with resorcinol, and with H-acid to form azo-derivatives.

Tri-5-nitrotri-*m*-xylylstibine dinitrate is hydrolysed to the oxide (IV) by a large excess of phosphorous acid, whereas tri-nitrotritolyarsine oxide is reduced to the free arsine (Michaelis, *loc. cit.*, p. 212). The same oxide results when the dinitrate is treated with sodium hypophosphite. On dissolution in glacial acetic acid, it is converted into the *diacetate*, although in the case of the tritolylstibines only hydroxyacetates have been isolated (Michaelis and Genzken, *Annalen*, 1887, **242**, 176).

Bromination of the oxide results in the formation of a tribromo-derivative, a compound of considerable interest on account of the lability of the bromine atoms. It has been shown above that only one nitro-group can be introduced into each xylyl residue, the hydrogen atom in the second meta-position being unreactive, and it may be inferred that bromination cannot take place in this position. By treatment of the tribromo-derivative with zinc dust in alcoholic ammonia, the bromine atoms are eliminated and the nitro-groups reduced, tri-5-aminotri-*m*-xylylstibine, the orientation of which has already been determined, being produced. Further, it is known that in compounds containing a halogen atom in the ortho- or para-position to a nitro-group, one of the substituents is labile, reaction with hydrogen sulphide or sodium thiosulphate yielding a sulphide. In the present case, not only were the bromine atoms removed by boiling thiosulphate solution, but also the oxide was reduced to the known tri-5-nitrotri-*m*-xylylstibine. It is therefore to be inferred that the bromine substituents occupy position 6, ortho- both to the antimony and to the nitro-groups, and consequently the tribromo-derivative is tri-6-bromotri-5-nitrotri-*m*-xylylstibine oxide (VI).

When the free nitrostibine is brominated, it may be supposed that the tribromo-derivative produced is tri-6-bromotri-5-nitrotri-*m*-xylylstibine dibromide (VII).

The condensation product of the base (III) and picryl chloride in alcoholic solution in the presence of sodium acetate is the orange-coloured tripicryltri-5-aminotri-*m*-xylylstibine (IX). This product is readily brominated, yielding tri-6-bromotripicryltri-5-aminotri-*m*-xylylstibine dibromide, a lemon-yellow powder (X).

Although bromination products of arylstibines are not described in the literature, it is highly probable from these experiments that bromine can be directly introduced into such substances. This point is being more fully investigated.

EXPERIMENTAL.

Preparation of 4-Bromo-m-xylene.—To commercial xylene (1156 grams), cooled in a freezing mixture, about 1 gram of iron powder was added, and 800 grams of bromine were slowly run in during five hours. The mixture, after being kept for two days at room temperature, was treated with 1,500 c.c. of water, and the oil separated off and steam-distilled. The oil from the distillate was dried, and fractionated several times, about 200 grams of pure 4-bromo-*m*-xylene, b. p. 203.5° , being obtained. The quantity of the other isomerides produced varied with the sample of xylene used.

Tri-m-xylylstibine (I).—(a) By the Grignard reaction. To the solution prepared from 48 grams of bromoxylene and 7 grams of magnesium in 75 c.c. of ether, 18 grams of antimony trichloride in 25 c.c. of the same solvent were added and the mixture was boiled for six hours. After decomposition with water, the compound was extracted with benzene and worked up as below. Yield 7.2 grams (19 per cent.).

(b) By the Fittig reaction. Bromoxylene (56 grams) and 23 grams of antimony trichloride were dissolved in 150 c.c. of dry benzene, and 50 grams of metallic sodium (thrice the required amount) added in thin slices. After completion of the reaction, which usually had to be started by warming, the solution, having been kept over-night, was filtered, and the residue extracted three times with boiling benzene, these liquors being added to the main filtrate. The benzene was evaporated and the oily product poured into absolute alcohol, when long needles of the stibine separated in a few minutes. Yield 25 grams of crude product (57 per cent.) (Found: Sb = 27.56. $C_{24}H_{27}Sb$ requires Sb = 27.61 per cent.).

Tri-m-xylylstibine crystallises from alcohol in masses of felted needles. These melt at 148° to a clear liquid which becomes cloudy at about 255° and, when cooled, solidifies to a transparent mass. The stibine is soluble in cold chloroform, acetone, light petroleum, or pyridine, moderately soluble in alcohol, and is more soluble than the para-compound in glacial acetic acid.

Tri-m-xylylstibine Dichloride.—A chloroform solution of the stibine was saturated in the cold with dry chlorine and allowed to evaporate spontaneously. Small, white, granular crystals separated, m. p. 189° (Found: Cl = 13.81. $C_{24}H_{27}Cl_2Sb$ requires Cl = 14.01 per cent.).

Tri-m-xylylstibine Dibromide.—To 2 grams of the stibine in 5 c.c. of chloroform, bromine was added until the solution was just coloured. On evaporation, a syrup was obtained which solidified on treatment with alcohol. The product was best crystallised from chloroform-alcohol, a crystalline powder being deposited, m. p. 195° (Found: Br = 27.16. $C_{24}H_{27}Br_2Sb$ requires Br = 26.85 per cent.). The compound is moderately soluble in light petroleum.

Tri-m-xylylstibine Mercurichloride.—The stibine (1.18 grams) in 50 c.c. of absolute alcohol was added in the cold to 0.67 gram of mercuric chloride in 100 c.c. of the same solvent. The product obtained by slow evaporation of the solution was recrystallised from ether, fine needles being isolated, m. p. 158° (Found: Cl = 9.80. $C_{24}H_{27}Cl_2HgSb$ requires Cl = 9.70 per cent.).

Tri-5-nitrotri-m-xylylstibine Dinitrate (II).—Twenty-one grams of tri-m-xylylstibine were added slowly to 100 c.c. of nitric acid (d 1.16), complete solution taking place, and the mixture, after being warmed for twenty minutes on the water-bath, was poured into 3 litres of water. The white, flocculent precipitate that separated was collected after fifteen minutes and dried (38.2 grams). This crude product (Found: N = 8.71 per cent.) appeared to consist of the hydroxynitrate and the dinitrate. After six crystallisations from alcohol, the dinitrate, a white, crystalline powder, was obtained; it sintered at 150° and melted at 175° with frothing (Found: N = 10.06; Sb = 17.33. $C_{24}H_{24}O_{12}N_5Sb$ requires N = 10.09; Sb = 17.31 per cent.). The dinitrate is soluble in warm chloroform or acetic acid, slightly soluble in alcohol, and soluble in light petroleum.

Orientation Experiments.—One gram of the above dinitrate, 10 c.c. of chloroform, and 6 grams of phosphorus pentabromide were heated in a sealed tube at 130° for five hours. The chloroform was then removed by distillation in steam, very little other organic matter distilling over. The residue was crystallised several times from alcohol, when 4-bromo-6-nitro-*m*-xylene, m. p. 57°, was obtained, the yield being about 65 per cent. of the calculated amount (Found: Br = 34.93. Calc., Br = 34.78 per cent.).

Tri-5-nitrotri-m-xylylstibine (V).—(a) Two grams of the dinitrate were dissolved in 200 c.c. of absolute alcohol, 20 c.c. of concentrated aqueous ammonia were added, and hydrogen sulphide was passed into the boiling solution for six hours. The precipitate formed on cooling was collected, and recrystallised from alcohol, small needles of the stibine being obtained, melting at 192–193° to a clear liquid.

(b) Tri-6-bromotri-5-nitrotri-m-xylylstibine oxide (1.8 grams) in 40 c.c. of hot absolute alcohol was added to the boiling solution

of 1.4 grams of sodium thiosulphate in 25 c.c. of water, and the boiling continued for thirty minutes. A white solid containing neither sulphur nor halogen separated out, which melted at 192° after crystallisation from chloroform-petroleum solution (Found: N = 7.47, 7.34, 7.43; Sb = 21.59. $C_{24}H_{24}O_6N_3Sb$ requires N = 7.37; Sb = 21.57 per cent.).

Tri-5-aminotri-m-xylylstibine (III).—Five grams of the mixture of nitration products obtained by the action of fuming nitric acid on tri-*m*-xylylstibine were added to a boiling solution of 400 c.c. of absolute alcohol containing 3.5 grams of ammonium chloride, 20 c.c. of concentrated aqueous ammonia, and 22 grams of zinc dust. The boiling was continued for eight hours, a further five grams of zinc dust being added at the end of each hour. The solution was filtered while hot into 3 litres of ice-cold water, a pink precipitate separating out. This solid, after filtration, was warmed with 200 c.c. of 10 per cent. hydrochloric acid, any insoluble matter filtered off, and the filtrate treated with concentrated aqueous ammonia, when 3.5 grams of crude amine were obtained (yield 97 per cent.). This product was purified by several crystallisations from a mixture of chloroform and light petroleum, a brownish-pink powder resulting, which blackened at about 112° and melted rather indefinitely at 123–124° (Found: N = 8.76; Sb = 25.05. $C_{24}H_{20}N_3Sb$ requires N = 8.75; Sb = 25.02 per cent.).

Tri-5-benzoylaminotri-m-xylylstibine.—A mixture of the amine (1.2 grams), dissolved in 16 c.c. of pyridine, and 1.6 grams of benzoyl chloride was warmed on the water-bath and poured into water. The viscous product was freed from benzoic acid by repeated boiling with water, but it could not be crystallised. It contained antimony and melted at 99° (Found: N = 5.24. $C_{45}H_{42}O_3N_3Sb$ requires N = 5.19 per cent.).

Tri-5-iodotri-m-xylylstibine (VIII).—One gram of the amine, dissolved in 7 c.c. of concentrated hydrochloric acid and 200 c.c. of water, was diazotised with 0.66 gram of sodium nitrite. The diazonium chloride separated as a yellow precipitate, to which 1.5 grams of potassium iodide in 20 c.c. of water were added, the yellow colour changing to red, the precipitate resembling ferric hydroxide. After being warmed on the water-bath, and kept for three hours, the solid was filtered off (1.5 grams) and recrystallised five times from a mixture of chloroform and petroleum, a brownish-red, crystalline powder being obtained, which melted at 153° to a clear red liquid (Found: I = 46.80; Sb = 14.63. $C_{24}H_{24}I_3Sb$ requires I = 46.83; Sb = 14.78 per cent.).

Tri-5-nitrotri-m-xylylstibine Oxide (IV).—Five grams of the corresponding dinitrate were boiled for five hours with 300 c.c. of

absolute alcohol containing 25 grams of phosphorous acid. The resulting solution was poured into 2 litres of water, a flocculent, cream-coloured precipitate separating (3.8 grams). After this had been dried, and precipitated from chloroform solution by light petroleum, a white, crystalline powder was obtained which sintered slightly at 210° and melted at 218° (Found: N = 6.91, 7.08; Sb = 20.26. $C_{24}H_{24}O_7N_3Sb$ requires N = 7.17; Sb = 20.50 per cent.). The oxide is soluble in alcohol, and forms an orange-coloured solution in chloroform.

Tri-5-nitrotri-m-xylylstibine Diacetate.—The above oxide was dissolved in glacial acetic acid, and after partial evaporation, ether was added, a white precipitate of the diacetate being deposited which softened at 160° and melted at about 198° (Found: N = 5.92; Sb = 17.29. $C_{23}H_{30}O_{10}N_3Sb$ requires N = 6.11; Sb = 17.46 per cent.).

Tri-6-bromotri-5-nitrotri-m-xylylstibine Oxide (VI).—Trinitrotri-m-xylylstibine oxide (1.0 gram) was dissolved in chloroform and a solution of bromine in light petroleum added. The precipitate was purified by treatment with these two solvents, the product being a white, crystalline substance, melting at 162° to a yellow liquid, which decomposed with gas evolution at 168° (Found: N = 5.18; Br = 28.79. $C_{24}H_{21}O_7N_3Br_3Sb$ requires N = 5.07; Br = 28.92 per cent.).

To the oxide (1.7 grams) in 150 c.c. of alcohol, 1.5 grams of ammonium chloride, 5 c.c. of concentrated aqueous ammonia, and 11 grams of zinc dust were added and the mixture was boiled for seven hours. The product was worked up as in the case of tri-aminotri-m-xylylstibine, and 0.85 gram of this substance was obtained, m. p. $123-124^{\circ}$.

Tri-6-bromotri-5-nitrotri-m-xylylstibine Dibromide (VII).—A chloroform solution of the corresponding stibine was treated with bromine until the colour of the latter persisted. The dibromide was precipitated by light petroleum and recrystallised from a mixture of the above two solvents, a white, crystalline powder being obtained (Found: Br = 41.49. $C_{24}H_{21}O_6N_3Br_5Sb$ requires Br = 41.32 per cent.).

Tripicryltri-5-aminotri-m-xylylstibine (IX).—Two grams of the amine, dissolved in the smallest possible quantity of 10 per cent. hydrochloric acid, were added to 75 c.c. of alcohol containing 3 grams of picryl chloride and 8 grams of sodium acetate. The mixture was warmed at 30° for fifteen minutes, an orange precipitate separating. This crude condensation product (3.9 grams) was boiled with 75 c.c. of water to remove sodium acetate, then dissolved in dry chloroform to remove sodium picrate, and the stibine was

precipitated from the filtered solution by the addition of light petroleum. The compound thus isolated was a bronze, crystalline powder which sintered at 178° and then gradually blackened, but did not melt at 290° (Found: N = 14.60; Sb = 10.98. $C_{48}H_{33}O_{18}N_{12}Sb$ requires N = 15.10; Sb = 10.79 per cent.). The compound is soluble in alcoholic potash, giving a carmine solution, from which the potassium salt separates in scarlet, octahedral crystals on slow evaporation.

Tripicryltri-6-bromotri-5-aminotri-m-xylylstibine Dibromide (X).
—The above stibine (0.5 gram) was dissolved in 3 c.c. of chloroform, and bromine in light petroleum added until the colour changed from orange to red. Addition of light petroleum precipitated a lemon-yellow, crystalline powder (0.5 gram) (Found: N = 11.19. $C_{48}H_{30}O_{18}N_{12}Br_3Sb$ requires N = 11.13 per cent.). The compound, which contained both bromine and antimony, blackened at 183° and melted at 188° . It behaved towards alcoholic potash in the same way as the preceding compound.

The author is indebted to the Research Fund Committee of the Chemical Society for a grant which has partly defrayed the expenses of this investigation.

CCLX.—Some Properties of Electrolytic Manganese.

By ALAN NEWTON CAMPBELL.

METALLIC manganese having been prepared electrolytically by the author in conjunction with Professor A. J. Allmand (results not yet published), it was thought advisable to determine the properties of the pure product.

Density.—The following appear to be the best determinations of the density hitherto made:

Brunner (*Pogg. Ann.*, 1857, **101**, 264; 1858, **103**, 139), using metal containing a little silicon, obtained d 7.14–7.21. Bullock (*Chem. News*, 1889, **60**, 20) found d 7.231, but after the metal had been melted under fluorspar or sodium chloride the value was 7.072–7.153. Glatzel (*Ber.*, 1889, **22**, 2857), using manganese prepared by reduction of manganous chloride with magnesium, found d 7.392. Prelinger (*Monatsh.*, 1893, **14**, 353), using manganese obtained by the distillation of the mercury from the amalgam produced when a manganese salt solution was electrolysed with a mercury cathode, found d 7.4212.

Two determinations of the density were made with nodule selected from a crystalline electro-deposit. An ordinary specific gravity bottle was used. The values obtained were 7.034 and 7.080; the agreement is probably as good as can be expected considering the very small weight of manganese (2 to 3 grams volume about 0.3 c.c.) available. It is, of course, possible that even nodules contain interstices, either vacuous or filled with hydrogen, so that this is a minimum value.

Chemical Properties.—Almost all text-books state that manganese decomposes water. Accordingly, powdered manganese was kept over-night in cold water, in connexion with a nitrometer. No gas was evolved and the manganese remained dead black. A freshly cut manganese surface, however, exposed to moist air, soon tarnishes. This is presumably a phenomenon analogous to rusting atmospheric oxygen playing a necessary part.

Manganese is very slowly attacked by boiling water, turning brown and bubbles of gas being evolved. This is probably due to reduced hydrogen overvoltage at the higher temperature. Another portion of the metal was heated, in a current of steam, at the temperature of the Bunsen flame, and the issuing gas collected over water. Tiny bubbles of gas were evolved. No increase in the weight of the manganese was detectable. The action of steam must be very slow.

Manganese burnt brilliantly when heated in a current of oxygen but owing to volatilisation it was impossible to weigh the residue.

Manganese dissolves readily in dilute hydrochloric, sulphuric, or acetic acid. Action is no longer perceptible in *N*/200-sulphuric acid.

When manganese was boiled with concentrated sulphuric acid the quantity of sulphur dioxide evolved, estimated by standard iodine solution, was that required by the equation $\text{Mn} + 2\text{H}_2\text{SO}_4 = \text{MnSO}_4 + 2\text{H}_2\text{O} + \text{SO}_2$.

Portions of manganese were treated with nitric acid of various strengths, and the evolved gases analysed. The experimental procedure was as follows. The manganese was contained in a small tube placed upright in a small test-tube, almost full of the nitric acid. This test-tube was connected with a nitrometer, furnished with a three-way cock and a tube for the admission of absorbents. The nitrometer was filled with mercury. By tilting the test-tube, the manganese was brought in contact with the nitric acid. When all action had ceased and the apparatus cooled down, the volume of gas was measured, various absorbents were run in, and the contraction was observed. The absorbents used were, in order, absolute alcohol, for nitrous oxide; water, for nitrogen peroxide; ferrous sulphate solution, for nitric oxide. The experiments were

quite rough and only a qualitative value is attached to the results. These were :

% Nitric acid.	% Composition of gas.			
	NO ₂ .	NO.	N ₂ O.	H ₂ .
100	100	—	—	—
50	68	16	16	—
25	1	39	20	40
12.5	—	13	1	86

No action was perceptible when manganese was boiled with a strong solution of caustic potash or caustic soda.

When manganese was heated in a stream of chlorine, it took fire at a red heat and glowed brilliantly. The residue, which was light brown and highly crystalline, was probably manganous chloride, but the analytical results were not trustworthy, owing to the combustion of the manganese not having been complete.

Manganese remained apparently unchanged when it was treated with boiling bromine or heated with excess of sulphur.

Heated at the temperature of the blowpipe flame in a stream of nitrogen for ten minutes, manganese gave a nitride which, when treated with cold water, evolved ammonia in quantity.

Displacement of Less Electro-negative Metals.—Martin and Dan-caster (Friend's "Text-book of Inorganic Chemistry," vol. VIII, p. 263) state that manganese readily displaces the metals arsenic, antimony, bismuth, tin, lead, copper, iron, nickel, cobalt, chromium, cadmium, and zinc from solutions of their salts. These observations have been verified, except in the case of chromium, which was not investigated.

Single Electrode Potential.—The electrode potential was measured as follows. The cathode, bearing a small, but light and adherent deposit of metallic manganese, was removed from the bath at the end of an electrolysis, washed, and immersed in *M*-manganese sulphate solution. The potential of the half element $\text{Mn}|\text{MnSO}_4$ (molar) was then measured at 12° in the usual way, against a normal calomel electrode, a 3*N*-solution of potassium chloride being used to minimise liquid potential difference, thus :

The mean of four determinations, each made with a fresh deposit, was — 0.797 volt (absolute scale), the measurements agreeing within 0.002 volt. The potential of the half element $\text{Mn}|\text{M}/10\cdot\text{MnSO}_4$ was — 0.821 volt (absolute scale). Hence the potential of the manganese becomes more negative with dilution of its salt solution. All these values were constant, and the manganese showed no signs of attack by the solution.

Hydrogen Overvoltage at a Manganese Surface.—This was determined in the following manner. The cathode, covered with an adherent coating of manganese, was removed from the electrolysis bath and placed in an electrolyte, which was $N/1$ with respect to sodium sulphate and $N/50$ with respect to caustic soda. The cathode was surrounded by a cylindrical anode of platinum at a uniform distance of about 3 cm. A Lugin capillary was pressed against the manganese surface, which was smooth. Current was passed and the potential of the manganese determined at various current densities. It may be urged, against this method, that oxygen was free to diffuse to the cathode, and to exert there its well-known depressing effect on overvoltage. This effect was probably small, since the area of the anode was large in comparison with that of the cathode, and therefore the concentration of oxygen over its surface was very small; moreover, the evolution of hydrogen was very brisk at all current densities. A normal calomel electrode was used as standard of reference, in conjunction with a standardised cadmium cell. The results obtained at 16° are summarised in the following table :

Overvoltage	0.615	0.644	0.705	0.755	0.823	0.850	1.044	volts.
Current density	0.47	0.63	1.33	2.33	4.00	5.00	10.00	amp./ cm^2 .

The effect of temperature on overvoltage was next determined. The experimental details were as before, and the current density was 3.33 amp./ cm^2 .

Overvoltage	0.801	0.622	0.507	0.393	volt
Temperature	15.5°	53.5°	71°	84°	

Anodic Solution Potential.—Müller (*Z. Elektrochem.*, 1904, 10, 519) states that manganese dissolves in weakly acid sodium phosphate solution as manganic phosphate, at a high current density (7.5–15 amp./ cm^2); oxygen is simultaneously evolved. If the ammeter, or the *E.M.F.* of the manganese electrode is now observed, pulsations are seen to be set up. Simultaneously with the lowest value of the *E.M.F.*, hydrogen is violently evolved at the electrode. This evolution again ceases, and the issuing gas contains oxygen and hydrogen, the presence of which may be shown by exploding the mixture. The passivity of manganese is so labile that, as anode, it falls back into the active condition. The observation that hydrogen is evolved at a manganese anode seems peculiar in view of the fact that the sodium phosphate solution acts as a buffer solution, suppressing hydrogen-ions.

Kuessner (*Z. Elektrochem.*, 1910, 16, 754), using an electrolyte of neutral 0.5*N*. potassium sulphate and an anode of manganese ($\text{Mn} = 99.5$ per cent.), found that passivity increased with time with a current density of 0.5 amp./ cm^2 , the potential, initially

— 0.559 volt (hydrogen scale), increased to — 0.301 volt after 218 minutes.

Grube and Metzger (*Z. Elektrochem.*, 1923, 29, 17), working with hot, concentrated caustic soda solutions, found that manganese went into solution, at low current densities as bivalent atoms, at medium current densities as trivalent atoms, and at still higher current densities as hexavalent atoms, which formed manganate. At room temperature, however, or in dilute caustic soda solution, the manganese dissolved immediately in the septavalent condition.

In my determinations, neutral *M*-manganese sulphate solution was used. The specimen of manganese used was very nodular and crystalline. The temperature was 13°.

The potential of the manganese with no current flowing was — 0.795 volt (absolute). With a current density varying from 1.7 to 7 amps./dm.², it remained constant at — 0.725 volt. This gave 0.070 volt as the measure of the passivity. Hydrogen was freely evolved at the cathode, but no visible gas at the manganese anode. The solution became somewhat cloudy through precipitation of basic manganese sulphate in the neighbourhood of the cathode. Metallic manganese also was deposited on the cathode. There was no formation of permanganate. Determinations of potential were made at intervals of twenty minutes.

With regard to Kuessner's statement that passivity increases with time, it was thought advisable to conduct an experiment at constant current density for some time, determinations of the potential being made at intervals. Manganese sulphate solution was used, as before. The temperature was 16° and the current density 7 amp./dm.². The potential, determined at every half-hour during a period of two hours, remained constant at — 0.724 volt. At the end of the run the heavy deposit on the anode had almost completely disappeared. The electrolyte had deposited basic sulphate, but itself remained neutral. The small passivity measured may, of course, have been due to the metal having been charged with hydrogen.

Summary.

The following properties of electrolytic manganese have been investigated: 1. Density. 2. Chemical properties. 3. Displacement of other metals from solution. 4. Single electrode potential. 5. Hydrogen overvoltage at a manganese surface. 6. Anode solution potential.

In conclusion, the author wishes to acknowledge his great indebtedness to Professor A. J. Allmand for advice and criticism.

KING'S COLLEGE, LONDON.

CCLXI.—*The Photochemical Decomposition of Chlorine Monoxide.*

By EDMUND JOHN BOWEN.

It is well known that the mechanisms of most photochemical changes are very obscure, and that this is due to the primary reactions between the absorbing substances and the light being obscured by a complex series of subsequent reactions, during which the energy absorbed and liberated in the reaction is redistributed in an unknown manner among other molecules. As radiant energy is only absorbed in quanta, those photochemical reactions in which the subsequent reactions are not extensive will provide a ratio Molecules reacting/Quanta absorbed not far removed from unity. The rarity of such reactions is probably exaggerated, because the most striking photochemical reactions are those of high so-called "light sensitivity."

In continuation of previous work (this vol., p. 1199) the photochemical decomposition of gaseous chlorine monoxide in blue and violet light has been investigated. The source of light was a 1000 c.p. "Pointolite" lamp. A condensed beam of light, filtered through solutions of copper sulphate and of crystal-violet, passed directly into the photochemical cell. The energy in the radiation was determined in three ways, which gave concordant results; first, as previously described (*loc. cit.*); secondly, by calibrating a Melloni thermopile with a small, thin, flat coil in which known amounts of electrical energy were expended, the coil being placed as close as possible between the face of the thermopile and a blackened metal plate; and, thirdly, by the use of a special air-thermometer. This consisted of a cylindrical glass vessel with a plane side through which the light entered, to fall on a screen inside made of the thinnest rice paper blackened with Indian ink. A coil of constantan wire wound on the paper served for calibrating, and pressure changes due to the heating effect of the radiation were measured on an aniline-water differential manometer. Although the thermopile and potentiometer is a more sensitive arrangement, it is thought that this air-thermometer is more accurate for absolute measurement, because the heating by the radiation and by the calibrating current take place under closely similar conditions.

The absorption measurements were made with the thermopile and potentiometer. The photochemical cell consisted of a piece of glass tubing 3.2 cm. in diameter and 4.5 cm. long, the ends of which were closed by pieces of thin plate glass fused on, and fitted with two capillary tubes and taps. It was filled by condensing in it a

quantity of liquid chlorine monoxide, prepared by passing dry chlorine through a long tube containing precipitated mercuric oxide which had previously been heated for several hours at 350°, and allowing the liquid to evaporate. The photochemical reaction was followed by measuring the changes of pressure on exposure, the cell being connected by a ground glass joint through a capillary "air buffer" to a sulphuric acid manometer. The vessel was immersed in water at constant temperature before initial and final pressures were read.

Several filters isolating the blue and violet rays were used. In the calculation of the number of quanta absorbed a mean wavelength of 4600 Å.U. has been employed; that is, $h\nu = 4.28 \times 10^{-12}$ erg.

Summary of Results.

Quanta per second in light $\times 10^{-16}$.	Absorption.	Molecules decomposed per second $\times 10^{-16}$.	Molecules decomposed Quanta absorbed.
15.4	0.59	21.0	2.30
15.2	0.52	17.3	2.19
14.4	0.55	17.4	2.09
12.0	0.36	9.92	2.30
11.7	0.49	12.7	2.22
11.3	0.46	11.6	2.22
10.2	0.42	10.8	2.52
8.19	0.25	4.45	2.18
7.82	0.28	4.66	2.13
6.86	0.54	9.25	2.50
5.38	0.60	7.1	2.20

The amount of decomposition in the above experiments was of the order of 3 per cent.

More accurate comparative experiments on the same sample of gas showed that the photochemical rate was strictly proportional to the light intensity over a range of 1 : 4, a rotating sector being used to vary the light intensity.

The chlorine monoxide contained varying quantities of chlorine as an impurity, the elimination of which apparently is not easy. The uniformity of the results suggests, however, that the presence of chlorine does not seriously affect the rate of decomposition.

The results indicate that two molecules are decomposed for each quantum absorbed; the reaction therefore seems a comparatively simple one. Two alternative and indistinguishable mechanisms explain the results.

Either the decomposition is unimolecular,

this being the only possible unimolecular decomposition in violet

light (see previous reference), and is followed by a spontaneous reaction,

or the change is

followed by

Both possibilities satisfy the condition that the spontaneous reactions shall be exothermic. It should be noted that the very large heat evolutions in either case do not lead to further decomposition, as would be expected if the views of Baly (*Trans. Faraday Soc.*, 1922, 17, 588), that this energy would be liberated at infra-red frequencies capable of re-absorption, are correct.

When chlorine peroxide is exposed to light a more complex decomposition takes place, with formation of large quantities of an unstable brown liquid. This disappears with formation of white fumes when a trace of water vapour is admitted. Traces of white fumes are also observed when chlorine monoxide which has been exposed to light is allowed to come into contact with moist air. It seems that in both cases some formation of other oxides of chlorine occurs besides the simple decomposition. These reactions are being further investigated.

Summary.

Two molecules of chlorine monoxide in the gaseous state appear to be photochemically decomposed for each quantum of blue and violet light absorbed. The mechanism of the reaction has been discussed on this basis.

Part of the apparatus used in this work was purchased with the aid of a grant from the Research Fund Committee of the Chemical Society.

CCLXII.—Benzbisthiazoles. Part IV.

By STEPHEN RATHBONE HOLDEN EDGE.

THE paper by Mills and Smith entitled "The Reactivity of Methyl Groups in Heterocyclic Bases" (*T.*, 1922, 122, 2724) suggested that similar experiments with the dimethylbenzbisthiazoles described in the previous papers might disclose a relationship between the

curious differences of basicity which have been noticed and the reactivity of the adjacent methyl groups.

2:6-Dimethylbenzbisthiazole (I) and 2:6-dimethyl- β -benzbisthiazole (II) were chosen for the experiments because these compounds are very similar in structure and yet show quite decisively the difference in basicity, the first being a mono-acid base and the second a di-acid base. The condensation of the methiodides of the

bases with *p*-dimethylaminobenzaldehyde in alcoholic solution containing a drop of piperidine proceeded exactly as described by Mills and Smith, except that the red colour was noticed on warming even before any piperidine had been added. As was expected, since 2:6-dimethylbenzbisthiazole forms only a monomethiodide, this compound gave only a monostyryl derivative (III), whilst the dimethiodide of 2:6-dimethyl- β -benzbisthiazole gave the distyryl derivative readily (IV).

A more interesting experiment was the condensation of the free bases with benzaldehyde by heating in a sealed tube with a trace of zinc chloride. Mills and Smith have shown that this condensation occurs readily in compounds where the methyl group is connected with a carbon of the ring which is itself doubly linked to the nitrogen atom. Both the benzbisthiazoles used should therefore give distyryl derivatives readily. The condensations were carried out under identical conditions, the mixtures being heated in the same water-bath for thirty hours. 2:6-Dimethyl- β -benzbisthiazole (II) was completely converted into a stable crystalline distyryl derivative. 2:6-Dimethylbenzbisthiazole (I), on the other hand, although it certainly gave a small amount of the distyryl derivative, yielded several other products, the exact nature of which could not be determined with the small quantities available, but it was ascertained that the main product was not a styryl derivative of the benzbisthiazole.

Thus there appears to be good evidence for the belief that the reactivity of the methyl groups is considerably less pronounced

in the mono-acid base (I) than in the di-acid base (II), and that whatever it is that causes the difference in the properties of the nitrogen atoms affects the methyl groups too.

EXPERIMENTAL.

2 - *p*-Dimethylaminostyryl-6-methylbenzbisthiazole Monomethiodide. —0.35 Gram of 2:6-dimethylbenzbisthiazole monomethiodide was boiled for some hours with 0.35 gram of *p*-dimethylaminobenzaldehyde in 15 c.c. of absolute alcohol containing a drop of piperidine. A deep purple colour developed quickly and small, steely blue, needle-shaped crystals were slowly deposited from the hot solution; m. p. 240° with decomposition (Found: I = 25.55. $C_{20}H_{20}N_2I_2S_2$ requires I = 25.76 per cent.). Even in very dilute water solution the substance is a powerful dye.

2:6-Bis-*p*-dimethylaminostyryl- β -benzbisthiazole dimethiodide, prepared as described above, forms a deep purple matt of very fine crystals having a marked bronze lustre, especially when rubbed. This compound too is a powerful dye. It melts and decomposes at 246–250° (Found: I = 33.69. $C_{30}H_{32}N_4I_2S_2$ requires I = 33.16 per cent.).

2:6-Distyryl- β -benzbisthiazole. —0.5 Gram of 2:6-dimethyl- β -benzbisthiazole was heated in a sealed tube in a water-bath with 0.7 gram of benzaldehyde and a trace of zinc chloride for thirty hours. The product was crystallised from acetone, fine, canary-yellow, needle-shaped crystals, m. p. 213–214°, being obtained in almost theoretical yield. This substance is also soluble in alcohol or light petroleum. In solution in any of these solvents the substance shows a beautiful blue fluorescence (Found: C = 72.83; H = 4.12. $C_{24}H_{16}N_2S_2$ requires C = 72.73; H = 4.04 per cent.).

2:6-Distyrylbenzbisthiazole. —The quantities and the time of heating were the same as in the preceding preparation. The yellow solid product crystallised from alcohol in small, yellow leaflets. By repeating the preparation three times, about 0.25 gram of this substance, m. p. 204°, was obtained (Found: C = 72.71; H = 4.38. $C_{24}H_{16}N_2S_2$ requires C = 72.73; H = 4.04 per cent.).

On concentrating the alcoholic mother-liquors, a further quantity of yellow crystals was obtained which melted at 240–300°. These were obviously too impure to analyse and the quantity obtained was too small to purify. They contained sulphur and nitrogen.

On further concentration, oily matter only was produced, but it was discovered that concentrated hydrochloric acid gave a canary-yellow, crystalline precipitate of a hydrochloride with either the oil or the concentrated alcoholic solution. The second and the third preparations yielded together about 0.75 gram of this com-

pound, from 1 gram of the benzbisthiazole. It could not be recrystallised and therefore it was washed well, dried in an air-oven at 100° and in a vacuum desiccator, and analysed (m. p. 255° with decomp.). It was not pure, as the two preparations gave different results on combustion, but it cannot be any of the possible hydrochlorides of mono- or di-styrylbenzobisthiazole, or any mixture of these, the carbon content being far too low and the chlorine content far too high (Found : 1st prep., C = 42.20; H = 3.44; 2nd prep., C = 43.03; H = 3.83; Cl = 24.98. $C_{11}H_{10}N_2Cl_2S_2$ requires C = 43.28; H = 3.28; Cl = 23.28. $C_{12}H_{10}N_2Cl_2S_2$ requires C = 45.42; H = 3.17; Cl = 22.40 per cent.).

Figures similar to the above would be obtained by analysis of either of these two compounds, if it were contaminated with a little adsorbed hydrogen chloride.

On pouring the strongly acid alcoholic solution into water, a yellow, flocculent precipitate was obtained, in small quantity only. It contained nitrogen and sulphur, and melted completely below 80°.

In conclusion, the author desires to express his thanks to Dr. W. H. Mills for permission to undertake this piece of work.

KING'S COLLEGE, LONDON.

[Received, July 25th, 1923.]

CCLXIII.—6 : 6'-Diacetylamino-1 : 1'-diethylcarbo- cyanine Iodide.

By FRANCES MARY HAMER.

6 : 6'-DIACETYLAMINO-1 : 1'-DIETHYLCARBOCYANINE IODIDE was first prepared by Mills and Pope (*Phot. J.*, 1920, 40, 253) and its photographic sensitising action was examined. Because 6-acetyl-aminoquinoline ethiodide is but slightly soluble in alcohol, the condensation was carried out in rectified spirit diluted with water. Mees and Gutekunst modified this preparation by using undiluted spirit (*Brit. J. Phot.*, 1922, 49, 474; *J. Ind. Eng. Chem.*, 1922, 14, 1060). They stated that a different product was obtained and claimed that their carbo-cyanine acted as a powerful sensitiser when added to an emulsion, showing a maximum not possessed by that previously described. But when they used the dye in aqueous solution for bathing plates, the extent of the band of sensitisation was found to be diminished and this they regarded as manifesting the presence of an entirely different substance. They considered that, in the preparation of the carbo-cyanine, the water content must be kept to a minimum, since otherwise the same, more weakly sensitising,

product is obtained. To explain these anomalies, Mees and Gutekunst suggested that 6 : 6'-diacetylamino-1 : 1'-diethylcarbocyanine iodide is hydrolysed by water, the acetyl radicles being removed.

But the explanation is improbable, since acetyl groups attached to nitrogen are generally stable. Moreover, in this particular instance, 6-acetylaminoquinaldine ethiodide—as also the base from which it is derived—is unchanged by boiling with water and is indeed best purified by recrystallisation from water, so that the acetylamino-groups in the corresponding carbocyanine would be expected to show a similar stability.

The preparation of the carbocyanine was repeated, following the method of Mills and Pope. A spectroscopic examination of the recrystallised dye confirmed their results and, although the extension of sensitisation into the red was greater than previously observed, the form of the spectrograph bore no resemblance to that depicted by Mees and Gutekunst. Tests were kindly carried out by Messrs. Ilford, who found that, whether the plate was bathed in a solution of the dye, or whether this was applied in the emulsion, the nature of the sensitising bands was essentially the same. A complete analysis of the substance gave values which concurred with those calculated for 6 : 6'-diacetylamino-1 : 1'-diethylcarbocyanine iodide. It was found that, although the yield was improved by using undiluted alcohol in the preparation, yet the product was identical. Thus the original observations were confirmed.

6 : 6'-Diamino-1 : 1'-diethylcarbocyanine iodide was prepared by hydrolysing its diacetyl derivative with concentrated hydrochloric acid, and a complete analysis of it also was carried out. It differed from the diacetylamino carbocyanine in appearance, solubility, and optical properties.

EXPERIMENTAL.

6 : 6'-Diacetylamino-1 : 1'-diethylcarbocyanine Iodide.—One mol. of 6-acetylaminoquinaldine ethiodide (14.2 grams) and one mol. of quinoline ethiodide (11.4 grams) were dissolved in rectified spirit (400 c.c.) diluted with water (60 c.c.). To the hot liquid were added 2.7 mols. of 37 per cent. formaldehyde (9 c.c.) and then a solution of 1.2 atoms of sodium (1.1 grams) in spirit (50 c.c.). After boiling for twenty minutes, the hot mixture was filtered and the very insoluble carbocyanine was thus freed from impurities. It was further purified by two extractions with boiling methyl alcohol (200 c.c. each). On recrystallisation from methyl alcohol (2 litres per gram), the yield (2.8 grams) diminished to one-third. The pure carbocyanine formed minute, green needles, which were unmelted at 320°. It was so slightly soluble in rectified spirit that the 1 in 10,000 solution deposited crystals on cooling. For analysis, a

specimen was dried in a vacuum at 120–130° to constant weight and, since it is very hygroscopic, precautions were taken against the uptake of water (Found : C = 58.37; H = 5.33; N = 9.55; I = 21.26. Calc. for $C_{28}H_{31}O_2N_4I$: C = 58.57; H = 5.26; N = 9.43; I = 21.36 per cent.).

The dye possesses two absorption bands, of which that in the red is the stronger; their maxima lie at 6250 and 5750. It is a weak sensitiser showing two maxima, and that in the red is relatively intense, with its crest at 6550, whilst the other is broader, extending from 5200 to 6300. For an exposure of eight minutes, the sensitisation extended to 7500, whilst a weaker band appeared with its crest at about 7100. An emulsion test showed the sensitising action to be the same as when the plate was bathed in a solution of the carbocyanine.

In another preparation, rectified spirit was used undiluted by water, so that the method of Mees and Gutekunst was followed as exactly as might be. It was not, however, found possible to dissolve the acetylaminquinoline ethiodide in the amount of alcohol mentioned, but three times that quantity was required. The yield was improved (4.3 grams of product instead of 2.8 grams). Comparison of a recrystallised specimen with one, in the preparation of which diluted alcohol had been employed, showed the two to be the same in appearance, solubility, and behaviour on heating, and the spectrographs also were identical.

6 : 6'-Diamino-1 : 1'-diethylcarbocyanine Iodide.—6 : 6'-Diacetyl-amino-1 : 1'-diethylcarbocyanine iodide (3 grams) was dissolved in concentrated hydrochloric acid (30 c.c.), and the solution boiled for half an hour. The red liquid was cooled, diluted with water, and carefully neutralised with ammonia. The precipitated diamino-compound was filtered, and dried on a porous plate. Its solution in hot methyl alcohol was treated with sodium iodide and the product was recrystallised twice more, but even then was sometimes slightly impure. The pure compound forms very beautiful, bright green crystals, possessing a brilliant lustre and golden iridescence. Melting with decomposition occurred at 262–263°. The carbocyanine is much more soluble in hot methyl alcohol (300 c.c. per gram) than its diacetyl derivative. For analysis, it was dried in a vacuum at 120–130° until of constant weight (Found : C = 58.50; H = 5.38; N = 10.76; I = 24.93. Calc. for $C_{28}H_{27}N_4I$: C = 58.79; H = 5.34; N = 10.98; I = 24.87 per cent.).

Of the two bands in the absorption spectrum, that in the red is much stronger than the other; their maxima are at 6400 and 5950. This carbocyanine decreases the normal sensitiveness of the plate and produces fog, but both these effects are greatly diminished when

a solution of 20—25 per cent. of the usual concentration is used. There are two bands of extra sensitiveness, of which that with its crest at 6700 is by far the more intense. The broader and weaker band extends from 5250 to 6300, leaving a minimum in the green.

CCLXIV.—*The Estimation of Alkalies in Rocks by the Indirect Method.*

By FREDERICK WALKER.

WHEN the alkalies in rocks are estimated by the Lawrence Smith method, it is the almost invariable custom of analysts to separate the potassium from the sodium by conversion of the mixed chlorides of the two metals into chloroplatinates and removal of the soluble sodium chloroplatinate by means of ethyl alcohol, $d\ 0.86$ (Washington, "Chemical Analysis of Rocks," 1910, p. 153). The insoluble potassium chloroplatinate is then weighed, and after calculation of the corresponding weight of potassium chloride, the weight of sodium chloride is determined by difference. The percentages of alkali oxides in the rock may then be calculated.

This method has, however, two possible sources of error.

(a) Some impurities present in the mixed chlorides are wholly or partially undissolved by the alcohol and remain with the potassium chloroplatinate, thus giving a high potash and a low soda percentage.

The impurities in the reagents used, previously determined by a "blank experiment," are assumed to be sodium chloride, and a corresponding correction is applied to the weight of sodium chloride, but examination of the residue in a blank experiment shows that besides sodium chloride, at least calcium chloride and carbon are present.

(b) Some of the potassium chloroplatinate will be dissolved by the alcohol, and removed along with the sodium salt, this tending to give a low potash and a high soda percentage.

Many investigators have suggested the indirect estimation of sodium and potassium by titration of the mixed chlorides with silver nitrate using potassium chromate as indicator, and Collier (*Amer. J. Sci.*, 1865, 37, 344) has shown the method to be accurate when pure salts are used. A discussion of the merits of the indirect method has been given by Mellor ("Treatise on Quantitative

Inorganic Analysis," 1913, pp. 227—229) together with an account of the calculations involved and a very complete bibliography.

No experimental details have apparently been given when the mixed chlorides have been actually derived from rocks, nor have any figures been published which would serve as a comparison of the chloroplatinate and indirect methods. The author has endeavoured to remedy these omissions in the present communication.

Method of Titration.—*N/50*. Silver nitrate solution was prepared by dissolving 3.398 grams of pure silver nitrate in distilled water and making up to 1 litre. This solution was standardised in the following manner under exactly the same conditions as prevailed in the actual titration of the mixed chlorides.

About 50 mg. of pure sodium chloride or 60 mg. of pure potassium chloride were weighed to 1/20th mg. and dissolved in about 20 c.c. of distilled water in a white porcelain basin. To this solution 0.25 c.c. of potassium chromate solution (*N/5*) was added. The silver nitrate was then run in, 0.5 c.c. at a time, from a 50 c.c. burette, and the contents of the basin were vigorously stirred after each addition of the silver nitrate. When the calculated end-point was approached, the silver nitrate was run in very cautiously with continued vigorous stirring. The end-point is indicated by a change in the colour of the solution from very pale yellow to very pale salmon-pink. If the colour of the solution is pale, the end-point will be exceedingly sharp, but if too much indicator is used, several drops of silver nitrate may have to be added to produce a perceptible change of colour. To facilitate the detection of the end-point, the following solution was used as a standard for comparison. A few c.c. of a chloride solution to which 0.25 c.c. of *N/5* potassium chromate had been added were partly precipitated in a white porcelain basin by silver nitrate solution so that an abundant precipitate of silver chloride was produced, the chromate, however, being unaffected. The total volume of the solution for comparison should be about 60 c.c. to correspond with the volume used in the titration.

Modifications of the Lawrence Smith Method Employed.—To obtain the mixed chlorides of sodium and potassium from the rock, the Lawrence Smith method as described by Hillebrand and Washington (Hillebrand, "Rock Analysis," 1910, pp. 171—173; Washington, *op. cit.*, pp. 143—161) was used with the following modifications:

(1) The ignition of the powdered rock with calcium carbonate and ammonium chloride was carried out in an ordinary platinum crucible, the finger type being found unnecessary. This crucible

had a ventilated lid and was placed in a perforated silica plate, beneath which two-fifths of the crucible projected. After the slow volatilisation of the ammonium chloride, the ignition was completed over a moderate bunsen flame. Extremely fine rock powder was always used.

(2) The bulk of the calcium was removed by double precipitation with a slight excess of ammonium carbonate in a porcelain basin, at the maximum temperature attainable on a water-bath. The solution was stirred vigorously during precipitation, and the precipitate allowed to settle. Two drops of ammonium oxalate solution were then added, and the solution was kept on the water-bath for five minutes, after which it was decanted through a 9 cm. filter-paper into a platinum basin, the precipitate being retained in the porcelain basin as much as possible. The precipitate was then redissolved in the minimum quantity of dilute hydrochloric acid (about 4 c.c.), reprecipitated as before, and filtered into the platinum basin with repeated thorough washings with small quantities of hot water.

(3) After the first evaporation to dryness on the water-bath, the platinum basin was placed in an air-oven at 140°. The basin was covered by a clock-glass which had already been in the oven for twenty minutes. Fifteen minutes in this oven ensured the removal of all moisture, and when decrepitation took place the particles did not adhere to the clock-glass. The slight film of ammonium salts on the clock-glass was washed into the platinum basin before the third and final precipitation of calcium. After removal from the oven, the uncovered basin could be heated over an open flame without risk of spurling. The final precipitation of calcium was effected by addition of one drop of ammonia and five drops of ammonium oxalate solution.

(4) When microscopic examination showed the presence of sulphur in the rock, two or three drops of barium chloride solution were added before the final precipitation of the calcium, as the presence of sulphates in the mixed chlorides is highly detrimental to the accuracy of the indirect method. The excess of barium chloride was precipitated by a few drops of ammonium carbonate.

(5) The jet of the wash-bottle was reduced to a minimum and many small washings were given. The alkali chlorides were extracted from the ignited mass by about 80 c.c. of water and the filtrates at the commencement of the first evaporation to dryness rarely exceeded 125 c.c. Much time was thus saved.

When chloroplatinate determinations were made for comparison with the indirect method, absolute methyl alcohol was used for extraction of the sodium chloroplatinate as recommended by

Cumming and Kay ("Quantitative Chemical Analysis," 1919, p. 229).

Blank Experiment and Purity of Reagents.—To ensure accuracy, all the reagents used in the Lawrence Smith method were tested, and purified if necessary. The author found that Kahlbaum's calcium carbonate (*zur Analyse*) was very satisfactory without purification. The residue obtained in the blank experiment did not exceed 1.5 mg. After it had been weighed, it was dissolved in 1 c.c. of water and titrated in the crucible with standard silver nitrate, one drop of potassium chromate ($N/5$) being added as indicator. The volume of the silver nitrate used was deducted from the titre obtained in the actual determination, whilst the weight of residue was deducted from the weight of the mixed chlorides. In the indirect method, provided that the composition of the residue is constant, its nature is of no importance.

In his determinations, the author found the weight of residue to vary between 1 mg. and 1.5 mg. (compare Hillebrand, *op. cit.*, p. 171). The volume of silver nitrate used varied between 0.35 c.c. and 0.60 c.c.

In the actual determination it is well to take sufficient rock powder to yield at least 40 mg. of mixed chlorides, but if the weight of the mixed chlorides exceeds 60 mg. there is a risk of using more than 50 c.c. of standard silver nitrate, that is, the capacity of the burette. In practice it is easy to determine fairly accurately the probable percentages of alkalis and the probable weight of mixed chlorides by microscopic examination of thin sections of the rock analysed. The weight of the rock powder used will seldom exceed 0.6 gram or be less than 0.35 gram to yield the above amount of mixed chlorides, and with these weights the customary 4 grams of calcium carbonate and 0.5 gram of ammonium chloride give satisfactory decomposition.

After the mixed chlorides had been weighed, they were dissolved in about 20 c.c. of water and transferred to a porcelain basin, in which they were titrated against standard silver nitrate exactly as described above. From the burette reading the weights of potassium and sodium chlorides were calculated and finally the percentages of alkali oxides present in the rock were obtained. The details of this calculation are given by Mellor (*op. cit.*, p. 227).

The results given below were obtained with three representative Scottish igneous rocks, the first having potash and soda present in almost equal proportions, the second having a large preponderance of soda, and the third a slight preponderance of potash.

A. Quartz-Monzonite from Priestlaw, E. Lothian.

Weight of residue obtained in blank experiment, 1.5 mg.

Volume of silver nitrate used in blank experiment, 0.60 c.c.

	Indirect.		Chloro- platinate.
Weight of rock powder used (gram)	0.4485	0.4921	0.4962
Corrected weight of mixed chlorides (gram)	0.0551	0.0606	0.0609
Weight of potassium chloroplatinate (gram)	—	—	0.0372
Corrected volume of silver nitrate used (c.c.)	42.95	47.30	—
Weight of potassium chloride referred to weight taken in chloroplatinate determin- ation (mg.)	25.6	25.4	26.7
Weight of sodium chloride referred to weight taken in chloroplatinate determination (mg.)	35.5	35.7	34.2
Percentage of K_2O	3.25	3.23	3.40
Percentage of Na_2O	3.79	3.81	3.65

B. Theralite from Whitehouse Point, Mid Lothian.

Weight of residue in blank experiment, 1.0 mg.

Volume of silver nitrate used in blank experiment, 0.35 c.c.

	Indirect.		Chloro- platinate.
Weight of rock powder used (gram)	0.4083	0.4002	0.3241
Corrected weight of mixed chlorides (gram)	0.0545	0.0538	0.0429
Weight of potassium chloroplatinate (gram)	—	—	0.0356
Corrected volume of silver nitrate used (c.c.)	43.95	43.50	—
Weight of potassium chloride referred to weight taken in chloroplatinate determin- ation (mg.)	10.1	10.0	10.9
Weight of sodium chloride referred to weight taken in chloroplatinate determination (mg.)	33.2	33.5	32.0
Percentage of K_2O	1.96	1.95	2.12
Percentage of Na_2O	5.43	5.48	5.23

C. Granite from Corrennie, Aberdeenshire.

Weight of residue in blank experiment, 1.0 mg.

Volume of silver nitrate used in blank experiment, 0.35 c.c.

	Indirect.		Chloro- platinate.
Weight of rock powder used (gram)	0.3460	0.3536	0.3474
Corrected weight of mixed chlorides (gram)	0.0526	0.0542	0.0528
Weight of potassium chloroplatinate (gram)	—	—	0.0903
Corrected volume of silver nitrate used (c.c.)	39.85	40.90	—
Weight of potassium chloride referred to weight taken in chloroplatinate determin- ation (mg.)	27.3	28.0	27.6
Weight of sodium chloride referred to weight taken in chloroplatinate determination (mg.)	25.5	25.2	25.2
Percentage of K_2O	4.97	5.08	5.02
Percentage of Na_2O	3.87	3.85	3.84

The above results seem to indicate that the indirect method is capable of giving results which show reasonable agreement with those obtained by the chloroplatinate method.

The purity of all the reagents is a *sine qua non* when the indirect method is employed, as the presence of impurities in the mixed chlorides affects the accuracy much more than in the chloroplatinate method. In this connexion it is significant to note that the rock in the analysis of which the purest reagents were used (C) showed the closest agreement between the three determinations.

The time saved by the use of the indirect method, in conjunction with the modifications of the Lawrence Smith method described above, is considerable. The average time taken for the indirect determinations was four and a half hours. Thus two complete alkali determinations may be completed in one day (compare Washington, *op. cit.*, p. 142).

When expense is considered, the indirect method has a distinct advantage over both the chloroplatinate method and the less accurate perchlorate method.

CCLXV.—*Equilibrium of the Ternary System Bismuth-Tin-Zinc.*

By SHEIKH D. MUZAFFAR.

THIS problem was investigated in order to ascertain the influence of tin on the immiscibility of bismuth and zinc. From another point of view, it supplied the opportunity of recording the effect of immiscibility of two metals on the constitution of a ternary system.

Former work on this problem consists in the attempts made by Wright and Thomson (*Proc. Roy. Soc.*, 1891, 49, 156) to determine the influence of tin on the solubility of bismuth in zinc and of zinc in bismuth. Experiments were made with mixtures of equal weights of bismuth and zinc to which varying proportions of tin were added. After the resulting mixtures had been brought into equilibrium (by keeping them for eight hours) at (i) 600–700° and (ii) 700–800°, the corresponding upper and lower layers were separated and analysed. From the solubility data thus obtained, it was concluded that the miscibility of bismuth and zinc is considerably favoured by the addition of tin and is completely attained by the addition of 18.7 (wt.) per cent. of tin at 600–700° and of 15.3 per cent. at 700–800°. Similarly, attempts were made to determine the effect of successive additions of zinc to mixtures

of equal weights of bismuth and tin and of bismuth to similar mixtures of zinc and tin; in both cases, no immiscibility was met with.

The results of these trials are confirmed by the present work, but since they are all solubility estimations they convey no idea about the freezing point of the alloys and therefore cannot be shaped into a thermal diagram of the system.

The three binary systems involved in the problem are bismuth-zinc, bismuth-tin, and tin-zinc. The necessary thermal data are taken from the "Landolt-Bornstein Physikalische-Chemische Tabellen," 1912, which contains a summary of previous work.

Thermal Investigation.

Procedure.—Zinc and bismuth (both 99.9 per cent.) and tin (99.5 per cent.) were employed throughout the work. They contained the merest trace of foreign material, and their freezing points agreed with the standards.

The freezing points and the other thermal arrests of the alloys were taken by means of a nichrome-constantan thermo-couple. The wires were 28 S.W.G. and the free ends of the couple were attached to a sensitive mirror-galvanometer. By tracing a spot of light reflected from the galvanometer needle on to a moving screen, the thermal arrests were obtained on direct time-temperature cooling curves. The couple wires, at their brazed end, were covered with a very thin layer of fireclay cement and inserted in the molten alloy. This formed an effective protection for the couple against the attack of the metals and at the same time did not impair its sensitiveness. On account of its fragile nature, the coating had to be repaired from time to time, but this was not a long or a tedious process. The thermo-couple was standardised by means of the following fixed points: b. p. of water (100°); f. p. of tin (232°); f. p. of lead-tin eutectic (183°); f. p. of lead (327.5°); f. p. of zinc (418.5°).

A 100-gram sample of each ternary alloy was prepared by weighing out the requisite quantities of the metals on a balance sensitive to 0.05 gram. All proportions of the metals in the alloys were reckoned in weight per cent. The rate of cooling and the speed of the screen were regulated to be the same for all alloys. It took usually thirty-five to forty minutes for an alloy to cool from 420° to 70° . The cooling curves were taken for the same interval. The results of the thermal analysis are given in the following table.

The Numbering of the Alloys.—In Fig. 1, the scheme of the numbering of the alloys is given. The percentage of a metal in an alloy is represented on the well-known system of distances from the sides of an equilateral triangle. Starting from the apex, or the Sn corner, the alloys are numbered from left to right on lines parallel to the

zinc-bismuth base. By this system, it is easy to locate an alloy in Figs. 2 and 3.

The Liquidus Surface.—In Fig. 2, the isothermals of the freezing points of the alloys are given. It is clear that the immiscible zone is bounded by Zn *C D* or the alloys Nos. 96, 90, 80, 66, 55, 71, 84, 92, 102. At 390°, the addition of 28 per cent. of tin brings about complete miscibility in a mixture of equal weights of bismuth and zinc. As the relative proportion of bismuth and zinc varies

FIG. 1.
Numbering of Alloys.

from 1:1 by weight, the amount of tin required also becomes less.

The ternary eutectic, lying at *O*, corresponding to 56 per cent. Bi, 40 per cent. Sn, and 4 per cent. Zn, and the binary valleys *O X*, *O Y*, and *O W* running from it to the respective binary eutectic points are also shown in the same figure. Since the Bi-Zn binary eutectic at *W* also lies at 4 per cent. Zn, the valley *O W* joining it to the ternary point, *O*, is parallel to Bi-Sn base. The valley *O X* joining the ternary to the Sn-Zn eutectic point runs parallel to the same base from the ternary eutectic till alloy No. 11 is reached. It rounds off to alloy No. 7 and, further up, runs straight into the

Sn-Zn eutectic at X . The valley OY joining the Bi-Sn eutectic to the ternary eutectic point is a straight line.

The study of successive isothermals suggests the shape of the *liquidus* surface. From the Zn corner, a slope runs towards the binary valleys XOW . It is very steep between OW and CD and has been a source of great difficulty in recording the exact freezing points of the alloys containing 5 per cent. of zinc. This steepness is well marked in Fig. 6, which is a section of the *liquidus* surface along the median through Zn, and also in Fig. 5. Across

FIG. 2.
Freezing points of the alloys.

the binary valleys XOW there is a tendency for the *liquidus* surface to rise to the freezing points of the binary alloys or the pure metals. This gradient is not steep.

The immiscible zone gives to the *liquidus* surface a characteristic flat shape, which slopes towards the centre of the triangle. The slope of the surface over the immiscible zone stands in a contrast to the general slope of the *liquidus* surface.

Phase Rule Considerations.—An alloy lying in the immiscible zone, on cooling in the liquid state, separates out in two layers. At its freezing point there are three phases present (pure zinc metal

as a solid phase, and the two liquid layers). The system therefore has one degree of freedom. In other words, fixing the temperature fixes the composition of the two layers and vice versa. Thus we see lines parallel to the Zn-Bi base in Fig. 2 joining up alloys freezing at the same temperature. All alloys lying on such a tie line separate out in two layers, whose compositions are represented by points on the end of the tie line. On rapid cooling, however, the change in composition does not follow the change in temperature, on account

FIG. 3.
Binary isothermals.

of the lack of diffusion between the two layers. They freeze out independently of each other, and each may consist of two or three similar distinct phases. All alloys lying in the immiscible zone, therefore, solidify in two layers, the relative proportion of which varies with the initial composition of the alloy.

In the case of alloys lying in the area Zn X O W D C in Fig. 2, there are only two phases present at their freezing point. The system has therefore two degrees of freedom, or the composition of the liquid as well as the temperature may change independently of each other. Because pure zinc separates out from these alloys

as the first solid phase on cooling, the change of composition of the liquid follows a straight line, which passes through the alloy from the Zn corner, until it meets one of the two binary valleys XO or OW . On its reaching these, a new solid phase, the binary eutectic, appears. There are therefore three phases present. The system becomes univariant and the composition of the liquid, with the change of temperature, follows the course of the binary valley XO or WO . On reaching the ternary eutectic point, another solid phase (the ternary eutectic) appears. The system then is invariant. Thus the alloys the compositions of which are represented by points lying in the area specified above, consist of three phases, that is, pure zinc, one of the two binary eutectics (Bi-Zn

FIG. 4.

FIG. 5.

or Sn-Zn) and the ternary eutectic; with the exception of those which lie on the line joining Zn and O , because from these none of the binary eutectic separates out. Consequently, they consist of two phases only, pure zinc and the ternary eutectic.

The alloys lying on the binary valleys OY , OW , and OX (Fig. 2) also consist of two solid phases, the binary and the ternary eutectics. The ternary eutectic alloy at O is one homogeneous phase.

In the area $BiWOY$ (Fig. 2), 3 per cent. zinc-in-bismuth solid solutions separate out, and in the area $SnYOX$ (Fig. 2) solid solutions of more complex nature are formed. The phase rule considerations applicable to these areas are similar to those summed up above.

Isothermals of the Binary Arrests.—From the alloys lying in the area $Zn\ XOWDC$ in Fig. 3 (which corresponds to the same area of Fig. 2) pure zinc separates out, on freezing, as the first solid phase. The change in composition of the liquid portion of the alloy, therefore, always follows a straight line drawn from the Zn corner through the alloy in question. All alloys lying on a similar line have the same binary arrest, because on change of composition of their liquids they meet the binary valley at the same point. This is illustrated by the isothermals of the binary arrests given in Fig. 3. The alloys lying on the line joining the Zn corner to the ternary point do not meet any of the binary valleys on the separation of zinc from them on freezing. They give no binary arrest. The

FIG. 6.

FIG. 7.

$Zn\ O$ line forms a valley by itself from which on either side the binary temperatures rise up as the sides of the triangle are approached (see Figs. 4, 7, and 8).

In the immiscible zone and the other areas, the binary arrests cannot be interpreted by a simple rule.

Effect of Tin on the Miscibility of Bismuth and Zinc.

Fig. 4 illustrates the effect of adding increasing amounts of tin to a mixture of equal weights of bismuth and zinc. It is a section of the diagram along a median through Sn and the middle point of the $Zn-Bi$ base. The freezing points fall until the content of tin becomes 90 per cent., and between alloys 4 and 1 the

binary valley $O X$ (Fig. 2) is met. Further on, a rise in the freezing points of the alloys is recorded to the freezing point of pure tin. The binary arrest falls at first until alloy No. 50 is reached (this is the nearest point to the line joining Zn and O), and rises further with increasing percentages of tin. The freezing point of the ternary eutectic is given by all alloys except those in which solid solutions are formed.

Fig. 5 is a section of the diagram at 15 per cent. Sn. The immiscible zone is broken into from both sides, and other features are similar to those described above. The steep rise in the freezing point between 4 and 25 per cent. Zn is also illustrated.

FIG. 8.

FIG. 9.

Effect of Zinc on the Miscibility of Tin and Bismuth.

Fig. 6 shows the effect of adding increasing quantities of zinc to a mixture of equal weights of bismuth and tin. The rise in the freezing point is very rapid until the content of zinc reaches 40 per cent. With further additions of zinc, the rise continues to the freezing point of zinc, but is not so rapid. The binary arrests are all constant, because all the alloys in this section of the diagram lie on the median through Zn. The freezing point of the ternary eutectic is given by all the alloys.

Fig. 7 illustrates a section of the diagram at 5 per cent. Zn. The binary arrests have their minimum at alloy No. 39, because it lies on the line joining Zn and O (Fig. 2).

Effect of Bismuth on the Miscibility of Tin and Zinc.

Fig. 8 shows the effect of adding increasing amounts of bismuth to a mixture of equal weights of tin and zinc. The freezing point rises slightly until the content of bismuth amounts to 60 per cent. With further additions of bismuth, the freezing point falls, comes to a minimum at 92 per cent. Bi, and then rises to the freezing point of pure bismuth. This figure is a section of the diagram along a median through Bi and the middle point of the Zn-Sn base. The minimum of the binary arrests falls at 43 per cent. Bi, because this point lies on the line joining Zn and O (Fig. 2). The temperatures of the ternary point are also shown.

Fig. 9 is a section of the diagram at 10 per cent. Bi. The steep rise in the freezing point between 7 and 30 per cent. Zn is well marked.

Microscopic Investigation.

The conclusions drawn from the phase rule considerations discussed above were tested by a micro-analysis of the alloys, and the following photographs are shown to confirm the views. Fig. 10 shows the photomicrograph of alloy No. 40, which is the ternary eutectic, and illustrates its structure.

Figs. 11 and 12 were respectively reproduced from the Bi-Zn eutectic and alloy No. 77, which lies on the *OW* valley (Fig. 2). Since zinc or a solid solution does not separate out from it, this alloy consists of only two phases, the ternary eutectic and the Bi-Zn eutectic. Fig. 12 helps to fix the course of the valley.

A photomicrograph of alloy No. 91 at the boundary line of the two immiscible layers is shown in Fig. 13. All immiscible alloys were found to have the same appearance. The structure of the two layers is further illustrated in Figs. 14 and 15. In order to fix accurately the boundary line of the immiscible zone, the alloys Nos. 96, 90, 80, 66, 55, 71, 84, 92, and 102 were cut through vertically and examined after being polished. They were all found to be homogeneous and free from two layers. The alloys Nos. 97, 67, 70, 83, 101, 91, and 99 showed the presence of two layers. The top layers consisted of zinc and the ternary eutectic only, whilst the bottom layers showed zinc, the Bi-Zn eutectic, and the ternary eutectic to be present.

In alloys lying in the area *CODW* (Fig. 3) three phases, zinc, the Bi-Zn eutectic, and the ternary eutectic, should be present and these are found in Fig. 16, which is a photomicrograph of the alloy No. 94.

The alloys lying on the *CO* line (Fig. 3) should consist of only two phases. Fig. 17, a photomicrograph of such an alloy (No. 44), shows only zinc and the ternary eutectic.

The alloys lying in the area $CZnXO$ consist of the three phases zinc, the Sn-Zn eutectic, and the ternary eutectic. This was found to be the case in alloy No. 9 (Fig. 19). A photomicrograph of the Sn-Zn eutectic with excess of zinc is shown in Fig. 18 for comparison.

Fig. 20 was produced from alloy No. 19 lying on the binary valley OX (Fig. 2). Here again only two phases were found, namely, the Sn-Zn eutectic and the ternary eutectic.

Fig. 21 was photographed from the Bi-Sn eutectic.

Summary.

Thermal and micro-investigations of ternary alloys of bismuth, tin, and zinc have been made. The system is found to contain a ternary eutectic of freezing point 130° and composition corresponding to 56 per cent. of bismuth, 40 per cent. of tin, and 4 per cent. of zinc. There is no ternary compound formed. The immiscibility of bismuth and zinc, in the liquid state, disappears on the addition of 28 per cent. of tin to a mixture of equal weights of the two metals. The amount of tin required if their mixtures deviate from the ratio 1 : 1 is even smaller.

Pure zinc separates out from all alloys containing more than 4 per cent. of zinc, except those that contain more than 75 per cent. of tin at the same time. In the case of the others, solid solutions are formed.

If the percentage of bismuth in the alloys is increased, the freezing points are very little affected until the percentage exceeds 80. On further additions of bismuth, the freezing point is lowered to its melting point, with a minimum at 92 per cent. of bismuth.

Increase in the percentage of tin in the alloys lowers their freezing points until the Sn-Zn binary valley is reached, after which a small rise to the freezing point of tin occurs.

Addition of 0-4 per cent. of zinc to the bismuth-tin alloys lowers their freezing points. The minima lie in the binary valleys. The freezing points of the alloys vary greatly when the percentage of zinc lies between 4 and 25. On increasing the percentage of zinc above 25, the freezing points of the alloys rise to that of pure zinc, but the variation in the freezing point with the increase in the percentage of zinc is not so great as before.

In conclusion, the author wishes to express his thanks to Mr. C. I. Heycock, M.A., F.R.S., for the facilities provided for this research, and to Mr. M. Cook, M.Sc., for his valuable suggestions.

CCLXVI.—*Studies in the Benzothiazole Series. Part I.*
The Pseudo-bases of the Benzothiazole Quaternary Salts.

By WILLIAM HOBSON MILLS, LESLIE MARSHALL CLARK, and JOHN ALFRED AESCHLIMANN.

It was found by W. K. T. Brauholtz and one of us that in the isocyanine condensation, brought about by treating a mixture of a quinoline- and a quinaldine-alkyl salt with an alkali hydroxide, the quinaldine alkyl salt could be replaced by a 1-methylbenzothiazole alkyl salt, a cyanine dye with mixed nuclei thus being produced; but that when the corresponding replacement of the quinoline derivative by a benzothiazole alkyl salt was attempted no such dye was formed. This observation indicated that a considerable difference existed between the ψ -bases which result from the action of alkalis on the quinolinium salts and those produced from the quaternary salts of benzothiazole. It is shown in the present communication what the nature of this difference is.

We were led to discover it through studying the oxidation of benzothiazole methiodide by alkaline potassium ferricyanide. If the methylbenzothiazolonium ψ -base corresponded in constitution with the quinolinium ψ -bases it would be expected to yield 2-methylbenzothiazolone (I) on oxidation.

The latter compound has already been described. It was prepared by Besthorn (*Ber.*, 1910, **43**, 1523) from the nitroso-compound (II), by the elimination of nitrogen by heating, and since we have obtained the same substance by the interaction of 2-methylamino-phenyl mercaptan (III) and carbonyl chloride, there can be no doubt that Besthorn's compound actually is the benzothiazolone.

When, however, benzothiazole methiodide is oxidised with alkaline ferricyanide, a crystalline compound is formed which melts at 108° and is thus not the thiazolone, which melts at 76°. The empirical formula of this substance ($\text{C}_8\text{H}_8\text{ONS}$) contains one atom of hydrogen more than that of the thiazolone. Its molecular formula must therefore, from the laws of valency, be double the empirical formula, and this was verified by direct determinations of the molecular weight.

This bimolecular oxidation product was readily reconverted by acid reducing agents into methylbenzothiazolium salts. Since the union between the two residues of the ψ -base can be broken in this manner, it is unlikely that it is effected through a carbon-carbon linking. The linking must therefore probably take place through oxygen or sulphur, and we obtained a very clear indication that it took place through sulphur; for when benzothiazole methiodide was dissolved in excess of ammonia and exposed to atmospheric oxidation this oxidation product of melting point 108° was slowly deposited, but when it was similarly treated with sodium hydroxide a substance was deposited which proved to be 2 : 2'-dimethylamino-diphenyl disulphide (IV). The difference in composition of these two products indicated that the caustic alkali had brought about

the elimination of two formyl groups. It was therefore exceedingly probable that the oxidation product of melting point 108° was 2 : 2'-diformylmethylaminodiphenyl disulphide (V). We were able to prove definitely that it had this constitution by showing that it was formed when 2 : 2'-dimethylaminodiphenyl disulphide (IV), prepared by oxidising the corresponding mercaptan, was formylated by boiling with formic acid.

After we had thus determined the constitution of this product, we found that it had already been obtained by Rassow, Döhle, and Reim (*J. pr. Chem.*, 1916, [ii], 93, 183) whilst studying the oxidation of a substance the constitution of which they were unaware, but which is shown in the following communication to be thio-2-methylbenzothiazolone. Rassow, Döhle, and Reim suggested the constitution (V) for this compound, but whilst they showed that formic acid was produced when it was boiled with dilute acids, and that methylaniline, methylaminophenyl mercaptan, and formic acid were formed when it was fused with potash, they did not establish this formula definitely.

The ψ -base by the oxidation of which this disulphide is produced is clearly the mercaptan of the formula VI. This is isomeric with the ammonium base of the benzothiazole methyl quaternary salts (VII) and with the carbinol base (VIII) corresponding in constitution with the ψ -bases of the alkylquinolinium salts.

Investigation of the action of alkalis on benzothiazole methiodide

and methosulphate has fully confirmed the conclusion that the ψ -base of these salts is formylmethylaminophenyl mercaptan.

A dilute solution of the methiodide can be titrated with $N/10$ -sodium hydroxide and phenolphthalein, and a definite end-point is obtained when two equivalents of alkali have been added. The " ψ -base" must therefore be an acidic compound, capable of forming a sodium salt which is so little hydrolysed that it can be titrated with $N/10$ -alkali and phenolphthalein.* The reaction between benzothiazole methiodide and sodium hydroxide accordingly proceeds as follows:

The solution of the ψ -base thus obtained can then be titrated back again with decinormal acid and methyl-orange, and a well-marked end-point obtained when two equivalents of acid have been added. The neutral solution of the sodium salt of the ψ -base is thus reconverted into a neutral salt of the quaternary ammonium base. By adding the necessary quantity of hydriodic acid to a solution of the sodium salt, we were able to recover a large proportion of the benzothiazole methiodide originally taken. This explains why diformylmethylaminodiphenyl disulphide is reconverted into methylbenzothiazolonium salts by reduction in presence of acids.

When only one equivalent of sodium hydroxide is added to a solution of benzothiazole methiodide, half the methiodide remains unchanged and half an equivalent of the sodium salt of the ψ -base is formed, for ether extracts only a very small amount of material from the solution, and this probably only on account of slight hydrolysis of the sodium salt.

The solution of the sodium salt of the ψ -base shows the properties to be expected of a salt of a thiophenol. It gives immediate precipitates with salts of the heavy metals. The silver mercaptide obtained in this way gave results on analysis in agreement with the formula IX. When the solution of the sodium salt is treated

* The electrolytic dissociation constants of the thiophenols seem not to have been determined; but in view of the well-known increase in the acidity of a compound consequent upon the replacement of oxygen by sulphur, phenyl mercaptan must be an acid of considerably greater strength than phenol, and we find that it can, in fact, be sharply titrated in aqueous alcoholic solution with $N/10$ -alkali and phenolphthalein.

with benzoyl chloride and alkali, a stable benzoyl derivative, $C_{15}H_{13}O_2NS$, is formed. This clearly has the formula X.

The solution is also oxidised to the disulphide by other oxidising agents which convert mercaptans into disulphides. When a solution of iodine is added gradually, the drops are immediately decolorised, the disulphide being precipitated, until a sharply marked end-point is reached. The amount of iodine thus added is in exact agreement with the equation

Hydrogen peroxide acts similarly; when added to the cold solution, it causes an immediate precipitation of the disulphide, and oxidation in this manner provides the best method for preparing the compound.

Whilst the presence of the thiophenolic ψ -base (VII) (in the form of its sodium salt) is thus sufficiently established, we have also obtained evidence of the formation, as an intermediate product, of the carbinolic ψ -base (VIII). When benzothiazole methiodide was added to an alkaline solution of hydrogen peroxide, so that the transformation of the ammonium base took place in presence of an oxidising agent, a small amount of 2-methylbenzothiazolone (I) was always produced. This can scarcely be formed otherwise than by oxidation of the carbinolic ψ -base (VIII).

If the carbinol, as this indicates, forms an intermediate step between the ammonium base and the thiophenolic ψ -base when benzothiazole methiodide is treated with alkali, it is probable that it is also an intermediary in the retransformation of the thiophenolic ψ -base into benzothiazole methyl salts by acids.

On this view, the small amount of free ψ -base existing in a solution of benzothiazole methiodide to which alkali has been added would consist of a mixture of thiophenolic and carbinolic ψ -bases in dynamic equilibrium:

On addition of alkalis, the former is removed as its sodium-derivative; on addition of acids, the latter is converted into the corresponding benzothiazole quaternary salt.

In studying quantitatively the reduction of 2:2'-diformyl-methylaminodiphenyl disulphide by zinc and hydrochloric acid it was found that more hydrogen was absorbed than corresponded

with the formation of benzothiazole methochloride. Moreover, we were able to separate from the tin salts obtained by reducing the disulphide with tin and hydrochloric acid a more soluble fraction which, treated with excess of sodium hydroxide, gave, not the soluble sodium salt of the thiophenolic ψ -base, but an oil insoluble in alkalis. This indicated the formation in the reduction of a certain amount of a more highly reduced product, presumably 2-methylbenzothiazoline. We then found that this base can be easily prepared by reducing benzothiazole methiodide with zinc and hydrochloric acid. It is a liquid which resinifies on keeping. It is oxidised by iodine to benzothiazole methiodide and contains a reactive methylene group, for it condenses with nitrosodimethylaniline to give a colourless compound to which the formula

EXPERIMENTAL.

Action of Alkalis on Benzothiazole Methiodide.—An aqueous solution of benzothiazole methiodide, titrated with sodium hydroxide solution and phenolphthalein, required 2 molecular proportions of the alkali for neutralisation. When the resulting solution was titrated with methyl-orange and hydrochloric acid, an end-point was obtained when two equivalents of acid had been added (0.277 gram of benzothiazole methiodide required 20.0 c.c. of 0.1N-NaOH. Male, 20.0 c.c. For the back titration, 20.27 c.c. of 0.1N-HCl were required).

To show that the reacidification regenerated the benzothiazole quaternary salt, benzothiazole methiodide (2.5 grams) was treated with *N*-sodium hydroxide (18 c.c.; 2 equivalents). To the resulting neutral solution 4 grams of a 57 per cent. solution of hydriodic acid were added. The mixture was concentrated to 10 c.c., when benzothiazole methiodide (2.12 grams), melting alone or mixed with pure benzothiazole methiodide at 210° , was obtained.

The Silver Mercaptide of the ψ -Base.—To obtain this substance benzothiazole methosulphate was required. This was prepared by mixing equivalent quantities of benzothiazole and methyl sulphate. The mixture became completely solid after one and a half hours. The product was digested with ether and the residue was crystallised from a mixture of alcohol and ether. It formed colourless, deliquescent needles, m. p. 103° , giving a neutral solution in water (Found: S = 24.40. $\text{C}_9\text{H}_{11}\text{O}_4\text{NS}_2$ requires S = 24.52 per cent.).

A neutral solution of the sodium mercaptide of the ψ -base was prepared by mixing a solution of the quaternary salt (0.52 gram) in water (20 c.c.) with two equivalents of sodium hydroxide (40 c.c.

of a 0.1*N*-solution). This was treated with one equivalent of silver nitrate (20 c.c. of a 0.1*N*-solution), corresponding small volumes of the two solutions being run alternately into 20 c.c. of water with rapid stirring. The resulting cream-coloured precipitate of the silver mercaptide was collected, washed, and dried. It melted and decomposed at 145–150°, beginning to darken at 105° (Found: C = 34.3; H = 2.9; Ag = 39.4. C_6H_5ONSAg requires C = 35.0; H = 2.9; Ag = 39.5 per cent.).

Benzoylation of the ψ -Base of Benzothiazole Methiodide.—Benzothiazole methiodide (3 grams) was dissolved in water and 10 per cent. sodium hydroxide solution (9 c.c.) added. Benzoyl chloride (1.5 grams) was added gradually with constant shaking and the pasty substance which separated was extracted with ether. The residue left after evaporation of the ether, crystallised from light petroleum, formed colourless plates, m. p. 71.5–72° (Found: C = 66.68; H = 4.87; N = 5.03. $C_{15}H_{13}O_2NS$ requires C = 66.42; H = 4.80; N = 5.16 per cent.).

Oxidation of the Methyl ψ -Base. 2 : 2'-Diformylmethylaminodiphenyl Disulphide.—A. *Oxidation with Potassium Ferricyanide.* A cold saturated aqueous solution of benzothiazole methiodide (25 grams) was added gradually to an ice-cold solution of potassium ferricyanide (125 grams) in water (1 litre) containing sodium hydroxide (67 grams). A nearly colourless pasty solid was precipitated. The mixture was stirred at 0° for one hour after the addition was complete. The product was collected, washed with water, and, after drying, was dissolved in benzene and precipitated by the addition of ether as fine platelets, m. p. 108°. Yield: 6–9 grams, or 40–60 per cent. of the theoretical [Found: C = 57.9, 57.9; H = 4.97, 4.97; N = 8.45; S = 19.35; *M* (cryoscopically in camphor; Rast, *Ber.*, 1922, **55**, [B], 1051) = 357, 326, 350, 336, 323. $C_{16}H_{16}O_2N_2S_2$ requires C = 57.8; H = 4.82; N = 8.42; S = 19.27 per cent.; *M* = 332].

B. *Oxidation with Hydrogen Peroxide.* A nearly saturated aqueous solution of benzothiazole methiodide (12.5 grams) was mixed with one equivalent of sodium hydroxide (45 c.c. of a *N*-solution) and the mixture was added gradually at room temperature to a 3½ per cent. solution of hydrogen peroxide (60 c.c.). The pasty product precipitated was washed with a little cold alcohol and purified in the manner described above. Yield 4.2–5 grams, 56–67 per cent. of the theoretical quantity.

It was possible to modify the conditions so that a small quantity of 2-methylbenzothiazolone was produced. Benzothiazole methiodide (2.5 grams), dissolved in water (20 c.c.), was run slowly into a well-stirred mixture of 3.5 per cent. hydrogen peroxide solution

(12 c.c.) and 10 per cent. sodium hydroxide solution (10 c.c.). Temperatures of 0–15° were employed without altering the result. The product was extracted with ether and the residue left on evaporation of the ether was distilled in steam. From the distillate, small quantities of 2-methylbenzothiazolone (0.05–0.2 gram) crystallised on standing, melting at 75–76°, alone or mixed with the pure thiazolone.

Synthesis of 2-Methylbenzothiazolone.—*o*-Aminophenyl mercaptan (1.3 grams) was dissolved in toluene (10 c.c.). To the ice-cold solution was added carbonyl chloride (0.455 gram) dissolved in toluene. Aminophenyl mercaptan hydrochloride, which was rapidly precipitated, was filtered off and the toluene was removed from the filtrate by distillation in steam. The product left was taken up in ether, and the dried solution evaporated. The residue, crystallised from light petroleum, gave colourless platelets melting at 76°. 2-Methylbenzothiazolone, prepared by the method of Besthorn (*loc. cit.*), melts at 76°, and the mixture of the two products melted at the same temperature.

C. Oxidation with Iodine. The sodium salt of the “ ψ -base” is oxidised quantitatively by iodine to the disulphide. A solution of 0.2124 gram of the methiodide in water (10 c.c.) was treated with 2 equivalents of 0.1*N*-sodium hydroxide, and the resulting neutral solution titrated with a 0.1*N*-iodine solution. Required 7.50 c.c. Calc. 7.66 c.c.

D. Atmospheric Oxidation. Benzothiazole methiodide (2.5 grams) was dissolved in water and a 10 per cent. ammonia solution (10 c.c.) was added. A slight immediate turbidity was produced. On keeping in the dark, crystals of 2:2'-diformylmethylaminodiphenyl disulphide were gradually formed at the surface of the liquid. After crystallisation from alcohol, these melted at 107°, and at the same temperature after mixture with the pure disulphide.

When sodium hydroxide was used instead of ammonia, formic acid was eliminated and 2:2'-dimethylaminodiphenyl disulphide was produced instead. To an aqueous solution of benzothiazole methiodide (5 grams) a 10 per cent. solution of sodium hydroxide (15 c.c.) was added and the mixture was kept in the dark. Crystals appeared at the surface as before, but they were yellow, and after crystallisation from alcohol melted at 69–71° (Found: C = 61.0; H = 6.0; N = 10.2; S = 23.44. Calc., C = 60.9; H = 5.80; N = 10.15; S = 28.2 per cent.). Dimethylaminodiphenyl disulphide was described by Harries and Lowenstein (*Ber.*, 1894, 27, 867) as melting at 67–68°. A specimen of this substance, prepared by oxidising *o*-methylaminophenyl mercaptan (from the potash fusion of 2-methylthiobenzothiazolone), melted at 69–70.5°

after purification by repeated crystallisation from alcohol and then from light petroleum, and a mixture of this with the above described product melted at the same temperature.

Synthesis of 2:2'-Di-formylmethylaminodiphenyl Disulphide.—Dimethylaminodiphenyl disulphide (0.3 gram) was boiled for four and a half hours with 90 per cent. formic acid (5 c.c.). The mixture was poured into water, when a colourless oil was precipitated. This was taken up in ether, and the ethereal solution washed with dilute sulphuric acid and then with sodium carbonate solution and dried with potassium carbonate. The residue left on evaporation of the ether was taken up in light petroleum, b. p. 60–80°. This solution, on cooling, deposited at first a gummy material, but after removal from this, and rubbing with a glass rod, the formyl derivative separated in crystalline form. After recrystallisation from light petroleum, it was obtained as small platelets melting at 106.5–107.5° and showing no depression of melting point after mixture with the pure disulphide (Found: S = 19.46. Calc., S = 19.28 per cent.).

Reduction of 2:2'-Di-formylmethylaminodiphenyl Disulphide.—The disulphide (2 grams) was dissolved in concentrated hydrochloric acid (10 c.c.), and granulated tin (2 grams) was added gradually. On standing after solution of the tin, a mixture of crystalline double tin salts was deposited. These were dissolved in hot dilute hydrochloric acid and freed from tin with hydrogen sulphide. The solution was evaporated and the perfectly dry residue, crystallised from ether-alcohol, yielded pure benzothiazole methochloride, m. p. 190° (Found: C = 51.5; H = 4.4; Cl = 18.96. Calc., C = 51.7; H = 4.3; Cl = 19.13 per cent.). To establish conclusively the identity of this reduction product with benzothiazole methochloride, a series of benzothiazole methyl salts was prepared from it and compared with those obtained directly from benzothiazole.

Picrate. Bright yellow, flat needles, m. p. 155–157°, not depressed by addition of pure benzothiazole methopicate prepared from picric acid and the methiodide (Found: N = 14.8. $C_{14}H_{10}O_7N_4S$ requires N = 14.8 per cent.).

Stannochloride. Colourless needles, m. p. 145–147°, not depressed by addition of the stannochloride prepared from pure benzothiazole methochloride (Found: Cl = 28.1; Sn = 31.48. $C_8H_8NSCl, SnCl_2$ requires Cl = 28.4; Sn = 31.68 per cent.).

Zincichloride. Colourless prisms, m. p. 258.5–260°, not depressed by addition of the pure salt from benzothiazole methochloride [Found: Cl = 28.16; S = 12.83. $(C_8H_8NCIS)_2, ZnCl_2$ requires Cl = 28.0; S = 12.62 per cent.].

2-Methylbenzothiazoline, $C_8H_4\langle\begin{smallmatrix} S \\ NMe \end{smallmatrix}\rangle CH_2$.—Benzothiazole methiodide (14 grams) was dissolved in concentrated hydrochloric acid (100 c.c.), and zinc (30 grams) added gradually to the hot solution. After the zinc had dissolved, excess of ammonia was added to the cold solution and the base was extracted with ether. The dried ethereal residue was distilled under diminished pressure. 2-Methylbenzothiazoline was thus obtained as a colourless oil of characteristic sweet odour, b. p. 163–165°/50 mm. (Found: C = 63·8, 63·7; H = 6·2, 6·1. C_8H_5NS requires C = 63·6; H = 6·0 per cent.).

Methylbenzothiazoline is oxidised by iodine to benzothiazole methiodide. The base (1 gram) and anhydrous sodium acetate (0·5 gram) were dissolved in absolute alcohol (20 c.c.). Iodine (1·68 grams) was added in small portions to the hot solution. After the solution had been decolorised with sulphur dioxide, the alcohol was evaporated and the residue crystallised from water. From the benzothiazole methiodide thus obtained the pure picrate was precipitated with picric acid. It melted at 155–156·5° and at the same temperature after mixture with pure benzothiazole methopicate (Found: N = 14·8. Calc., N = 14·8 per cent.).

Condensation with Nitrosodimethylaniline.—2-Methylbenzothiazoline (1·7 grams) was heated with nitrosodimethylaniline (1·7 grams) and four drops of glacial acetic acid for five hours at 100°. The product crystallised after standing for several days. It was washed with ether and crystallised from alcohol. Colourless needles, m. p. 127° (Found: C = 67·8; H = 6·02; N = 14·5. $C_{16}H_{17}N_3S$ requires C = 67·85; H = 6·0; N = 14·11 per cent.).

Oxidation of the Ethyl ψ -Base. 2:2'-Diformylethylaminodiphenyl Disulphide.—A solution of benzothiazole ethiodide (70 grams) in water (700 c.c.) was added gradually to a well-stirred solution of potassium ferricyanide (340 grams) in a 5 per cent. solution of sodium hydroxide (2700 c.c.), kept at 0°. The pasty product, crystallised from alcohol, gave the pure disulphide as colourless needles, m. p. 114–115° (Found: C = 59·8, 60·5; H = 5·7, 5·6. $C_{18}H_{20}O_2N_2S_2$ requires C = 60·0; H = 5·6 per cent.).

The disulphide is also formed when a solution of benzothiazole ethiodide in excess of sodium hydroxide is exposed to atmospheric oxidation, no elimination of the formyl groups being brought about as occurs when the methiodide is treated in the same way. Benzothiazole ethiodide (9·3 grams) was dissolved in water, a 10 per cent. solution of sodium hydroxide (15 c.c.) added, and the mixture kept in the dark for three weeks. A colourless, crystalline deposit formed at the surface of the liquid. Recrystallised from alcohol, this melted at 114–115° and at the same temperature

after mixture with pure 2:2'-diformylethylaminodiphenyl disulphide (Found: N = 7.58. Calc., N = 7.66 per cent.).

Reduction of 2:2'-Diformylethylaminodiphenyl Disulphide.—The disulphide (5 grams) was dissolved in concentrated hydrochloric acid (20 c.c.), and tin (4 grams) added gradually to the hot solution. On cooling, an abundant crystallisation of tin salts took place. These were collected, dissolved in dilute hydrochloric acid, and freed from tin with hydrogen sulphide. The filtrate from the tin sulphide was evaporated and this residue crystallised from ether-alcohol. Pure benzothiazole ethochloride was thus obtained, m. p. 216° (Found: Cl = 18.0; S = 16.25. Calc., Cl = 17.8; S = 16.07 per cent.).

One of us (L. M. C.) desires to express his indebtedness to the Department of Scientific and Industrial Research for a grant which enabled him to take part in this work.

[Received, July 31st, 1923.]

CCLXVII.—*Studies in the Benzothiazole Series. Part II.* *Thio-2-methylbenzothiazolone and its Oxidation Products.*

By WILLIAM HOBSON MILLS, LESLIE MARSHALL CLARK, and JOHN ALFRED AESCHLIMANN.

IN preparing benzothiazole for use in various investigations, the method described by Möhlau and Krohn (*Ber.*, 1888, 21, 59) of heating dimethylaniline with sulphur was employed. Our attention thus became directed to a crystalline by-product of the composition $C_8H_7NS_2$ which is produced in this reaction in very considerable quantity and is of interest since it forms an intermediate stage in the production of benzothiazole, for it was shown by Möhlau and Krohn to give benzothiazole when further heated with sulphur.

Möhlau and Krohn assigned to it the constitution I, and this formulation was retained, after further discussion, by Möhlau and Klopfer (*Ber.*, 1898, 31, 3164). The substance was again investigated by Rassow, Döhle, and Reim (*J. pr. Chem.*, 1916, [ii], 93, 183). They also regarded their results as harmonising with Möhlau's formula, and they named the substance benzothiazolmethensulfid.

In view, however, of the properties of the compound and of the manner in which it is formed such a constitution is manifestly improbable. It seemed to us that the substance was much more likely to be thio-2-methylbenzothiazolone (II).

This view of its constitution proved to be correct, for we find that it can be synthesised in a simple manner which leaves no doubt as to its structure. It is formed by the interaction of *o*-methylaminophenyl mercaptan and thiocarbonyl chloride. The formation of a substance of the formula $C_6H_7NS_2$ from these reagents can only take place as follows :

This proof of the constitution is confirmed by another method of formation. The compound is obtained when 1-nitrosoimino-2-methylbenzothiazoline (which, heated in an indifferent solvent, gives nitrogen and the thiazolone) is heated with phosphorus pentasulphide :

It is also formed by the action of phosphorus pentasulphide on 2:2'-diformylmethylaminodiphenyl disulphide.

The reactions of the substance further confirm this view of its constitution. When the more mobile of the two sulphur atoms which it contains is replaced by oxygen, as can be done, either by heating the alcoholic solution with mercuric oxide, or by treating the substance with bromine water (compare Rassow and Reim, *J. pr. Chem.*, 1916, [ii], **93**, 232), 2-methylbenzothiazolone results :

Now that the constitution of this product is known the action of sulphur on dimethylaniline can be very simply represented. Writing dimethylaniline in the form III, it is seen that the formation of the thiothiazolone consists in the replacement of each of the two pairs

of hydrogen atoms shown in clarendon type by an atom of sulphur.

This formula also enables the oxidation of the substance, which was studied by Möhlau and Rassow and their pupils, to be simply interpreted. Möhlau and Krohn (*loc. cit.*) found that the thiothiazolone was easily oxidised by nitric acid. One atom of sulphur

was removed as sulphuric acid and the nitrate of a base was formed. They were unable to obtain the base from this nitrate, but they prepared and analysed the chloroplatinate and found that their analytical results were in agreement with those which would be required by the chloroplatinate of a base of the formula IV. They accordingly assigned this formula to the base, naming it *iso-μ*-methylbenzothiazole. Möhlau and Klopfer (*loc. cit.*) re-examined the salts obtained by oxidation of the thiothiazolone. By treating the sulphate in alcoholic solution with the equivalent quantity of potassium hydroxide, they succeeded in isolating a very small quantity of a base melting at 202° and giving analytical results in accordance with formula IV. This base, *iso-μ*-methylbenzothiazole, was also prepared by Rassow, Döhle, and Reim (*loc. cit.*) who succeeded in obtaining it in considerable quantity.

We had concluded from the difficulty which Möhlau and his pupils had experienced in isolating a base corresponding with the salts which they had obtained that these must be derived from a quaternary base and that the base which they actually isolated was only a subsidiary product. Investigation showed that this conclusion was correct.

The product obtained by oxidising the thiothiazolone with dilute nitric acid consists, at any rate to a very large extent, of the methonitrate of benzothiazole (VI) mixed with a smaller quantity of the corresponding bisulphate. The chloroplatinate which this product gives is identical with benzothiazole methochloroplatinate,

perchlorate precipitated from the aqueous solution of the product are the methopicrate and the methoperchlorate of benzothiazole. The oxidation of the thiothiazolone can be carried out even more smoothly with hydrogen peroxide. The product is then pure benzothiazole methyl hydrogen sulphate.

The product obtained by Rassow, Döhle, and Reim was probably a mixture, for, when treated with ammonia, it deposited an oil from which *iso-μ*-methylbenzothiazole could be isolated. The greater part, however, consisted of methylbenzothiazolium salts, for they state that it dissolved in ammonia and the solution on keeping slowly deposited 2:2'-diformylmethylaminodiphenyl disulphide. It was thus that Rassow, Döhle, and Reim discovered this compound. Evidently the ammonia con-

verted the quaternary salts into the ammonium salt of the thio-phenolic ψ -base, as we have shown in the preceding paper, and this was then gradually oxidised to the disulphide by atmospheric oxygen.

The way in which the thiothiazolone on oxidation yields benzothiazole methyl salts and sulphuric acid can be readily explained. The thiothiazolone has distinct, although very weak, basic properties; it forms a chloroplatinate (Möhlau and Klopfer, *loc. cit.*), a methiodide, and an ethiodide (Rassow, Döhle, and Reim, *loc. cit.*).

On treatment with nitric acid, it must therefore form a salt which, from analogy with the evident constitution of the alkiodides, will have the formula V.

The action of nitric acid accordingly consists in the replacement of the thiol group in this salt by hydrogen.

The thiol group in the complex VII thus shows the same behaviour when oxidised with nitric acid as is characteristic of this group when present in the somewhat similar complex VIII.

The property of a thiol group, in the latter complex, of being eliminated by oxidation with dilute nitric acid was discovered by Wohl and Marckwald (*Ber.*, 1889, **22**, 575), who found that phenyliminazolyl mercaptan could be converted in this manner into phenyliminazole, and it has since been not infrequently employed for eliminating this group from heterocyclic compounds (*Ber.*, 1889, **22**, 1359; 1892, **25**, 2361; 1893, **26**, 2204; *Annalen*, 1904, **331**, 68).

The discovery of the true nature of "benzothiazolmethen-sulphid" and its oxidation products removes most of the difficulties which Rassow, Döhle, and Reim, and also Rassow and Reim, found in interpreting the behaviour of the sulphonic acids derived from these compounds and of the corresponding derivatives of toluethiazole.

We have also obtained further information respecting *iso*- μ -methylbenzothiazole. We have been able to identify it with a base melting at 204° which we have obtained in various ways from compounds containing the grouping $\text{S}\cdot\text{C}_6\text{H}_4\cdot\text{NMe}^{(1)}$. This base has the formula $\text{C}_{15}\text{H}_{14}\text{N}_2\text{S}_2$. Its composition thus differs somewhat from that assigned by Möhlau and Rassow and their pupils to *iso*-

μ -methylbenzothiazole (C_8H_7NS). It is most easily prepared by heating 2:2'-diformylmethylaminodiphenyl disulphide with phenylhydrazine. This reaction involves the elimination of one of the two formyl groups from the disulphide, for the phenylhydrazine is converted into its formyl derivative. Since, in addition to the two residues $\cdot NMe \cdot C_6H_4 \cdot S \cdot$, the molecule of the base contains only a single carbon atom, it can scarcely have any other constitution than that represented by the formula IX.

We have been able to confirm this constitution by synthesizing the compound from 1-nitrosoimino-2-methylbenzothiazoline (Besthorn, *Ber.*, 1910, 43, 1523) and *o*-aminophenyl mercaptan, condensation taking place very readily when the two substances are heated together:

The product is probably a racemic form, since a spirocyclic compound of this structure should exist in two enantiomorphous modifications (compare Mills and Nodder, *T.*, 1921, 119, 2094).

The corresponding diethyl derivative (X) has been prepared in a similar manner by heating the diethyl disulphide with phenylhydrazine.

EXPERIMENTAL.

Synthesis of Thio-2-methylbenzothiazolone from o-Methylaminophenyl Mercaptan and Thiocarbonyl Chloride.—*o*-Methylaminophenyl mercaptan (Harries and Löwenstein, *Ber.*, 1894, 27, 861) (1.95 grams) was dissolved in chloroform (10 c.c.) and treated with a solution of thiocarbonyl chloride (0.6 c.c.) in chloroform (5 c.c.) at 0°. The mixture, after standing for sixteen hours, was warmed for one hour and then washed with dilute hydrochloric acid. After being shaken with warm sodium hydroxide solution to destroy unchanged thiocarbonyl chloride, the solution was dried, and the crystalline residue left after evaporation of the solvent recrystallised several times from alcohol. It was thus obtained in colourless needles, m.p. 90°. The "benzothiazolmethensulfid" of Möhlau and Krohn was described as melting at 89°, but by recrystallisation the melting point can be raised to 90°, and a mixture of the purified substance with the synthesised thiothiazolone melted also at this temperature.

Thio-2-methylbenzothiazolone from 1-Nitrosoimino-2-methylbenzothiazoline.—The nitroso-compound (10 grams) was mixed with phosphorus pentasulphide (10 grams) and heated at 110–120°, when a vigorous reaction began and was completed in a few moments. The product was extracted with benzene and the solution digested with copper powder. After removal of the benzene and crystallisation from alcohol, pure thio-2-methylbenzothiazolone was obtained melting at 90° (Found: S = 35.1, 35.33. $C_8H_7NS_2$ requires S = 35.36 per cent.).

Thio-2-methylbenzothiazolone from 2:2'-Di-formylmethylamino-diphenyl Disulphide.—A mixture of the disulphide (1 gram) with phosphorus pentasulphide (1 gram) was heated at 100°. When fusion began, a vigorous reaction started and was completed by heating for several minutes. The product was extracted with benzene and purified as before. The melting point and the "mixed melting point" with purified "benzothiazolmethensulfid" were 90° (Found: C = 52.5; H = 3.96; N = 7.72; S = 35.4, 35.36. $C_8H_7NS_2$ requires C = 53.04; H = 3.87; N = 7.9; S = 35.36 per cent.).

Conversion of Thio-2-methylbenzothiazolone into 2-Methylbenzothiazolone.—(a) *By Mercuric Oxide.* The thiothiazolone (10 grams), dissolved in boiling absolute alcohol (200 c.c.), was digested with freshly precipitated mercuric oxide for four hours. The solution was concentrated and unchanged thiothiazolone allowed to crystallise. The filtrate was evaporated and the residue distilled in steam. A small quantity of 2-methylbenzothiazolone crystallised from the distillate. Recrystallised from light petroleum, it melted at 76°, and the mixture with pure 2-methylbenzothiazolone (Besthorn, *loc. cit.*) melted at the same temperature (Found: S = 19.7. Calc., S = 19.4 per cent.).

(b) *By Bromine Water.* Finely powdered 2-methylbenzothiothiazolone (5 grams) was shaken with bromine water, addition of bromine being continued until it persisted after standing for half an hour. The slightly red solid thus formed was freed from excess of bromine with sulphur dioxide and then treated with hydrochloric acid (*d* 1.18), which dissolved the thiazolone and left the thiothiazolone. The solution was precipitated by dilution with water and the product crystallised from aqueous alcohol and then from light petroleum. It melted at 75° and after mixture with pure 2-methylbenzothiazolone (m. p. 76°) at 75–76° (Found: C = 58.2; H = 4.2. Calc., C = 57.9; H = 4.2 per cent.).

Oxidation of Thio-2-methylbenzothiazolone.—The thiothiazolone (10 grams) was added gradually to a mechanically stirred mixture of nitric acid (*d* 1.4; 20 c.c.) and water (10 c.c.), the temperature

being kept below 12°. Crystals separated towards the end of the reaction and after keeping at 0° for two hours the mixture became semi-solid. The solid collected, washed with ether-alcohol, and dried, weighed 12.1 grams. It was found to be a mixture of benzothiazole methonitrate with a little benzothiazole methobisulphate. This was established by the preparation from it of a number of characteristic methylbenzothiazolonium salts.

Picrate.—Precipitated by a saturated aqueous solution of picric acid. M. p. 155–157°. Mixed m. p. with pure benzothiazole methopicrate 155–157°.

Chloride.—The picrate was decomposed with hydrochloric acid and the picric acid removed by extraction with amyl alcohol and then with ether. The aqueous solution was evaporated and the dried residue crystallised from ether-alcohol (Found: Cl = 19.14. Calc., Cl = 19.13 per cent.).

Chloroplatinate.—Prepared from the chloride. M. p. 257° (Found: Pt = 27.39. $C_{16}H_{16}N_2S_2 \cdot PtCl_6$ requires Pt = 27.54 per cent.) (Compare Möhlau and Klopfer, *loc. cit.*).

Iodide.—Prepared by precipitation from the chloride by addition of potassium iodide. M. p. 209°. A mixture with pure benzothiazole methiodide (m. p. 210°) melted 209–210° (Found: I = 46.0. Calc., I = 45.85 per cent.).

The oxidation product was recrystallised from ether-alcohol and analysed. The results were in accordance with those which would be required for a mixture of 96.4 per cent. of benzothiazole methonitrate and 3.6 per cent. of benzothiazole metho-hydrogen sulphate (Found: $NO_3 = 28.5$; $SO_4 = 1.44$. Calc., $NO_3 = 28.2$; $SO_4 = 1.40$ per cent.). These analyses were confirmed by titrating the substance with sodium hydroxide and phenolphthalein, and then with iodine, when the behaviour characteristic of the alkyl benzothiazolonium salts (see preceding communication) was observed (Found: 0.2236 required 21.5 c.c. of 0.1N-sodium hydroxide solution and 10.25 c.c. of 0.1N-iodine solution. Calc., 21.3 c.c. of sodium hydroxide and 10.5 c.c. of iodine solution).

Oxidation of Thio-2-methylbenzothiazolone with Hydrogen Peroxide.—The thiothiazolone (4 grams) was dissolved in acetone and to the warm solution 28 per cent. hydrogen peroxide (2.8 c.c.) was added. A colourless oil separated which was removed after twenty-four hours. This was dissolved in alcohol, and the solution, on standing, deposited benzothiazole metho-hydrogen sulphate in colourless needles, m. p. 167–168°. Yield 1 gram (Found: C = 38.9; H = 3.7; N = 5.74; S = 26.2. $C_8H_8NS \cdot HSO_4$ requires C = 38.9; H = 3.6; N = 5.66; S = 25.9 per cent. 0.2272 required 5.60 c.c. of 0.5N-sodium hydroxide. Calc., 5.62

c.c.). There was recovered from the acetone solution 1.5 grams of unchanged thiothiazolone.

Bis-2-ethylbenzothiazoline-1:1-spiran.—2:2'-Diformylethylamino-diphenyl disulphide (10 grams) and phenylhydrazine (6 grams) were heated together at 100° for ten hours, when ammonia was evolved. The residue, which solidified on standing, was distilled with steam to remove unchanged phenylhydrazine. From the aqueous layer in the distillation flask colourless crystals, m. p. 144°, separated on cooling. These were shown to be formylphenylhydrazine (Found: N = 20.3. Calc., N = 20.6 per cent.). The melting point of a mixture of this substance with pure formylphenylhydrazine, prepared as described by Just (*Ber.*, 1886, 19, 201), was 144° and the characters of the two substances were identical.

The oily residue from the steam distillation crystallised from alcohol in colourless plates, m. p. 136° (Found: C = 64.66, 64.99; H = 5.81, 5.89; N = 9.19. $C_{17}H_{18}N_2S_2$ requires C = 64.97; H = 5.73; N = 8.92 per cent.). The substance is insoluble in water, but dissolves readily in dilute hydrochloric acid.

Bis-2-methylbenzothiazoline-1:1-spiran.—2:2'-Diformylmethylaminodiphenyl disulphide (10 grams) and phenylhydrazine (7 grams) were heated together at 100° for six hours. Ammonia was evolved and after two hours the melt had become solid. The product was extracted with boiling water, which removed formylphenylhydrazine (identified by the m. p. and mixed m. p. [144°] as already described). The residue was crystallised from alcohol and thus obtained as colourless, iridescent platelets, m. p. 204° (Found: C = 63.1; H = 4.99; N = 9.85. $C_{15}H_{14}N_2S_2$ requires C = 62.9; H = 4.89; N = 9.79 per cent.).

Methiodide. The spiran (1 gram) was heated with methyl iodide (2.1 grams) in a sealed tube for twenty-four hours at 60°. The solid product, crystallised from alcohol, gave the pure mono-methiodide as clusters of fine needles, m. p. 186° (Found: I = 29.50, 29.58. $C_{16}H_{17}N_2S_2I$ requires I = 29.7 per cent.).

Methocamphorsulphonate. Prepared in the usual way from the methiodide and silver camphorsulphonate and crystallised from ethyl acetate, this salt formed colourless needles, m. p. 147–148° (Found: C = 59.0; H = 6.12; S = 17.7. $C_{26}H_{32}O_4N_2S_3$ requires C = 58.55; H = 6.20; S = 18.0 per cent.).

Methobromocamphorsulphonate. Similarly prepared and crystallised from ethyl acetate, it formed colourless platelets, m. p. 164–165° (Found: Br = 13.21; S = 16.08. $C_{26}H_{31}O_4N_2S_3Br$ requires Br = 13.10; S = 15.71 per cent.).

Synthesis of Bis-2-methylbenzothiazoline-1:1-spiran.—o-Methylaminophenyl mercaptan (1.9 grams) was heated at 100° in hydrogen

and 1-nitrosoimino-2-methylbenzothiazoline (2.51 grams) was added in small quantities, each addition being followed by a very vigorous reaction. The heating was continued for three hours, the mixture gradually solidifying. The product, crystallised from alcohol, gave 1.54 grams of the spiran, m. p. 203.5–204°. A mixture with the spiran prepared from the disulphide and phenylhydrazine melted at the same temperature (Found: C = 63.4; H = 4.93; N = 9.74. Calc., C = 62.9; H = 4.89; N = 9.79 per cent.).

Identity of Bis-2-methylbenzothiazoline-1:1-spiran with iso- μ -Methylbenzothiazole.—In carrying out the oxidation of thio-2-methylbenzothiazolone with nitric acid as described by Rassow, Döhle, and Reim (*loc. cit.*), we always got good yields of benzothiazole metho-nitrate and -bisulphate, but only once obtained "iso- μ -methylbenzothiazol," and then only in small quantity, when the crude salt was treated with ammonia.

The iso- μ -methylbenzothiazole melted at 202–204° (the German investigators give the m. p. as 202°) and a mixture with the spiran synthesised from o-methylaminophenyl mercaptan and nitrosoimino-methylbenzothiazoline melted at the same temperature.

One of us (L. M. C.) wishes to express his indebtedness to the Department of Scientific and Industrial Research for a grant which enabled him to take part in this work.

CCLXVIII.—*The Kinetics of the Reaction between Ferrous Phosphate and Sulphur Dioxide in Phosphoric Acid Solution.*

By SYDNEY RAYMOND CARTER and JOHN ALFRED VALENTINE BUTLER.

THE oxidation of ferrous phosphate in phosphoric acid solution by sulphur dioxide (Wardlaw, Carter, and Clews, T., 1920, 117, 1241), a reaction which may be expressed by the equation

shows several unusual features. Starting with pure ferrous phosphate, the reaction appeared to attain equilibrium after two or three days at a ferric content of about 40 per cent., and the authors expressed an opinion that it is reversible. However, the reverse

reaction, the reduction of ferric phosphate by sulphur could not be realised, and it was found that synthetic mixtures of ferrous and ferric phosphates behaved differently from mixtures formed in the course of the reaction, as the former were still oxidised to some extent by sulphur dioxide even when the proportion of ferric iron was about 80 per cent.

It seemed likely that a study of the kinetics of the reaction might give an explanation of these features and also throw some light on the mechanism of the oxidising action of sulphur dioxide. The reaction is the most suitable of the series for experiments of this nature owing to the non-volatility of phosphoric acid and the absence of side reactions which occur in other cases (T., 1920, 117, 1093; 1922, 121, 210).

Only a few instances are recorded in which the rate of reaction between a gas and a liquid has been measured. In such cases the rate of reaction is determined by two factors; the rate of absorption of gas and the rate of reaction between the dissolved gas and the solution. In order to obtain a measure of the rate of chemical action it is essential that the rate of absorption should be great compared with the rate of reaction in the liquid, otherwise the observed rate is merely a measure of the former. In the experiments to be described, an atmosphere of sulphur dioxide was maintained above the solution of ferrous phosphate in phosphoric acid and the rapid absorption of the gas was ensured by the use of a Luther stirrer (Luther and Plotnikow, *Z. physikal. Chem.*, 1907, 61, 513) which kept up a continual circulation of gas through the solution. Since the reaction was comparatively slow, the liquid was thus kept saturated with gas, except perhaps in the first few minutes after the start of the reaction, and the rate of reaction measured was that at constant concentration of sulphur dioxide. Since both phosphoric acid and water were present in large excess, the only concentrations that varied during the experiments were those of ferric and ferrous iron.

EXPERIMENTAL.

Description of Apparatus.—As the result of preliminary experiments the following apparatus was employed (Fig. 1).

The reaction flask, *A*, was a wide-necked flask of 500 c.c. capacity, fitted with a rubber bung through which passed the glass bearing of the Luther stirrer, *K*, and the tubes communicating with the other parts of the apparatus. The entrance of air was prevented by means of a mercury seal, *L*, and this was sufficiently deep to permit moderate variations of pressure. The flask was immersed in an oil-bath heated by a gas flame and kept within 0.2° by a

mercury thermoregulator. The temperatures given are in every case the temperatures of the oil-bath.

The sulphur dioxide was confined over mercury in the bulb, *B*, and admitted to the flask as fast as it was absorbed, the connecting tube, *C*, being fitted with a water condenser to prevent distillation of the acid into the bulb. The bulb could be refilled with gas by means of the three-way tap, and a tube dipping under mercury was introduced at *D* to prevent the accidental development of a high pressure of gas in the tubes.

The sampling apparatus consisted of a syphon tube passing from the bottom of the reaction flask into the upper end of the burette, *E*, which was provided with a side tube communicating with the

FIG. 1.

mercury bulbs, *F*, and a tube with tap, *G*, connecting the sampling apparatus with the gas space above the solution. In order to withdraw a sample the tap, *G*, is closed, the pressure in the burette reduced by lowering the mercury level in the bulbs, and the solution drawn over into the burette. The mercury level is now raised and on opening the tap, *G*, the solution in the syphon tube flows back into the reaction flask. The solution in the burette can now be run into a flask for analysis. This arrangement proved to be very convenient and should be useful in other cases in which it is necessary to withdraw samples of a liquid without admitting air and without removing any part of it permanently from the region in which the main bulk of liquid is undergoing reaction.

All rubber connexions in the apparatus were made with stout pressure tubing, and firmly wired.

Preparation of the Solution.—Solutions of ferrous phosphate in

phosphoric acid were prepared by dissolving iron in the warm acid in an oxygen-free atmosphere. The best iron wire available contained a small amount of carbon, and since its presence was not desirable, the solutions were filtered before introduction into the reaction flask. This operation, which had, of course, to be carried out in absence of air, was accomplished by forcing the solution under pressure of carbon dioxide from the flask in which it was prepared into a second flask by way of an asbestos filter, and thence at the proper time into the reaction flask through the tube, *H*. The filter itself was provided with a by-pass so that a stream of carbon dioxide could be passed through the apparatus in order to remove the air.

Method of Carrying out Experiments.—A stream of carbon dioxide is passed through every part of the apparatus for about two hours in order to displace the air, and by proper manipulation all dead spaces are cleared out.

The tap, *H*, communicating with the flasks in which the solution is prepared is now closed and the carbon dioxide in the reaction flask replaced by passing through it a stream of sulphur dioxide. Meanwhile the iron is dissolved in phosphoric acid in a stream of carbon dioxide and the solution filtered. Its temperature is now adjusted to that of the oil-thermostat and it is forced by pressure of carbon dioxide into the reaction flask as rapidly as possible, the displaced gas escaping through the mercury at *D*. A sample is immediately withdrawn for analysis and the stirrer started. The speed of the stirrer was usually about 1200 r. p. m., but no special precautions were taken to keep it constant. The initial time for the experiment was counted from the time of starting the stirrer.

In the early stages of the experiment absorption of sulphur dioxide is rapid and a continuous stream of sulphur dioxide is maintained, excess escaping by *D*. After this initial stage, absorption is slow and the gas is fed in from the bulb, *B*, which is refilled as occasion requires from the syphon by means of the three-way tap. The pressure inside the apparatus is adjusted to 1 cm. of mercury above atmospheric pressure so that any slight leak will be outwards. Samples of the solution are withdrawn at suitable intervals and analysed.

Method of Analysis.—In order to avoid the necessity of measuring definite quantities of hot solution for analysis, the ratio of ferric to total iron in a sample is determined and consequently the amount of liquid withdrawn is immaterial.

The liquid from the sampling burette is received in a conical flask containing 80 c.c. of a 20 per cent. solution of sulphuric acid, the air having been expelled by boiling in a current of carbon

dioxide. A stream of carbon dioxide is maintained through all solutions for analysis containing ferrous iron in order to prevent oxidation by contact with air. In most cases, about 15 c.c. of the solution in the flask were taken for an analysis. After the solution has been boiled in a current of carbon dioxide for about ten minutes in order to remove the sulphur dioxide, the flask is cooled in water, and the amounts of ferric and total iron in two equal portions of the solution are determined by means of titanous chloride by Knecht and Hibbert's methods. Two portions of 25 c.c. of the solution are taken, the first of which gives the ferric iron by direct titration with titanous chloride solution, potassium thiocyanate being used as indicator. The total iron is determined in the second portion by oxidation to the ferric state in one of two ways, either of which gives accurate results.

1. About 1 gram of sodium peroxide is added and the solution is boiled for fifteen minutes in order to remove excess of hydrogen peroxide.

2. The liquid is diluted with an equal quantity of water and the iron oxidised by adding dilute potassium permanganate solution until a faint pink tinge remains. The oxidation is not satisfactory unless the solution is previously diluted, apparently on account of spontaneous decomposition of the permanganate in the concentrated acid.

The ferric iron in the oxidised portion is estimated as before and the ratio of the two titres gives the percentage oxidation.

At the concentration of acids chosen, sulphur dioxide gives rise to no appreciable oxidation or reduction before being expelled; moreover, a sharp end-point is obtained with thiocyanate as indicator which is not the case in pure phosphoric acid.

Blank Experiments.—In order to show that the possibility of oxidation by air had been eliminated, experiments were carried out using carbon dioxide alone, the temperature being 98°.

Experimental Data.—In the experiments carried out, the only factor which varied was the initial concentration of iron. The temperature of the thermostat in every case was 98° and the phos-

phoric acid employed was a syrupy liquid (d 1.75) containing 89 per cent. of H_3PO_4 . In the earlier experiments samples were taken at intervals of about thirty minutes. The following may be given as examples :

FIG. 2.

It is obvious that the greater part of the action observed occurs in the earlier stages. Later efforts were therefore directed towards following the course of the reaction more closely in its earlier stages, and for this purpose a number of flasks for the reception of samples were prepared before the experiment. The samples were taken at intervals of from ten to twenty minutes and, after the sulphur dioxide had been boiled off, were protected from air by bubbling carbon dioxide through them until analysis was possible.

Some curves, typical of those obtained, are shown in Fig. 2. The total concentrations of iron for the curves shown are 7.22 grams (Curve I), 5.10 grams (Curve II), and 2.88 grams (Curve III) of iron in 450 c.c. of phosphoric acid.

Effect of Initial Oxidation.—The percentage of ferric iron in the initial sample varied from 1 to 3 per cent. The greater part of this

can be ascribed to oxidation happening during the time occupied in running the solution into the atmosphere of sulphur dioxide; slight oxidation also occurred in some cases, due to air contained in the filter and its packings. However, the effect of small percentages of initial oxidation on the shape of the curve is small.

An experiment was carried out with a mixture containing initially 38 per cent. of ferric iron (Fig. 3), the total iron content being 5.62 grams per litre. The curve illustrates the distinction between synthetic mixtures of ferrous and ferric iron and those of the same composition as regards the iron, formed in the course of the reaction. Judging from the other experiments, the oxidation of a solution, initially of ferrous phosphate alone, would proceed extremely slowly at 38 per cent. oxidation, yet the synthetic mixture of this composition is oxidised initially at a rate nearly as great as the initial rate with pure ferrous phosphate solutions, although,

FIG. 3.

as might be expected, the initial rate slows down in the former case much more rapidly.

Discussion of Curves.—In the first place, the concentration of iron has little effect on the percentage rate of oxidation or on the shape of the curves. The chief characteristic of the reaction is the initial stage of rapid action quickly passing into a stage in which the action continues at a slower, almost uniform rate, which is moreover practically the same (reckoning in percentages) with widely differing concentrations of iron.

The rapid slowing down of the reaction is not in accordance with the behaviour of a simple single reaction even of, say, the fourth order, nor do the curves exhibit the characteristics of an ordinary reversible reaction. In the time during which the reaction was followed, the curve does not appear to be approaching an equilibrium state asymptotically; and, as was shown by Wardlaw, Carter, and Clews (*loc. cit.*), the reaction will proceed to more than 40 per cent. oxidation and some oxidation occurs even with mixtures containing initially more than 70 per cent. of ferric iron.

The form of the curves and the peculiarities of the reaction seem to be explicable if it be assumed that the primary reaction is reversible, but that one of the products is unstable under the conditions of the experiment and decomposes, giving rise to other products which have no influence on the course of the reaction. Thus instead of reaching a state of equilibrium as the early parts of the curves suggest, the reaction will continue owing to the disappearance of the substance that causes the reverse reaction and the second, comparatively slow and uniform stage will be reached in which the reaction proceeds at a rate dependent on the velocity of decomposition of the reducing substance.

In the former communication it was suggested that the characteristics of the reaction are due to the interaction of sulphur with the ferric phosphate produced at the moment of its formation, and before being taken up in the form of a complex. It now seems more probable that the active reducing agent is a reduction product of sulphur dioxide which has the power of reducing ferric phosphate.

If we designate the intermediate reduction product by X , this hypothesis may be expressed in the form of equations,

The kinetic development of these equations leads to the following differential equations for the rate of reaction under the experimental conditions,

$$\begin{aligned} dx/dt &= k_1(a-x)^m - k_2x^ny^p \\ dy/dt &= dx/dt - k_3y^q, \end{aligned}$$

where a = initial concentration of ferrous phosphate, x = concentration of ferric phosphate at time t , y = concentration of active substance at time t , m , n , and p are integers representing the orders, and k_1 , k_2 the velocity coefficients of the direct and reverse reactions; q and k_3 are analogous coefficients for the decomposition of the active substance.

Unfortunately, it has not been found possible to obtain a solution for equations of this type. However, taking a special case, which is probably not very different from the actual one, namely,

$$\begin{aligned} dx/dt &= k_1(a-x)^2 - k_2x^2y \\ dy/dt &= dx/dt - k_3y, \end{aligned}$$

and assigning the constants the arbitrary values $a = 100$, $k_2 = 2 \times 10^{-3}$, $k_1 = 2 \times 10^{-3}$, and $k_3 = 2 \times 10^{-3}$, a curve has been obtained giving the relation between x and t by an approximate method of calculation (Fig. 4).

This curve shows a very close resemblance to the experimental curves and, although this may be due to some extent to a fortunate choice of constants, the conclusion may be drawn that the hypothesis put forward is capable of accounting for the form of the curves.

The assumption of the formation of an active intermediate compound also gives a simple explanation of the difference in the behaviour of synthetic mixtures of ferrous and ferric salts and those formed in the course of the reaction. The former contain initially none of the active substance and the reaction proceeds rapidly until the reverse reaction is brought into play by the formation of the active product.

The Limit of Oxidation.—It became of interest to examine the upper limit of oxidation in the light of the hypothesis advanced in

FIG. 4.

this paper, and with this object experiments were arranged in which the course of the reaction could be followed for a considerable period of time. The apparatus was designed to preclude the accidental entrance of air when operated over long periods and the method of analysis by means of titanous chloride was capable of considerable accuracy in detecting small changes in the ferric iron content.

Several experiments were carried out at 98° and the following is a typical result:

TABLE V.

3 Grams of iron in 500 c.c. of phosphoric acid (89 per cent.).					
Time in days	0.25	1.0	3.0	5.0	10.0
Ferric, per cent. ...	12.1	24.1	36.2	40.7	45.8

These results represent the second or what has been called the uniform stage of the reaction in distinction from the rapid changes of rate in the first fifteen minutes.

In the course of a few hours the rate assumes a fairly constant

value, but over a period of several days it undergoes a gradual diminution. Probably a very long period would be necessary before a point would be reached at which no further oxidation could be observed.

This is a somewhat different conclusion from that drawn from earlier experiments (T., 1920, 117, 1243), in which it was supposed that equilibrium was attained within two or three days. The rate of reaction at this stage is so slow that the change in a few hours is scarcely appreciable.

The improved apparatus and the more accurate method of analysis now used indicate clearly the existence of a slow drift in what was previously thought to be a true equilibrium. This was not due to a small accidental leakage of air, for in one experiment the apparatus was allowed to cool down after the reaction had been in progress for three days, the flask remained cold for thirteen days, and at the end of this period the contents were analysed; the percentage oxidation was found to be slightly less than on the third day—a circumstance which was probably due to the continued action of the reducing product in the cold.

According to the present hypothesis, the reversible reaction $\text{Fe}^{++} + \text{SO}_2 \rightleftharpoons \text{Fe}^{+++} + \text{X}$ is tending to an equilibrium state defined by the equilibrium constant $K = [\text{Fe}^{+++}] [\text{X}] / [\text{Fe}^{++}] [\text{SO}_2]$. By reason of the instability of the intermediate compound X, however, this equilibrium is never quite reached. If at any stage equilibrium were practically attained, X would continue to disappear and to replenish it some ferrous iron must become oxidised to ferric. Moreover, the gradual decrease in the ratio of ferrous to ferric iron brings about a corresponding decrease in the concentration of X which will satisfy the equilibrium constant.

It will thus be seen that eventually the concentration of X will be so small that the adjustment in the ferrous-ferric ratio consequent on its decomposition will be negligible in the periods of time available for observation.

Summary.

1. The rate of reaction between sulphur dioxide and ferrous phosphate in phosphoric acid solution has been measured under definite conditions.
2. The form of the curves and the characteristics of the reaction are explicable on the assumption that an active reducing compound is produced in the primary reaction, which is reversible, but by a secondary irreversible reaction this active substance decomposes with the formation of sulphur.

Numerous experiments have been carried out with the object of

identifying the active intermediate compound, and to test some of the consequences of the hypothesis, and the results will be communicated in due course.

THE UNIVERSITY OF BIRMINGHAM.

CCLXIX.—*The Reaction between Ferrous Phosphate and Sulphur Dioxide in Phosphoric Acid Solution; the Nature of the Decomposition Products.*

By SYDNEY RAYMOND CARTER and JOHN ALFRED VALENTINE BUTLER.

It has been shown (preceding paper) that the main characteristics of the oxidation of ferrous phosphate by sulphur dioxide can be explained by the assumption that the reaction consists of a primary reversible reaction in which ferrous phosphate is oxidised to ferric phosphate by sulphur dioxide, the latter being reduced to an active intermediate product which decomposes irreversibly in a secondary reaction with the formation of sulphur.

The object of the experiments here described was to obtain some information as to the nature of the intermediate product and if possible to identify it.

In the first place, the intermediate product postulated must have the power of reducing ferric phosphate in phosphoric acid solution. It has been shown in an earlier paper (Wardlaw, Carter, and Clews, T., 1920, 117, 124) that neither sulphur dioxide nor ordinary sulphur effects this to an appreciable extent. Secondly, it must decompose under the conditions of the experiments by an irreversible reaction giving rise to sulphur and products that have no further influence on the course of the reaction. No sulphate is formed in the reaction, consequently substances which would give rise to sulphate in their decomposition are excluded. Since sulphur appears at a very early stage of the reaction, the decomposition of the substance in question must be very rapid and the quantity present in the solution at any instant correspondingly small. It follows that it must be a very active reducing agent.

The possible intervention of the following substances has been suggested in the earlier papers: 1. Hyposulphurous acid $\text{H}_2\text{S}_2\text{O}_4$, 2. Thiosulphuric acid $\text{H}_2\text{S}_2\text{O}_3$, 3. An active or nascent sulphur, 4. Hydrogen sulphide. All these substances would give rise to sulphur under the experimental conditions—the first three by spontaneous irreversible reactions, the fourth by reaction with the sulphur dioxide present.

Experiments were instituted to determine their action on ferric phosphate in concentrated phosphoric acid solution. Solid sodium hyposulphite and sodium thiosulphate added to the warm solution in an inert atmosphere caused considerable reduction. No appreciable reduction occurred when hydrogen sulphide was passed through a warm solution. A mixture of hydrogen sulphide and sulphur dioxide was also tried, but here again no reduction was observed.

The reduction of sulphurous acid and sulphites to hyposulphites is a well-known reversible reaction that has been extensively studied in alkaline solution by Jellinek (*Z. Elektrochem.*, 1911, 17, 157). On the other hand, the direct reduction of sulphites or sulphur dioxide to thiosulphates has not been observed, although under certain conditions thiosulphates are formed as a stage in the decomposition of hyposulphites (Jellinek, *Z. anorg. Chem.*, 1911, 70, 93). It therefore seemed more probable that the active product was hyposulphurous acid, and the earlier experiments were designed to test this view.

Attempts were made to test directly for hyposulphite in the reaction mixture, but all the reactions for this acid that are applicable under the conditions of the experiment depend on its powerful reducing properties, and in phosphoric acid ferrous phosphate itself is a powerful reducing agent and can effect all these reductions. No distinctive test could be found.

The influence of additions of sodium hyposulphite on the course of the reaction was studied in the apparatus employed for following the course of the reaction. The hyposulphite was dissolved in dilute alkali (free from air) in an inert atmosphere in a tap funnel inserted through the bung of the reaction flask, and introduced into the flask at a suitable time. The course of the reaction was followed before and after the addition in the way already described. The results of two experiments are given in Fig. 1. It will be seen that the effect of the addition of a quantity of hyposulphite probably large in comparison with that which might be expected to exist in the solution, is hardly appreciable.

A more direct test of the formation of hyposulphite during the reaction was based on the following considerations. Whilst a solution of sodium hyposulphite decomposes on being acidified without forming any sulphate in the absence of air, in the presence of air partial oxidation occurs at the same time and sulphate is formed (Meyer, *Z. anorg. Chem.*, 1903, 34, 43).

It was first shown that the same occurs in phosphoric acid. Some solid sodium hyposulphite was added to phosphoric acid and shaken with air while the decomposition was in progress. A marked formation of sulphate was observed. Sulphur dioxide and

air were now passed together through a solution of ferrous phosphate in phosphoric acid at 100° . Sulphur was formed, showing that reduction of sulphur dioxide had occurred, but no sulphate could be detected in the solution. If hyposulphurous acid were formed in the reduction of sulphur dioxide, it might be expected to be partially oxidised to sulphate by the air; the non-formation of sulphate, therefore, is evidence against the formation of hyposulphurous acid in the reaction.

A more conclusive method of distinguishing between the various possibilities would consist in a determination of the rates of decomposition under the experimental conditions and comparison with the course of the reaction.

FIG. 1.

2.88 Grams of iron in 450 c.c. of phosphoric acid.

(a) Addition of 0.094 gram of $\text{Na}_2\text{S}_2\text{O}_4$. (b) Addition of 0.435 gram of $\text{Na}_2\text{S}_2\text{O}_4$.

Unfortunately, hyposulphurous and thiosulphuric acids decompose so rapidly that this is not practicable. Some experiments were arranged in order to form an idea of the rate of decomposition of a hyposulphite in phosphoric acid at room temperature. A solution of sodium hyposulphite was made slightly alkaline to hinder its decomposition and added at room temperature to a considerable excess of phosphoric acid, air being rigorously excluded, when it was found that only about 20 per cent. remained undecomposed after three minutes. It is obviously impracticable to determine the velocity coefficient of the decomposition at the higher temperature, but a rough comparison may be made from the following considerations.

It was shown in the earlier paper that the reaction between sulphur dioxide and ferrous phosphate resolves itself into two stages, a rapid initial stage followed by a slower and almost uniform action.

In the first stage, the intermediate product is being formed faster than it decomposes; it accumulates until its rate of decomposition is equal to its rate of formation. Thus the amount present reaches a maximum value which remains almost constant for a considerable period, giving rise to the second uniform stage. Here the rate at which the reaction proceeds is equal to and determined by the rate at which the intermediate product decomposes. Consider a typical case (this vol., p. 2375, Fig. 2, Curve I); in the uniform stage the rate of oxidation is about 1 per cent. in forty minutes, corresponding to the decomposition of about 2.4×10^{-5} equivalent of the intermediate product per minute. To form an estimate of the quantity of the intermediate product present during this stage, consider the first stage in which it is accumulating. An oxidation of 5 per cent. of the iron occurs in about fifteen minutes. The total amount of the intermediate product formed in this stage (as the net result of the direct and reverse reactions) corresponding to the oxidation of 0.25 gram of ferrous iron is 5×10^{-3} equivalent. Even if we assume that this quantity is present for the whole time, the total quantity decomposed during the interval is 2.4×10^{-5} equivalent per minute or fifteen minutes or 0.36×10^{-3} equivalent, and we arrive at an estimate of 4.6×10^{-3} equivalent of the intermediate product during the uniform stage. It appears, therefore, that the fraction of the intermediate product decomposing per minute is less than 1 per cent. under the experimental conditions, which is very much less than the fraction for hyposulphurous acid even at room temperature (80 per cent. in three minutes).

Summary.

The intermediate product resulting from the interaction of ferrous phosphate and sulphur dioxide in phosphoric acid has been further considered. It is probable that hydrogen sulphide is not a direct decomposition product of sulphur dioxide, although it may be a by-product in certain other cases.

Hyposulphurous acid ($\text{H}_2\text{S}_2\text{O}_4$) and thiosulphuric acid ($\text{H}_2\text{S}_2\text{O}_3$) possess the necessary reducing properties, but would not have a long enough life in the strong acid solution. They might, however, exist for a brief interval and decompose into another substance.

A nascent or active form of sulphur could quite conceivably possess the necessary reducing properties and decompose into the inactive sulphur at a rate required by the theory.

Colloidal sulphur has not been investigated beyond the experiments previously mentioned.

Theoretical.

Since the conclusion of our experimental work the remarkable properties of the polythionates in acid solution and their surprising stability have been brought into prominence (*Z. anorg. Chem.*, 1921, 119, 225; 1922, 125, 86). They are, moreover, capable of interacting with ferric salts and could conceivably possess the properties required for the intermediate product X. The only objection appears to be the well-recognised statement that a polythionic acid in acid solution decomposes on heating with the formation of sulphur dioxide, sulphur, and a *sulphate*. It is, however, conceivable that in reacting in the presence of a reducing agent like a ferrous salt, a polythionic acid would not give a sulphate but would simply break up into sulphur dioxide and sulphur. Further it is doubtful if the decomposition of the thionic acids by heat and acids under rigid exclusion of air has been studied.

In connexion with these views, it may be mentioned that Wardlaw and Sylvester (this vol., p. 968) quote strong evidence for the formation of a tetrathionate in a sulphuric acid solution of sulphur dioxide which has been reduced by tervalent molybdenum.

The recent studies on the nature of colloidal sulphur are also of special interest in this connexion. Colloidal sulphur can be produced by treating a solution of sodium thiosulphate with concentrated sulphuric acid and in this form can exist in very concentrated acids. It is thought that the sulphur sol exists as a micelle of μ -sulphur, a polythionic acid, and water, and Odén associates its stability with the presence of the thionic acids. If the sulphur sol has the power of interacting with a ferric salt it may be the active compound X we are seeking.

CCLXX.—*Chlorosulphonyl Derivatives of Aromatic Amines.*

By ROWLAND NICHOLAS JOHNSON and SAMUEL SMILES.

It has been recently shown (Stewart, T., 1922, 121, 2535) that acetanilide-*p*-sulphonyl chloride may be readily obtained directly from acetanilide by the action of chlorosulphonic acid; and the method has obvious advantages over the commoner process of preparing this substance from acetanilide-*p*-sulphonic acid with phosphorus pentachloride. Since the study of certain thio-derivatives of aromatic amines was necessary to the progress of other

work, the experiments described in the following pages were undertaken in order to explore the application of the method to other aromatic aminoacetyl derivatives. The behaviour of three derivatives of acetanilide with chlorosulphonic acid has been investigated; these were aceto-*p*-toluidide, phenacetin, and aceto-*p*-xylylide, and in each case satisfactory yields of the corresponding chlorosulphonyl derivatives were obtained. As might be anticipated, the orientations of these products are the same as those of the sulphonic acids obtained from the acylamine with sulphuric acid. Thus, in the case of aceto-*p*-toluidide, the product was found to be aceto-*p*-toluidide-2-sulphonyl chloride (I); it is identical with the substance obtained by Zincke (*Ber.*, 1912, **45**, 1495) on treating the salt of the corresponding acid with phosphorus pentachloride. The sulphonation of phenacetin has been studied by Cohn (*Annalen*, 1899, **309**, 233), who showed that the product was 4-acetylaminophenetole-2-sulphonic acid (compare II), since it was easily converted into the corresponding aminophenolsulphonic acid and could

be obtained from 2-bromophenacetin. Cohn did not describe the corresponding sulphonyl chloride, but on preparing this from a salt of his acid we found it to be identical with the product formed from phenacetin and chlorosulphonic acid. The sulphonation of aceto-*p*-xylylide was examined by Junghahn (*Ber.*, 1900, **33**, 1364), who found that the product was a monosulphonic acid (compare III) which gave on hydrolysis the 1 : 4-xylene-3-amino-6-sulphonic acid of Nölting (*Ber.*, 1885, **18**, 2664) and furnished *p*-xyloquinone on oxidation. The chloride (III) of this acid is identical with that now obtained by the action of chlorosulphonic acid on aceto-*p*-xylylide. These sulphonyl chlorides may be converted by the usual methods into sulphinic acids and other thio-derivatives; some of these are described in the present communication.

EXPERIMENTAL.

Aceto-p-toluidide-2-sulphonyl Chloride (I).—A solution of aceto-*p*-toluidide (1 mol.) in chlorosulphonic acid (5 mols.) was kept at 80° for one hour, and then, after being cooled, was poured over ice. The solid product was collected, washed with ice-cooled water, and dried. The crude sulphonyl chloride, which was thus obtained in

85 per cent. yield, was purified by recrystallisation from aqueous acetone. It formed colourless prisms which melted at $124-125^{\circ}$; Zincke (*loc. cit.*) gives 124° (Found: Cl = 14.1. Calc., Cl = 14.3 per cent.). The anilide was prepared in the usual manner; after recrystallisation from alcohol, it formed leaflets which melted at 230° .

Aceto-p-toluidide-2-sulphinic Acid.—Ten grams of the crude sulphonyl chloride were added to a solution of 30 grams of sodium sulphite in 200 c.c. of water. The mixture was shaken until the reaction was complete, care being taken to add aqueous sodium hydroxide at intervals to maintain alkalinity throughout the reaction. Concentrated hydrochloric acid was then added to the filtered solution, when the required sulphinic acid separated in the crystalline state, the yield being about 80 per cent. of that required by theory. After recrystallisation from hot water, in which it is sparingly soluble, the substance was obtained in small, colourless needles which melted and decomposed at about 160° (Found: N = 6.7; S = 15.3. $C_9H_{11}O_3NS$ requires N = 6.6; S = 15.0 per cent.).

4 : 4'-Diacetylamino-ditolyl 2 : 2'-disulphide was prepared by reduction of the sulphonyl chloride; the properties of the product agreed with those assigned to this substance by Zincke (*loc. cit.*).

4-Acetylamino-phenetole-2-sulphonyl Chloride (II).—Twenty grams of phenacetin were gradually added to 38 c.c. of chlorosulphonic acid, care being taken that the temperature did not rise above 50° during the process. The solution was kept at 50° for one hour, the product being eventually isolated in the usual manner. The crude material formed a semi-solid mass, but it was readily purified by gradually adding water to the solution in cold acetone. A 50 per cent. yield of the crystalline product was thus obtained. After further purification, the required sulphonyl chloride was obtained in colourless prisms which melted at 133° (Found: Cl = 12.6; S = 11.8. $C_{10}H_{12}O_4NClS$ requires Cl = 12.8; S = 11.55 per cent.). The anilide separated from hot alcohol in colourless needles which melted at $182-183^{\circ}$ (Found: N = 8.6. Calc., N = 8.4 per cent.). The sodium salt of the phenacetinsulphonic acid, prepared by Cohn's method (*loc. cit.*), was converted into the sulphonyl chloride and anilide. These products were found to be identical with the corresponding substances described in the foregoing paragraphs.

4-Acetylamino-phenetole-2-sulphinic acid was prepared from the crystalline sulphonyl chloride by the method described in the case of aceto-p-toluidide-2-sulphinic acid. A 75 per cent. yield of the acid was obtained. The substance was sparingly soluble in hot water; it separated from this medium in needles which melted

and decomposed at about 155° (Found: N = 5.8; S = 13.5. $C_{10}H_{13}O_4NS$ requires N = 5.8; S = 13.2 per cent.).

4 : 4'-Diacetylaminodiphenetyl 2 : 2'-Disulphide.—Fifty c.c. of concentrated hydrochloric acid and 30 grams of zinc dust were very gradually added to a solution of 10 grams of the sulphonyl chloride in 120 c.c. of alcohol which was constantly shaken. When the reaction was complete, the unattacked zinc was removed and solid ferric chloride added to the solution, whereby the required disulphide (yield 50 per cent.) was precipitated in the crystalline state. The substance was readily soluble in hot acetone or alcohol, and after recrystallisation from the former solvent was obtained in colourless needles which melted at $192-193^{\circ}$ (Found: N = 6.8; S = 15.4. $C_{20}H_{24}O_4N_2S_2$ requires N = 6.66; S = 15.2 per cent.).

Aceto-p-xylylide-6-sulphonyl Chloride (III).—A solution of 20 grams of aceto-p-xylylide in 42 c.c. of chlorosulphonic acid was kept at 80° for one hour. The mixture was treated in the usual manner, and an almost theoretical yield of the crude sulphonyl chloride was isolated. This was purified by recrystallisation from aqueous acetone, when it was obtained in colourless needles which melted at 160° (Found: Cl = 13.5; S = 12.6. Calc., Cl = 13.5; S = 12.2 per cent.). The *anilide* melted at $213-214^{\circ}$ (Found: N = 8.9. Calc., N = 8.8 per cent.). The corresponding sulphonic acid was prepared from phenacetin by the method of Junghahn (*loc. cit.*), and the sulphonyl chloride prepared from it was found to be identical with that obtained from the process now described.

Aceto-p-xylylide-6-sulphinic acid was prepared by reducing the sulphonyl chloride with aqueous sodium sulphite in the usual manner. A 70 per cent. yield of the crude acid was isolated. After recrystallisation from hot water, the substance was obtained in colourless needles which melted and decomposed at about 125° (Found: N = 6.3; S = 13.8. $C_{10}H_{13}O_3NS$ requires N = 6.2; S = 14.1 per cent.).

3 : 3'-Diacetylaminodi-p-xylyl 6 : 6'-Disulphide.—A solution of 6 grams of the sulphonyl chloride in glacial acetic acid with a little concentrated hydrochloric acid was gradually treated with 10 grams of zinc dust, the mixture being constantly shaken. After the reaction was complete, the mixture was kept for twelve hours, when the greater part of the required disulphide separated in the crystalline state. A further quantity was isolated by adding ferric chloride to the mother-liquors. This disulphide is very sparingly soluble in hot alcohol or acetone; it was purified by recrystallisation from acetic acid, from which it separated in long needles melting at $284-285^{\circ}$ (Found: C = 62.1; H = 6.4; S = 16.8. Calc., C = 61.8; H = 6.2; S = 16.5 per cent.).

In conclusion, we desire to express our thanks to the Department of Scientific and Industrial Research for a grant which has enabled one of us to carry out these experiments.

KING'S COLLEGE, LONDON.

[Received, July 20th, 1923.]

CCLXXI.—*Derivatives of ortho-Thiolphenols.*

By DAVID TEMPLETON GIBSON and SAMUEL SMILES.

DERIVATIVES of benzothioxan are at present unknown and, since a knowledge of their properties was required in connexion with other work, experiments have been begun to effect their synthesis. The most promising type of synthesis appeared to be that based on an *o*-thiolphenol, since catechol may be converted by various methods into benzodioxan and its simple derivatives. Only a few *o*-thiol derivatives of phenols are described in the literature, and these are not very readily available; hence it became necessary to obtain other more suitable material. In the present communication, derivatives of 4-methoxytolyl 3-mercaptan (I) and of 4-chloro-1-naphthol 2-mercaptan (II) are described, together with preliminary experiments on the conversion of these into the cyclic compound in question. 4-Methoxytolyl 3-mercaptan, which is easily obtained in quantity from the sulphonyl chloride (Stewart, T., 1922, 121, 2558) by reduction, may be converted in the usual manner into the thiolacetic acid derivative (III), but on attempting to obtain the phenol from this by interaction with hydriodic acid it was found that the methoxyl group was remarkably inactive, and under more severe conditions than those usually employed thioalkyl compounds were formed owing to rupture of sulphur from the nucleus. Attention was then directed to derivatives containing the sulphone group,

since it was hoped that in these the methoxyl might be more reactive. Accordingly, the sulphonacetone and the sulphonacetophenone (IV and V) were prepared from the sulphinic acid, but neither of these could be successfully converted into the hydroxy-derivative. On the other hand, the methoxy-derivative of the sulphonacetic acid yielded the corresponding hydroxy-compound (VI), but the latter substance resisted all attempts to convert it into the cyclic anhydride

by dehydration, and the behaviour is in remarkable contrast to that of *o*-hydroxyphenoxyacetic acid, which yields the corresponding ketodihydrobenzodioxin on treatment with warm aqueous hydrochloric acid (Ghosh, T., 1915, **107**, 1594). Since these derivatives of *p*-cresol appeared to be unsuitable on account of the difficulty in obtaining the hydroxy-compounds from them, it seemed desirable, before abandoning this line of synthesis, to examine other mercaptans containing unmethylated hydroxyl. Of these, one of the most readily available is the 4-chloro-2-thiol derivative of α -naphthol (II), which is obtained by reduction of the disulphide, the latter being formed from sulphur monochloride and 4-chloro- α -naphthol. The structure assigned to this substance is proved by the facts that it is converted into phthalic acid on oxidation, and very readily yields the carbonate (VII) of simple molecular weight (compare Einhorn, *Annalen*, 1898, **300**, 139). This behaviour appears to be characteristic of ortho-hydroxy-mercaptans; for example, Zincke

(Ber., 1917, **50**, 116) has observed the formation of an analogous product during the reduction of 4-ethylcarbonatotoluene-3-sulphonyl chloride, whilst Friedländer (*Z. Text. Ind.*, 1904, **3**, 333) has recorded the production of the thion derivative from *o*-phenoxyxanthate. In view of the ease with which this five-membered ring system is formed, it is interesting to notice that when the mercaptan is treated with sulphur dichloride the trisulphide, $(C_{10}H_7Cl \cdot OH)_2S_3$, is formed, and not the cyclic dithio-compound (VIII). Experiments on the conversion of this mercaptan into the desired thioxan are being made, but the results hitherto obtained are now published, since one of the authors is unable to continue the work.

EXPERIMENTAL.

4-Methoxytoluene-3-sulphinic acid, which has been previously obtained (Gattermann, *Ber.*, 1899, **32**, 1144; Hilditch, T., 1911, **99**, 1099), is most suitably prepared in quantity by reduction of the corresponding 3-sulphonyl chloride (Stewart, *loc. cit.*) with a weakly alkaline solution of sodium sulphite. This reaction was carried out in the usual manner, and further comment is unnecessary, except to remark that the sulphonyl chloride employed was the crude product obtained from *p*-tolyl methyl ether and chloro-

sulphonic acid. This material did not entirely dissolve in the aqueous sulphite during reduction, and the residue was found to be 4 : 4'-dimethoxydip-*m*-tolylsulphone, which is soluble in hot benzene and melts at 214° (Found : S = 10.6. Calc., S = 10.4 per cent.). This substance had evidently been formed in small quantity during the preparation of the sulphonyl chloride. With the object of obtaining the corresponding hydroxysulphinic acid, the interaction of chlorosulphonic acid and *p*-tolyl acetate was examined. The acetyl group was very easily removed during this process, and the only definite product isolated was a dichlorosulphonyl derivative, which was prepared in the following manner. A solution of 40 c.c. of *p*-tolyl acetate in 200 c.c. of cooled chlorosulphonic acid was kept for six days at about 15° and then treated in the usual manner. The crude product (69 grams) was purified by precipitation with light petroleum from chloroform solution, and *p*-cresoldisulphonyl chloride obtained in pale yellow plates which melted at 105° (Found : S = 21.5; Cl = 23.3. $C_7H_6O_5Cl_2S_2$ requires S = 21.0; Cl = 23.2 per cent.). This substance was not further investigated.

4-Methoxytolyl 3-mercaptan (I) (10 grams) was prepared by reducing the sulphonyl chloride (20 grams) with tin and hydrochloric acid in the usual manner, the mercaptan being isolated by volatilisation in a current of steam. The substance, purified by the gradual addition of water to the cooled solution in alcohol, was obtained in very pale yellow leaflets which melted at 38° (Found : C = 62.0; H = 6.2; M = 146. Calc., C = 62.3; H = 6.5 per cent.; M = 154). Gattermann (*loc. cit.*, p. 1149), who prepared this substance by reduction of the sulphinic acid, describes it as a liquid boiling at 244°. This mercaptan gives a characteristic reddish-brown nickel derivative when treated with a solution of nickel sulphate.

4-Methoxytolyl-3-thiolacetic Acid (III).—A mixture of 19 grams of the corresponding mercaptan with an aqueous solution of 11 grams of sodium hydroxide and 13 grams of chloroacetic acid was heated at 90° for one hour, then cooled with ice, and finally mixed with excess of sulphuric acid. The crystalline product (25 grams) was purified by recrystallisation from hot water, when the substance was obtained in colourless prisms which melted at 79° (Found : S = 15.0. $C_{10}H_{12}O_3S$ requires S = 15.09 per cent.). This substance was not readily attacked by hydriodic acid; reaction did not appreciably begin below 150°, and above that temperature methylthiol compounds were obtained together with methyl iodide, indicating that the thiolacetic acid group was being attacked and eliminated.

4-Methoxytoluene-3-sulphonacetone (IV).—A solution of the sodium sulphinate (20 grams) and chloroacetone (10 grams) in alcohol was

boiled for two hours. The product (19 grams) was isolated by the addition of ice, and after purification from alcohol it was obtained in colourless needles which melted at 78° (Found: S = 13.4. $C_{11}H_{14}O_4S$ requires S = 13.2 per cent.). This substance also is not easily attacked by concentrated hydrogen iodide; a sample which had been treated for one hour with the boiling reagent was for the greater part recovered unchanged.

4-Methoxytoluene-3-sulphonacetophenone (V).—A solution of the sodium sulphinate (20 grams) and ω -bromoacetophenone (12 grams) in alcohol was rapidly evaporated on the water-bath. The residual oil was washed with water and then dissolved in warm carbon disulphide. This solution was allowed to evaporate spontaneously, when the oil which first separated was succeeded by crystalline material. The latter (10 grams) was purified from alcohol, when the desired substance was obtained as colourless prisms which melted at 79° (Found: S = 10.3. $C_{16}H_{16}O_4S$ requires S = 10.5 per cent.). The substance was unattacked by hydrobromic acid (d 1.48) or concentrated hydrochloric acid at 150° . From the reaction with hydriodic acid at 140° , no definite product was isolated.

4-Methoxytoluene-3-sulphonacetic Acid (compare VI).—An aqueous solution containing equivalent quantities of sodium chloroacetate and the requisite sodium sulphinate was evaporated to dryness on the water-bath. The residue was extracted with water, the cooled solution mixed with hydrochloric acid, and the solid which separated was purified by crystallisation from hot water, when the pure material was obtained in prisms, m. p. 82° (Found: C = 49.6; H = 4.8; S = 12.7. $C_{10}H_{12}O_5S$ requires C = 49.1; H = 4.9; S = 13.1 per cent.). Like phenylsulphonacetic acid, this substance readily yields the corresponding methyl sulphone when warmed with excess of aqueous alkali hydroxide. In fact, 4-methoxytolyl 3-methyl sulphone was encountered during the foregoing preparation; it was isolated as a crystalline material, m. p. 87° (Zincke, *Ber.*, 1917, 50, 120, gives m. p. 88°), and was identified by comparison with the product furnished by the methylation of the sulphinic acid.

4-Hydroxytoluene-3-sulphonacetic Acid (VI).—Twenty grams of the methoxy-derivative and 30 c.c. of hydriodic acid (d 1.7) were kept together for five hours at 120 – 130° . The solid (16 grams) which separated from the cooled mixture was collected, freed from adherent iodine, and then recrystallised from hot water. The required substance formed prisms which melted at 192° with liberation of carbon dioxide and gave a violet colour with aqueous ferric chloride (Found: C = 46.4; H = 4.5; S = 13.8. $C_9H_{10}O_5S$

requires C = 46.9; H = 4.4; S = 13.9 per cent.). Numerous attempts to dehydrate this substance were unsuccessful.

4-Chloro-1-naphthol 2-Disulphide (compare II).—A mixture of 18 grams of finely powdered α -naphthol with 100 c.c. of chloroform was slowly treated at 0° with a solution of 7 grams of sulphur monochloride in 25 c.c. of the same solvent. The mixture was constantly agitated during the progress of the reaction, and when the evolution of hydrogen chloride had ceased the solid (20 grams) was collected and separated by pressure as rapidly as possible from adherent mother-liquor. The crude material was decomposed somewhat rapidly by boiling alcohol or acetone, and was purified by recrystallisation from hot benzene, in which it was sparingly soluble. The substance was then obtained in orange prisms which melted at 147° (Found: C = 57.9; H = 3.1; Cl = 17.0; S = 15.5. $C_{10}H_7OClS_2$ requires C = 57.3; H = 2.9; Cl = 16.9; S = 15.5 per cent.). This disulphide exhibits a characteristic reaction with aqueous sodium hydroxide, which rapidly converts it into an amorphous insoluble blue material. The reaction is similar to that exhibited by the monosulphide (I., 1912, 101, 718), but it appears not to require the presence of oxidising agents as with the latter substance. The *diacetyl* derivative of the disulphide was prepared by acetylation with acetic anhydride in presence of sulphuric acid; after purification from alcohol, the substance formed prisms which melted at 148° (Found: C = 56.7; H = 3.4. $C_{14}H_{10}O_2ClS_2$ requires C = 57.2; H = 3.2 per cent.). This compound is not attacked by cold aqueous alkali. Oxidation of the disulphide with alkaline permanganate furnished phthalic acid.

4-Chloro-1-naphthol 2-Mercaptan (II).—Twelve grams of zinc dust were gradually added to a solution of the disulphide (12 grams) in hot glacial acetic acid to which a few drops of hydrochloric acid had been added. After all the zinc had dissolved, the mixture was cooled, the precipitated zinc derivative of the mercaptan redissolved by the addition of hydrochloric acid, and the solution mixed with crushed ice, when 4-chloro-1-naphthol 2-mercaptan was precipitated in the crystalline state. The product was purified by recrystallisation from hot alcohol, in which it was readily soluble, the mercaptan being obtained in pale yellow needles which melted at 86° (Found: S = 15.2; Cl = 16.7. $C_{10}H_7OClS$ requires S = 15.2; Cl = 16.8 per cent.). The substance dissolves in aqueous sodium hydroxide, and the yellow solution on agitation with air rapidly yields the insoluble blue material observed in the case of the disulphide. The *diacetyl* derivative, prepared in the usual manner, melted at 86° and was slowly attacked by boiling aqueous sodium hydroxide (Found: S = 11.2; Cl = 11.66; $C_2H_3O = 28.8$).

$C_{12}H_{11}O_3ClS$ requires $S = 10.9$; $Cl = 12.0$; $C_2H_3O = 29.2$ per cent.).

4-*Chloro-1-naphthol 2-Thiocarbonate* (VII).—To a solution of 4 grams of the mercaptan (II) and the requisite amount of carbonyl chloride in toluene in an atmosphere of coal gas, 20 c.c. of 2*N*-aqueous sodium hydroxide were gradually added with shaking. The solid residue obtained by evaporating the hydrocarbon was recrystallised from benzene, when the desired carbonate was obtained (2.5 grams) in colourless needles which melted at 132° (Found: $C = 55.4$; $H = 2.3$; $Cl = 14.6$; $M = 240$. $C_{11}H_5O_2ClS$ requires $C = 55.8$; $H = 2.1$; $Cl = 15.0$ per cent.; $M = 236$).

4 : 4' - *Dichloro-1 : 1' - dihydroxydi- β -naphthyl Trisulphide*, $(C_{10}H_5Cl-OH)_2S_3$.—A solution of 2 grams of the mercaptan in 10 c.c. of chloroform was treated with 1 gram of sulphur dichloride. The sparingly soluble product was recrystallised from hot chloroform and was thus obtained in small, yellow needles which melted at 146° . These were readily soluble in aqueous sodium hydroxide and did not exhibit with this reagent the behaviour characteristic of the disulphide (Found: $S = 22.0$. $C_{20}H_{12}O_2Cl_2S_3$ requires $S = 21.3$ per cent.).

In conclusion, we desire to express our thanks to the Commissioners of the 1851 Exhibition for a grant which has enabled one of us (D.T.G.) to take part in these experiments.

CCLXXII.—*Derivatives of Tetrahydrocarbazole.* *Part III. Amino-compounds.*

By GEORGE ALFRED EDWARDS and SYDNEY GLENN
PRESTON PLANT.

DURING the course of the investigations of Perkin and one of us into the chemistry of tetrahydrocarbazole (T., 1921, **119**, 1825; this vol., p. 676) it became important to study the amino-derivatives of this substance with the view of introducing other groups into the molecule by means of the diazo-reaction and, in this way, establishing the constitution of various substances, about which some doubt exists. The above authors (T., 1921, **119**, 1833) prepared 6-aminotetrahydrocarbazole (I), but the properties of this compound were not fully investigated.

The preparation of the 5-, 7-, and 8-aminotetrahydrocarbazoles by the reduction of the corresponding nitro-compounds has now

been studied. 5-Nitrotetrahydrocarbazole (II) was prepared by the nitration of 9-acetyltetrahydrocarbazole as described by Perkin

and one of us (*loc. cit.*), but the reduction of this substance and the isolation of the desired amine proved to be difficult. After studying a large number of different methods, it was ultimately found that reduction was best carried out in hot aqueous-alcoholic hydrochloric acid by the addition of zinc dust. After removal of the alcohol by evaporation, the hydrochloride of the amine separated as a colourless solid and the free base was obtained from this by treatment with ammonia. The same process of reduction served well for the preparation of both 7-aminotetrahydrocarbazole (III) and 8-aminotetrahydrocarbazole (IV). Borsche, Witte, and Bothe (*Annalen*, 1908, 359, 70) have reduced several derivatives of tetrahydrocarbazole to the corresponding hexahydrocarbazole compounds by the action of tin in aqueous-alcoholic hydrochloric acid. The possibility existed that the method of reduction adopted during the present work might result in the formation of the amino-derivatives of hexahydrocarbazole, but this was shown not to be the case by (1) using this method for the preparation of 6-acetylamino-tetrahydrocarbazole and (2) the synthesis of 7-aminotetrahydrocarbazole in the following way. Phenylhydrazine-*m*-oxamic acid (V) was pre-

pared from *m*-aminophenylloxamic acid by diazotisation and reduction with stannous chloride in the usual way (Griess, *Ber.*, 1885, 18, 964). This was then mixed with cyclohexanone in boiling acetic acid solution and the hydrazone first formed was converted at once into tetrahydrocarbazole-7-oxamic acid (VI). The identity of the amine, obtained from this substance by hydrolysis with concentrated hydrochloric acid, and 7-aminotetrahydrocarbazole, prepared by reduction of 7-nitrotetrahydrocarbazole, was proved by the determination of the melting point of the mixture.

The amino-derivatives of tetrahydrocarbazole are comparatively unstable substances, some of them decomposing when warmed with

a neutral solvent to a moderate temperature. All the amines can be acetylated by the action of acetic anhydride and they can also be readily converted into picrates. An extensive investigation was made with the object of preparing derivatives from 6-aminotetrahydrocarbazole by means of the diazo-reaction. Diazotisation is best carried out in 40 per cent. aqueous acetic acid, a clear solution of the diazonium compound being obtained on gradual addition of an ice-cold solution of nitrous acid, made by mixing an excess of dilute hydrochloric acid with a solution of sodium nitrite. Attempts to prepare halogen and cyano-derivatives of tetrahydrocarbazole from this diazonium compound by means of the Sandmeyer reaction failed, the products being resinous. The diazonium sulphate and a diazonium perbromide were isolated, but both were very unstable. Sodium tetrahydrocarbazole-6-diazosulphonate could not be converted into the corresponding hydrazine.

In failing to undergo these reactions, the amino-derivatives of tetrahydrocarbazole show a close resemblance to the corresponding carbazole compounds. Ruff and Stein (*Ber.*, 1901, **34**, 1668) and Morgan and Read (*T.*, 1922, **121**, 2709) have shown that 3-aminocarbazole can be made to give a diazonium chloride which yields an azo-dye with β -naphthol. Furthermore, Ruff and Stein (*loc. cit.*) reduced sodium carbazole-3-diazosulphonate, prepared by the action of sodium sulphite on the aqueous solution of the diazonium chloride, to sodium carbazole-3-hydrazinosulphonate by means of sodium amalgam, but they were unable to convert it into the corresponding hydrazine. The failure of 3-aminocarbazole to undergo the Sandmeyer reactions has also been observed by Schwalbe and Wolff (*Ber.*, 1911, **44**, 234; *T.*, 1911, **99**, 103), but Ruff and Stein (*loc. cit.*) obtained a 10 per cent. yield of 3-hydroxycarbazole from the corresponding amine.

An investigation of the other amino-derivatives of tetrahydrocarbazole has given similar results in every case.

EXPERIMENTAL.

5-Aminotetrahydrocarbazole.

5-Nitrotetrahydrocarbazole was dissolved in the minimum amount of a boiling mixture of equal quantities of alcohol and concentrated hydrochloric acid, excess of zinc dust added in small quantities at a time, and the liquid gently boiled, until the solution had just lost its orange-yellow colour. The mixture was at once filtered and the alcohol removed by evaporation. On cooling, the hydrochloride of 5-aminotetrahydrocarbazole separated slowly, and it was then purified by recrystallisation from glacial acetic acid. The free base, obtained by grinding the hydrochloride with ammonia (*d* 0.880), was, after

filtration, washed with ice-cold ammonia, dried in a vacuum desiccator, and recrystallised from a mixture of benzene and light petroleum, from which it separated in small, colourless plates melting at 101° . It slowly darkens on exposure to the air (Found: C = 77.5; H = 7.6. $C_{12}H_{14}N_2$ requires C = 77.4; H = 7.5 per cent.).

5-Acetylaminotetrahydrocarbazole was prepared by adding acetic anhydride (1.4 grams) to the amine (2.5 grams), dissolved in a small amount of ether. After removal of the ether the acetyl derivative was recrystallised from alcohol, from which it separated in small, colourless plates melting at 195° (Found: C = 73.4; H = 7.0. $C_{14}H_{16}ON_2$ requires C = 73.7; H = 7.0 per cent.).

It was readily hydrolysed on boiling for ten minutes with concentrated hydrochloric acid and, on cooling, 5-aminotetrahydrocarbazole hydrochloride separated as a colourless, crystalline mass.

The picrate of 5-aminotetrahydrocarbazole, prepared from the amine (1 gram) and picric acid (1.2 grams) in hot concentrated alcoholic solution, separated in bright red needles which melted at $193-195^{\circ}$ with decomposition.

6-Aminotetrahydrocarbazole.

The amine was obtained from *p*-acetylaminophenylhydrazine hydrochloride and cyclohexanone (Perkin and Plant, *loc. cit.*); however, the formation of cyclohexanone-*p*-acetylaminophenylhydrazone proceeded much better if these substances were mixed in alcoholic solution in the presence of an excess of sodium acetate, instead of sodium ethoxide as originally described.

The following process has been found to work well for the reduction of 6-nitrotetrahydrocarbazole. The nitro-compound was dissolved in the minimum amount of a mixture of equal parts of alcohol and concentrated hydrochloric acid, and zinc dust was added in excess at such a rate that the solution was kept gently boiling. As soon as it had become colourless, the mixture was filtered, and the alcohol removed by evaporation. An excess of strong sodium hydroxide solution was then added, the free amine extracted with ether, and a small excess of acetic anhydride added to the extract, which was then treated with an equal volume of water and the ether removed from the mixture by evaporation. The solid that separated was recrystallised from dilute acetic acid, and obtained in colourless plates melting at 208° . It was shown to be identical with 6-acetylaminotetrahydrocarbazole obtained as above.

Diazotisation of 6-Aminotetrahydrocarbazole.—The amine (1 gram), dissolved in 40 per cent. aqueous acetic acid (20 c.c.), was treated with 6 c.c. of a solution prepared as follows: sodium nitrite (1 gram) was dissolved in water (10 c.c.) and, after cooling to below 0° , a

mixture of concentrated hydrochloric acid (3 c.c.) and water (5 c.c.) was added. The solution of tetrahydrocarbazole-6-diazonium chloride was filtered from a small quantity of a solid impurity.

A solution of the diazonium chloride, prepared from the amine (2 grams), was treated with stannous chloride (4 grams), dissolved in concentrated hydrochloric acid (10 c.c.), at a temperature below 0°. A brown solid, free from tin, separated, and this, after filtration, was treated with an aqueous solution of sodium acetate. A yellow solid was obtained, but it could not be made to crystallise from any of the usual solvents. It possessed most of the reducing properties of a hydrazine, but it could not be made to react with ketones.

An aqueous solution of tetrahydrocarbazole-6-diazonium chloride, prepared from the amine (3 grams), was added slowly to sodium sulphite (10 grams), dissolved in 16 per cent. aqueous sodium hydroxide (25 c.c.), the temperature being maintained at 0°. A bright yellow solid, presumably sodium tetrahydrocarbazole-6-diazosulphonate, separated, but it was very unstable and could not be converted into the corresponding hydrazine.

Tetrahydrocarbazole-6-azo- β -naphthol.—To a solution of the diazonium chloride (from 1 gram of the amine), β -naphthol (0.6 gram), dissolved in 8 per cent. aqueous sodium hydroxide (6 c.c.), was added slowly with constant stirring, the temperature being kept at 0°. The red azo-dye separated at once, but it decomposed on heating and was not obtained pure.

Tetrahydrocarbazole-6-diazonium sulphate.—The amine (1 gram), dissolved in 25 c.c. of a mixture of concentrated sulphuric acid (4 c.c.) and alcohol (250 c.c.), was diazotised with careful cooling by the addition of a 20 per cent. solution of amyl nitrite in alcohol (8 c.c.). After filtration, the solution was carefully mixed with an equal volume of ether and the diazonium sulphate then separated as an olive-green, crystalline solid. On filtration, however, the substance decomposed rapidly and was completely resinified after two minutes.

7-Aminotetrahydrocarbazole.

In order to obtain 7-aminotetrahydrocarbazole in a pure condition, it was necessary to isolate it from the reaction mixture in the form of its acetyl derivative. 7-Nitrotetrahydrocarbazole was reduced with zinc dust in aqueous-alcoholic hydrochloric acid in the manner already described. After the alcohol had been removed by evaporation, the hydrochloride was treated with an excess of aqueous sodium hydroxide, the free amine extracted with ether, and to the extract, dried over potassium carbonate, the theoretical quantity of acetic anhydride was added. About half of the ether was removed by evaporation and the residue was treated with an equal volume

of water, after which the remainder of the ether was removed. The solid was dissolved in hot, aqueous alcohol and boiled for some time with animal charcoal. On cooling, 7-acetylamino-tetrahydrocarbazole separated in small, almost colourless plates, melting at 181° (Found: C = 73.7; H = 7.1. $C_{14}H_{16}ON_2$ requires C = 73.7; H = 7.0 per cent.).

The acetyl derivative was hydrolysed by boiling for ten minutes with concentrated hydrochloric acid, and the hydrochloride of the amine separated on cooling. This was treated with ammonia (d 0.880) and the amine was collected and dried in a vacuum desiccator. 7-Aminotetrahydrocarbazole is very soluble in most solvents and can be recrystallised from hot water, from which it separates in small, colourless plates melting at 128–131°. It darkens on exposure to the air.

The *picrate*, obtained from the amine (2.5 grams) and picric acid (3 grams) in hot, concentrated alcoholic solution, separated, on cooling, as bright red needles and, after recrystallisation from alcohol, melted at 201° with decomposition.

Synthesis of 7-Aminotetrahydrocarbazole.—Phenylhydrazine-m-oxamic acid (5 grams), prepared by Griess's method (Ber., 1885, 18, 964), was dissolved in glacial acetic acid (30 c.c.), and cyclohexanone (2.5 grams) added. The mixture was boiled for ten minutes and the product was then precipitated by the gradual addition of water. The tetrahydrocarbazole-7-oxamic acid was hydrolysed without further purification by boiling for half an hour with ten times its weight of concentrated hydrochloric acid. The resulting liquid was made alkaline by the addition of ammonia (d 0.880), and the free amine, which separated in a very impure condition, was collected after thorough cooling. It was boiled with animal charcoal in water and, on cooling, separated in colourless needles, melting at 124–127°. The yield was poor and the product was contaminated with a very small quantity of a resinous impurity, from which it could not be freed.

8-Aminotetrahydrocarbazole.

The actual reduction of 8-nitrotetrahydrocarbazole was carried out exactly as in the case of the 5-nitro-derivative. After removal of the alcohol by evaporation, the liquid was made strongly alkaline with sodium hydroxide solution and the amine was extracted with ether. The solvent was then removed and the dark-coloured solid which remained extracted with boiling water containing some animal charcoal. On cooling, 8-aminotetrahydrocarbazole separated in colourless needles melting at 159–160°. It rapidly darkens on

keeping (Found: C = 77.8; H = 7.8. $C_{12}H_{14}N_2$ requires C = 77.4; H = 7.5 per cent.).

8-Acetylaminoctetrahydrocarbazole.—The amine (2 grams) was dissolved in the minimum of alcohol and acetic anhydride (2 grams) was added. After standing for an hour, the solution was boiled and then allowed to cool. The acetyl derivative separated in colourless, well-developed, elongated prisms melting at 116°.

The *picrate* of 8-aminotetrahydrocarbazole was prepared in the usual way in hot alcoholic solution, from which it separated in brown prisms melting and decomposing at 127°.

THE DYSON PERRINS LABORATORY,
OXFORD.

mixture of concentrated hydrochloric acid (3 c.c.) and water (5 c.c.) was added. The solution of tetrahydrocarbazole-6-diazonium chloride was filtered from a small quantity of a solid impurity.

A solution of the diazonium chloride, prepared from the amine (2 grams), was treated with stannous chloride (4 grams), dissolved in concentrated hydrochloric acid (10 c.c.), at a temperature below 0°. A brown solid, free from tin, separated, and this, after filtration, was treated with an aqueous solution of sodium acetate. A yellow solid was obtained, but it could not be made to crystallise from any of the usual solvents. It possessed most of the reducing properties of a hydrazine, but it could not be made to react with ketones.

An aqueous solution of tetrahydrocarbazole-6-diazonium chloride, prepared from the amine (3 grams), was added slowly to sodium sulphite (10 grams), dissolved in 16 per cent. aqueous sodium hydroxide (25 c.c.), the temperature being maintained at 0°. A bright yellow solid, presumably sodium tetrahydrocarbazole-6-diazosulphonate, separated, but it was very unstable and could not be converted into the corresponding hydrazine.

Tetrahydrocarbazole-6-azo- β -naphthol.—To a solution of the diazonium chloride (from 1 gram of the amine), β -naphthol (0.6 gram), dissolved in 8 per cent. aqueous sodium hydroxide (6 c.c.), was added slowly with constant stirring, the temperature being kept at 0°. The red azo-dye separated at once, but it decomposed on heating and was not obtained pure.

Tetrahydrocarbazole-6-diazonium sulphate.—The amine (1 gram), dissolved in 25 c.c. of a mixture of concentrated sulphuric acid (4 c.c.) and alcohol (250 c.c.), was diazotised with careful cooling by the addition of a 20 per cent. solution of amyl nitrite in alcohol (8 c.c.). After filtration, the solution was carefully mixed with an equal volume of ether and the diazonium sulphate then separated as an olive-green, crystalline solid. On filtration, however, the substance decomposed rapidly and was completely resinified after two minutes.

7-Aminotetrahydrocarbazole.

In order to obtain 7-aminotetrahydrocarbazole in a pure condition, it was necessary to isolate it from the reaction mixture in the form of its acetyl derivative. 7-Nitrotetrahydrocarbazole was reduced with zinc dust in aqueous-alcoholic hydrochloric acid in the manner already described. After the alcohol had been removed by evaporation, the hydrochloride was treated with an excess of aqueous sodium hydroxide, the free amine extracted with ether, and to the extract, dried over potassium carbonate, the theoretical quantity of acetic anhydride was added. About half of the ether was removed by evaporation and the residue was treated with an equal volume

of water, after which the remainder of the ether was removed. The solid was dissolved in hot, aqueous alcohol and boiled for some time with animal charcoal. On cooling, 7-acetylamino-tetrahydrocarbazole separated in small, almost colourless plates, melting at 181° (Found: C = 73.7; H = 7.1. $C_{14}H_{15}ON_2$ requires C = 73.7; H = 7.0 per cent.).

The acetyl derivative was hydrolysed by boiling for ten minutes with concentrated hydrochloric acid, and the hydrochloride of the amine separated on cooling. This was treated with ammonia (d 0.880) and the amine was collected and dried in a vacuum desiccator. 7-Aminotetrahydrocarbazole is very soluble in most solvents and can be recrystallised from hot water, from which it separates in small, colourless plates melting at 128—131°. It darkens on exposure to the air.

The *picrate*, obtained from the amine (2.5 grams) and picric acid (3 grams) in hot, concentrated alcoholic solution, separated, on cooling, as bright red needles and, after recrystallisation from alcohol, melted at 201° with decomposition.

Synthesis of 7-Aminotetrahydrocarbazole.—Phenylhydrazine-m-oxamic acid (5 grams), prepared by Griess's method (*Ber.*, 1885, 18, 964), was dissolved in glacial acetic acid (30 c.c.), and cyclohexanone (2.5 grams) added. The mixture was boiled for ten minutes and the product was then precipitated by the gradual addition of water. The tetrahydrocarbazole-7-oxamic acid was hydrolysed without further purification by boiling for half an hour with ten times its weight of concentrated hydrochloric acid. The resulting liquid was made alkaline by the addition of ammonia (d 0.880), and the free amine, which separated in a very impure condition, was collected after thorough cooling. It was boiled with animal charcoal in water and, on cooling, separated in colourless needles, melting at 124—127°. The yield was poor and the product was contaminated with a very small quantity of a resinous impurity, from which it could not be freed.

8-Aminotetrahydrocarbazole.

The actual reduction of 8-nitrotetrahydrocarbazole was carried out exactly as in the case of the 5-nitro-derivative. After removal of the alcohol by evaporation, the liquid was made strongly alkaline with sodium hydroxide solution and the amine was extracted with ether. The solvent was then removed and the dark-coloured solid which remained extracted with boiling water containing some animal charcoal. On cooling, 8-aminotetrahydrocarbazole separated in colourless needles melting at 159—160°. It rapidly darkens on

keeping (Found : C = 77.8; H = 7.8. $C_{12}H_{14}N_2$ requires C = 77.4; H = 7.5 per cent.).

8-Acetylamino-tetrahydrocarbazole.—The amine (2 grams) was dissolved in the minimum of alcohol and acetic anhydride (2 grams) was added. After standing for an hour, the solution was boiled and then allowed to cool. The acetyl derivative separated in colourless, well-developed, elongated prisms melting at 116° .

The *picrate* of 8-aminotetrahydrocarbazole was prepared in the usual way in hot alcoholic solution, from which it separated in brown prisms melting and decomposing at 127° .

CCLXXIII.—*Derivatives of Tetrahydrocarbazole.* *Part IV.*

By WILLIAM HENRY PERKIN, jun., and GEORGE CLIFFORD RILEY.

DURING the course of a larger investigation having for its object the synthesis of complex derivatives of tetrahydrocarbazole which it is thought (Perkin and Robinson, T., 1910, 97, 305) may be allied to strychnine and brucine, it became desirable to study the condition of formation and the properties of certain similar substances of a simpler nature. The present communication contains an account of some of the experiments which have been made in this direction.

In the first place, nitrosophenylglycine ester,

was prepared and reduced to phenylhydrazinoacetic ester, $C_6H_5 \cdot N(NH_2) \cdot CH_2 \cdot CO_2Et$, by the method recommended by Harries (Ber., 1895, 28, 1224). This latter substance combines readily with cyclohexanone, and when the product is heated in glacial acetic acid solution, internal condensation readily takes place with the formation of *ethyl tetrahydrocarbazole-9-acetate* (I), m. p. 77° . This ester gives, on hydrolysis, the corresponding acid, which melts at 200° and exhibits no tendency to yield the corresponding anhydro-derivative (II) by the condensation of the carboxyl group with hydrogen of the benzene ring.

An interesting derivative of tetrahydrocarbazole of a somewhat different character was obtained in the following manner. Hydroxy-dihydroquinoxaline, prepared by the action of chloroacetic acid on *o*-phenylenediamine in the presence of ammonia

(compare Plöchl, *Ber.*, 1886, **19**, 6; Motylewski, *Ber.*, 1908, **41**, 800), was converted into the nitroso-derivative, which was then reduced with zinc dust and acetic acid in the presence of cyclohexanone. The product was *anhydro-8-aminotetrahydrocarbazole-9-acetic acid* (III):

The most interesting property of this anhydro-derivative, which melts at 285° and exists in well-defined, dimorphic modifications, is its behaviour on hydrolysis with methyl alcoholic potassium hydroxide, when it yields the corresponding acid (IV), which, however, even at the ordinary temperature, gradually passes again into the anhydro-derivative (III).

Experiments are in progress with the view of determining whether other tetrahydrocarbazole- or indole-carboxylic acids of this nature exhibit a similar tendency to pass spontaneously into anhydro-derivatives. When anhydro-8-aminotetrahydrocarbazole-9-acetic acid is reduced with tin and hydrochloric acid, it is readily converted into *anhydro-8-aminoheptahydrocarbazole-9-acetic acid* (V), which melts at 190° and is more basic than the tetrahydro-derivative. It is our intention to investigate this substance and its derivatives in more detail.

The next case investigated was the behaviour of 8-aminotetrahydrocarbazole with chloroacetic acid in the presence of ammonia, but the *tetrahydrocarbazole-8-aminoacetic acid* (VI) which was produced proved to be an amorphous substance, and all attempts

to convert it into the anhydro-derivative (VII) which we were desirous of investigating have so far been unsuccessful.

During the course of some experiments on the reduction of *cyclohexanone-o*-nitrophenylhydrazone, we found that this derivative is converted, by boiling with sodium hyposulphite in the presence of alcoholic ammonia, into a brilliant yellow substance, $C_{12}H_{15}N_3$, which melts at 142° . Since this substance yields *o*-phenylenediamine and *cyclohexanone* when its solution in glacial acetic acid is boiled with zinc dust, it seems probable that its formation is correctly represented by the scheme

EXPERIMENTAL.

Ethyl Tetrahydrocarbazole-9-acetate (I).—The first step in the synthesis of this substance was *as*-phenylhydrazinoacetic ester, and this was prepared from nitrosophenylglycine ester by reduction with zinc dust and acetic acid essentially by Harries's method (*loc. cit.*):

The nitroso-derivative boiled at $167^\circ/11$ mm., the distillate being a viscid, pale yellowish-brown oil (Found: $N = 13.3$. $C_{10}H_{12}O_3N_2$ requires $N = 13.4$ per cent.). When phenylhydrazinoacetic ester is mixed with half its weight of *cyclohexanone*, there is little rise of temperature or sign of interaction, but on heating the mixture for a quarter of an hour on the water-bath the colour darkens slightly and the mass becomes more viscid. The product may be distilled under reduced pressure, when practically the whole passes over at 208 – $211^\circ/11$ mm. and the distillate crystallises on cooling. On recrystallisation from methyl alcohol, *ethyl tetrahydrocarbazole-9-acetate* is readily obtained pure in colourless, slender needles melting at 77° (Found: $C = 74.6$; $H = 7.4$; $N = 5.5$. $C_{16}H_{19}O_2N$ requires $C = 74.7$; $H = 7.4$; $N = 5.4$ per cent.).

This substance may be obtained more conveniently by dissolving phenylhydrazinoacetic ester (2 parts) and *cyclohexanone* (1 part) in glacial acetic acid (5 parts) and heating the mixture for a quarter of an hour at 100°, during which the colour of the solution changes to a deep reddish-yellow.

After cooling, the addition of water precipitates a yellowish-brown oil which solidifies on rubbing, and the substance is then recrystallised from methyl alcohol. The yield is about 65 per cent. of the theoretical.

It was subsequently found that the preparation of this substance may be still further simplified and the isolation of the intermediate phenylhydrazinoacetic ester rendered unnecessary, with an increase in yield, by employing the following conditions. Nitrosophenylglycine ester (2 grams), dissolved in glacial acetic acid (20 grams), is reduced by the gradual addition of zinc dust (4 grams of 90 per cent.), the whole being well shaken and the temperature kept below 25°. The product is rapidly filtered, the zinc residue washed with a little acetic acid, *cyclohexanone* (1 gram) is then added, and the whole heated on the steam-bath and precipitated with water. The yield of tetrahydrocarbazole-9-acetic ester is about 75 per cent. of theory.

Tetrahydrocarbazole-9-acetic Acid.—The ester of this acid is insoluble in cold dilute sodium hydroxide and does not dissolve readily on boiling. It is, however, readily hydrolysed by boiling with 25 per cent. methyl-alcoholic potassium hydroxide, and, on cooling, the potassium salt of the acid separates in needles. On boiling off the alcohol, adding water, and acidifying, the acid is precipitated as a white, crystalline powder which is very sparingly soluble even in boiling water. It is soluble in ammonia and readily soluble in boiling glacial acetic acid or methyl alcohol, and crystallises in small, colourless, rhombic plates which melt at 200° (corr.) and decompose with evolution of gas at 210–215° (Found: C = 73.4; H = 6.6. $C_{14}H_{16}O_2N$ requires C = 73.4; H = 6.6 per cent.).

Hydroxydihydroquinoxaline, $C_6H_4 \begin{matrix} \text{NH} \cdot \text{CO} \\ \text{NH} \cdot \text{CH}_2 \end{matrix}$.—This substance was first obtained by Plöchl (*loc. cit.*) from *o*-nitrophenylglycine by reduction with tin and hydrochloric acid, and subsequently Motylewski (*loc. cit.*) described a method for its preparation which consists in heating *o*-phenylenediamine with chloroacetic acid in the presence of zinc dust. This latter method claims to give a yield of 25 per cent., but we found that the product is very crude and difficult to purify. It was also found that the use of zinc dust is unnecessary, since a similar product and yield are obtained by heating an

aqueous solution of equal molecular quantities of *o*-phenylenediamine and chloroacetic acid in a boiling water-bath for half an hour. Experiment showed, however, that when these substances are heated in neutral or alkaline solution a much better yield of product of excellent quality may be obtained. *o*-Phenylenediamine (30 grams), dissolved in nearly boiling water (250 c.c.), is mixed with a solution of chloroacetic acid (26.5 grams) in a slight excess of ammonia. The whole is heated in a boiling water-bath for an hour, the solution being kept distinctly alkaline by the frequent addition of small quantities of aqueous ammonia. On cooling, the liquid becomes filled with a mass of long, light brown plates of the hydrate of hydroxydihydroquinoxaline, $C_8H_8ON_2 \cdot H_2O$, which, after being collected and left exposed to the air until dry, weighs 32 grams, representing 70 per cent. of the theoretical yield. After drying at 100° , the substance melts at 135 – 137° and may be further purified by recrystallisation from benzene. The pure substance melts at 138° and dissolves readily in dilute hydrochloric acid, without any trace of the red coloration mentioned by previous observers, and this colour developed only very gradually when the acid solution was left exposed to the air. On the other hand, some of the by-products of the interaction impart a deep red colour to dilute acid and their presence in small quantity no doubt accounts for the above observation.

Nitrosohydroxydihydroquinoxaline is readily obtained by dissolving hydroxydihydroquinoxaline (30 grams) in water (1 litre) and concentrated hydrochloric acid (60 c.c.), cooling the solution below 10° , and then running in the theoretical amount of sodium nitrite in 10 per cent. aqueous solution. Crystallisation of the resulting pale yellow solid from boiling alcohol, in which it is sparingly soluble, must be carried out rapidly, otherwise there will be some decomposition with evolution of nitrous fumes and formation of hydroxyquinoxaline (see below). This decomposition is more noticeable on boiling with other solvents such as benzene and, to a still greater extent, glacial acetic acid, in which the substance is readily soluble.

When rapidly heated in a capillary tube, the nitroso-derivative sinters slightly at 165° and decomposes vigorously at 178° with liberation of nitrous fumes and formation of hydroxyquinoxaline.

Hydroxyquinoxaline, $C_8H_4 \begin{smallmatrix} \text{N}:\text{CH} \\ \text{N}:\text{C}\cdot\text{OH} \end{smallmatrix}$ —This substance has already been described by Hinsberg (*Annalen*, 1896, 292, 248), who obtained it from hydroxyquinoxalinecarboxylic acid by the elimination of carbon dioxide.

It may be readily obtained, in good yield, by boiling the con-

centrated alcoholic solution of nitrosohydroxydihydroquinoxaline for three hours, when, on cooling, long, narrow, pale brown, rectangular plates of hydroxyquinoxaline separate. After being washed with alcohol, the substance melts at 265° , as Hinsberg states (Found: C = 65.4; H = 4.3; N = 19.2. Calc., C = 65.8; H = 4.1; N = 19.2 per cent.).

Anhydro-8-aminotetrahydrocarbazole-9-acetic acid (III) is readily obtained under the following conditions. Nitrosohydroxydihydroquinoxaline (as obtained directly by the action of nitrous acid on hydroxydihydroquinoxaline and without recrystallisation; 10 grams) is suspended in glacial acetic acid (150 c.c.), and zinc dust (20 grams of 90 per cent.) gradually added with constant shaking, the temperature being kept below 25° . The nitroso-derivative gradually dissolves, and when solution is complete the whole is rapidly filtered, and the zinc residue washed with acetic acid before all the liquid has passed through the filter, otherwise the heating of the zinc residue in contact with the air causes decomposition of the hydrazine. The filtrate is immediately mixed with cyclohexanone (5 grams) and then gradually warmed to $30-40^{\circ}$, when interaction sets in with some rise of temperature and darkening of the solution. Slender needles soon commence to separate, and the whole is now kept at 50° for about ten minutes; the process will then be complete and the liquid almost filled with crystals. After being collected, washed with acetic acid, and dried in the steam-bath, the colourless substance weighs 7.2 grams, melts at 285° (corr.), and consists of *anhydro-8-aminotetrahydrocarbazole-9-acetic acid* (Found: C = 74.8; H = 6.2; N = 12.5. $C_{14}H_{14}ON_2$ requires C = 74.3; H = 6.2; N = 12.4 per cent.). When the above acetic acid solution is boiled with the needle modification of the crystals for a few minutes, a second modification results which crystallises in small, heavy, rhombic prisms and also melts at 285° *. Both modifications separate from methyl, ethyl, or amyl alcohol in light, feathery needles, but on standing in contact with the solution for a day or two these gradually disappear, and change into the heavier, rhombic modification. The anhydro-derivative, which is sparingly soluble in cold concentrated hydrochloric acid, dissolves more readily on boiling and is precipitated unchanged on the addition of water.

Hydrolysis. On boiling with excess of methyl-alcoholic potassium hydroxide (25 per cent.), the finely divided anhydro-derivative gradually passed into solution and the addition of water then gave an almost clear solution of the potassium salt. After filtering

* In the determination of the melting point the tube was sealed to prevent darkening and decomposition due to contact with the air.

and cooling in ice, the solution was acidified with acetic acid, when a grey precipitate separated which was largely but not completely soluble in dilute ammonia. After filtration, the acid was again precipitated, and dried in a vacuum desiccator over sulphuric acid, when it was observed that the substance was again not completely soluble in dilute ammonia, the free acid being evidently unstable.

The freshly precipitated substance seemed to be considerably more soluble in cold methyl alcohol than the anhydro-derivative, but all attempts to obtain the acid pure by crystallisation from this solvent led only to the separation of the anhydro-derivative.

Anhydro-8-aminohexahydrocarbazole-9-acetic acid (V).—This hexahydro-derivative is produced when the corresponding tetrahydro-derivative is reduced with tin and hydrochloric acid.

The tetrahydro-derivative (3 grams) is suspended in a mixture of alcohol (18 c.c.) and concentrated hydrochloric acid (18 c.c.) and heated on the steam-bath with granulated tin (6 grams) for an hour. A further quantity of tin (4 grams) is then added and the heating continued for another hour. The cold product is filtered from a small quantity of unreduced substance, the residue washed with equal volumes of alcohol and hydrochloric acid, and the filtrate diluted with three volumes of water and allowed to stand, when small, pale yellow prisms gradually separate. These are collected and crystallised from boiling alcohol, in which the hexahydro-derivative is readily soluble and from which it separates in diamond-shaped plates melting at 190° (corr.) (Found: C = 73.7; H = 6.9; N = 12.1. $C_{14}H_{16}ON_2$ requires C = 73.7; H = 7.0; N = 12.3 per cent.).

Anhydro-8-aminohexahydrocarbazole-9-acetic acid dissolves with difficulty in dilute hydrochloric acid, but is moderately readily soluble in cold concentrated hydrochloric acid and is reprecipitated when the solution is diluted to twice its volume with water.

—During the investigation of the action of chloroacetic acid on *o*-phenylenediamine, the above acid was obtained under the following conditions. *o*-Phenylenediamine (30 grams), dissolved in boiling water (250 c.c.), was mixed with a concentrated aqueous solution of chloroacetic acid (26.5 grams), and the whole heated in a boiling water-bath for thirty-five minutes. The resulting green solution deposited, on cooling, a greenish-blue powder which was collected and, after drying over sulphuric acid in a vacuum desiccator, weighed 18 grams, and was evidently a mixture. On digesting with benzene, about half dissolved; the insoluble portion,

consisting of grey needles (8 grams), separated from methyl alcohol in stout, pale brown needles (Found : C = 58.8; H = 5.1; N = 13.7. $C_{10}H_{10}O_3N_2$ requires C = 58.2; H = 4.8; N = 13.6 per cent.).

Hydroxydihydroquinoxalineacetic acid melts at 232° (corr.) with decomposition, which is considerably higher than the melting point (212°) given by Hinsberg (*Annalen*, 1896, **292**, 252) for the acid which he obtained by the hydrolysis of the ester (m. p. 163°) resulting from the action of chloroacetic ester on *o*-phenylenediamine. In order to determine whether the two preparations are or are not identical, the ester was prepared exactly according to the method recommended by Hinsberg and found to melt, as he states, at 163°. When this ester was hydrolysed by methylalcoholic potassium hydroxide (25 per cent.), a potassium salt separated in needles. The aqueous solution of this salt was acidified with hydrochloric acid, the acid collected, and crystallised from methyl alcohol, from which it separated in needles melting at 229–231° with decomposition. That this acid is identical with the acid which we had prepared by the method described above was proved by a careful examination of its properties and by the melting point of the mixture of the two.

That this acid is the product of the action of chloroacetic acid on hydroxydihydroquinoxaline is proved by the fact that it is actually formed, as we have found, when these substances are heated in aqueous solution. It is therefore evident that the acid must have the constitution represented at the head of this section and not the alternative formula, $C_6H_4 \begin{smallmatrix} N(CH_2 \cdot CO_2H) \\ NH \end{smallmatrix} \begin{smallmatrix} CH_2 \\ \text{---} \end{smallmatrix} CO$, suggested by Hinsberg (*loc. cit.*).

8-Aminotetrahydrocarbazole.—The 8-nitrotetrahydrocarbazole required in the preparation of this substance had already been obtained by Borsche, Witte, and Bothe (*Annalen*, 1908, **359**, 67) from the *o*-nitrophenylhydrazone of cyclohexanone by boiling with sulphuric acid (1 vol.) diluted with water (9 vols.).

We find that the yield under these conditions is only 35 per cent. of that theoretically possible and that a yield of 85 per cent. may be obtained by using more concentrated acid. Sulphuric acid (350 c.c.), diluted with water (700 c.c.), is heated at about 90°, well stirred, and the *o*-nitrophenylhydrazone (100 grams) gradually added, when an almost clear solution results which soon clouds whilst the temperature rises to 96–97°. In a short time, pale yellow plates commence to crystallise and soon fill the solution; after cooling, the mass is collected, washed with water and then with methyl alcohol; it then melts at 149–150° and consists of pure 8-nitrotetrahydrocarbazole.

8-Aminotetrahydrocarbazole may be obtained from the nitro-derivative by reducing it with alcoholic hydrochloric acid and zinc dust as recommended by Edwards and Plant (this vol., p. 2398) or by the following alternative method, which we have found to give excellent results.

8-Nitrotetrahydrocarbazole (12 grams), dissolved in boiling alcohol (240 c.c.), is mixed with saturated alcoholic ammonia (60 c.c.) and, while still boiling, sodium hyposulphite (155 c.c. of 25 per cent. aqueous solution) run in rapidly with stirring. The pale brown liquid is cooled, filtered, poured into three volumes of water, and the precipitate collected and recrystallised from ether, from which 8-aminotetrahydrocarbazole separates in pale brown needles melting at $163\text{--}164^\circ$ (Found: C = 77.1; H = 7.6. $\text{C}_{12}\text{H}_{14}\text{N}_2$ requires C = 77.4; H = 7.5 per cent.). The yield is 4 grams.

Tetrahydrocarbazole-8-aminoacetic Acid (VI).—The ammonium salt of this acid is produced when ammonium chloroacetate reacts with 8-aminotetrahydrocarbazole in alcoholic solution.

Chloroacetic acid (1 gram) is dissolved in a mixture of alcohol (15 c.c.) and concentrated ammonia (5 c.c.), 8-aminotetrahydrocarbazole (2 grams) is then added, and the whole heated on the steam-bath in a reflux apparatus for two to three hours. The cold dark brown solution is diluted to three or four times its volume with water and dilute ammonia so that the liquid smells strongly of the latter. After being stirred and kept, the solution is filtered from the grey precipitate of unchanged aminotetrahydrocarbazole, and the filtrate made just acid with hydrochloric acid, when a light, usually greenish-blue, precipitate is produced and this is collected. On allowing it to dry in a vacuum over sulphuric acid and finally at 100° , a pale greenish-blue powder (1.1 grams) is obtained which melts at about 190° .

It is completely soluble in dilute ammonia, but on attempting to crystallise it from hot alcohol or dilute acetic acid it separates in an amorphous state with a deepening of the blue colour. The purest acid was obtained by dissolving the crude material in alcohol, adding twice the volume of ether, and then washing the ethereal solution with water until it was free from alcohol. The solution having been dried over anhydrous sodium sulphate and the ether distilled off, a pale brown solid remained which separated from dilute alcohol as an amorphous powder and melted at about 198° (Found: C = 69.3; H = 6.7. $\text{C}_{14}\text{H}_{16}\text{O}_2\text{N}_2$ requires C = 68.8; H = 6.6 per cent.).

Several attempts were made to obtain the anhydro-acid from the acid by treatment with alcoholic hydrochloric acid under a variety

of conditions, but without success, tarry products being formed in almost all cases.

Reduction of cycloHexanone-o-nitrophenylhydrazone to the Compound (VIII).—In this experiment, the nitrophenylhydrazone (10 grams), dissolved in boiling alcohol (160 c.c.), was mixed with saturated alcoholic ammonia (50 c.c.) and then sodium hyposulphite (125 c.c. of a 25 per cent. aqueous solution) run in fairly rapidly, the whole being kept boiling during the addition. The deep orange colour of the solution gradually changed to light yellow, and at this stage the whole was cooled, filtered, diluted with water made slightly alkaline with ammonia, and extracted with ether. The ethereal solution was washed free from alcohol, dried over sodium sulphate, and the ether removed, when a syrup remained which, on rubbing, soon crystallised. The mass was then recrystallised from methyl alcohol, from which the new substance (3.2 grams) separated in brilliant yellow needles melting at 142° (Found: C = 71.7; H = 7.6; N = 20.8. $C_{12}H_{15}N_3$ requires C = 71.7; H = 7.4; N = 20.9 per cent.).

This substance is readily soluble in dilute mineral acids to a deep reddish-violet solution, and on boiling with dilute sulphuric acid (25 per cent. by volume) the colour changes to brown, but no indole formation takes place. It dissolves readily in hot alcohol to an orange solution and the colour is not discharged, but rather intensified, on addition of sodium. When the deep reddish-brown solution in glacial acetic acid was digested with zinc dust, the colour gradually faded. As soon as the solution was nearly colourless, it was filtered from the zinc dust, excess of potassium hydroxide added, and the whole distilled in steam; the cyclohexanone that passed over was recognised by its odour and by conversion into tetrahydrocarbazole. The liquid in the distillation flask contained a precipitate which was collected, dried, and distilled under reduced pressure, when a solid was obtained which was recognised as *o*-phenylenediamine by the intense reddish-brown colour produced when ferric chloride was added to its solution in dilute hydrochloric acid.

One of us (G. C. R.) wishes to express his thanks to the Department of Scientific and Industrial Research for a maintenance grant, and the other (W. H. P.) is indebted to the Research Fund Committee of the Royal Society for a grant which has covered much of the expense of this investigation.

CCLXXIV.—*Calcium Carbonate Hexahydrate.*

By JOHN EDWIN MACKENZIE.

THE formation of calcium carbonate by the action of carbon dioxide upon a "sugar-lime" solution, that is a solution made by dissolving calcium oxide in an aqueous solution of sucrose, appears to have been first recorded by Daniell (*J. Sci. Arts*, 1819, 6, 32), but he makes no mention of the crystals being hydrated. Becquerel (*Ann. Chim. Phys.*, 1831, 47, 5), repeating Daniell's experiment, obtained hydrated crystals. Pelouze (*ibid.*, 1831, 48, 301) found the density of these crystals to be 1.783/10° and stated that they lost five molecules of water of crystallisation at 100° and that after boiling with concentrated alcohol there remained a hydrate containing three molecules of water. He also prepared crystals of the hexahydrate by the "sugar-lime" process and by mixing solutions of calcium chloride and sodium carbonate at 0° (*Compt. rend.*, 1865, 60, 429).

The occurrence of crystals of calcium carbonate pentahydrate is recorded by Salm-Horstmar (*Pogg. Ann.*, 1835, 35, 515) and by Scheerer (*ibid.*, 1846, 68, 381).

The statement that calcium carbonate forms crystals containing five molecules of water of crystallisation seems to have been accepted without question until Bütschli (*Abhandl. königl. Gesel. Wiss. Göttingen*, Math. Phys. Kl., 1908, 6, nr. 31) published a comprehensive monograph "Untersuchungen über organische Kalkgebilde." A full bibliography is given, and it is unnecessary to repeat it in this place. Bütschli prepared hydrated calcium carbonate in various ways and more especially from the blood and shells of crustacea. After washing the crystals with distilled water and then with alcohol, and quickly drying them in air, he found the loss of water on heating at 400° to be between 51.27 and 52.32 per cent. ($\text{CaCO}_3 \cdot 6\text{H}_2\text{O}$ requires $\text{H}_2\text{O} = 51.92$ per cent.). The density was 1.752/1.8°.

Vetter (*Z. Kryst. Min.*, 1911, 84, 45) contributed further data as to the formation and properties of the hexahydrate, and Johnston, Merwin, and Williamson (*Amer. J. Sci.*, 1916, 41, 471) obtained it by the interaction of 0.1M-solutions of calcium chloride and potassium carbonate in presence of 0.3 per cent. potassium hydroxide solution at about 0°.

Copisarow (this vol., p. 785) has stated some very interesting points concerning "Marble, Synthetic and Metamorphic," but until the existence of a pentahydrate and a trihydrate is based upon more secure analytical and more definite physical data than have

yet been recorded, it might be well to hold in abeyance the names "hydrocalcite" and "subhydrocalcite" suggested by him for these hydrates.

When trying to isolate the compounds of sucrose with calcium oxide in 1913, the author unconsciously repeated the experiments of Daniell and of Pelouze and obtained, instead of the so-called sucrate of calcium, the hydrated carbonate. He has resumed the study of these compounds after an interruption of seven years and believing with Johnston, Merwin, and Williamson (*loc. cit.*) that the determination of two or more characteristics of the same specimen is of more value than that of a single property, offers the following observations.

The formation of hydrated calcium carbonate at temperatures between 0° and 10° by direct action of carbon dioxide upon solutions of calcium oxide or of solutions of carbonates upon solutions of other calcium salts is confirmed. The hydrate appears only to be formed under conditions which either ensure, or at least allow of, the dissolution of calcium carbonate in excess of carbonic acid and the subsequent breaking up of the bicarbonate thus produced.

The analysis of the hydrated calcium carbonate, in which water, carbon dioxide, and calcium oxide were estimated, has shown that when large crystals, say about 1 mm. in diameter, with unetched faces, are rapidly washed with water and dried with filter-paper at 4° , their composition is expressed by the formula $\text{CaCO}_3 \cdot 6\text{H}_2\text{O}$.

The crystalline forms described by Bütschli (*loc. cit.*) and by Vetter (*loc. cit.*) have been repeatedly recognised and the microscope allows of the easy distinction of the hexahydrate from calcite and aragonite. A number of the crystallographic data given by Johnston, Merwin, and Williamson (*loc. cit.*) have been generally confirmed by Mr. David Balsillie of the Royal Scottish Museum, to whom I desire to express my indebtedness.

The density of the hydrate has been found to be $1.777/3^{\circ}$, which is in close accordance with the numbers previously quoted.

Experiments on the temperature of transition from the hydrated to the anhydrous state have not shown the existence of a definite transition temperature and in no case has the reverse change from anhydrous to hydrated state been observed. The existence of Iceland spar under arctic conditions would point to the non-reversibility of the change from hydrated to anhydrous state. Dilatometric experiments with unetched crystals showed dehydration starting at about $+5^{\circ}$, but, once started, dehydration continues at lower temperatures and it is impossible to stop it. The very slight solubility of the hydrate in water only allows of a small depression of the freezing point, so that dilatometric measurements

below 0° are soon influenced by the separation of ice crystals. The expansion curves do not indicate the formation of any less hydrated forms than the hexahydrate.

Determinations of the solubility of the hexahydrate have shown that it is more soluble than either calcite or aragonite in boiled-out, distilled water. As compared with 0.01433 for calcite, 0.01528 for aragonite, both at 25° (Kendall, *Phil. Mag.*, 1912, [vi], 23, 958), the figures for the hexahydrate at $+2^{\circ}$ are between 0.03 and 0.04 gram per litre. These figures are only relative, the amount of carbon dioxide in the water and in the atmosphere above it not being accurately known (compare Johnston and colleagues, *J. Amer. Chem. Soc.*, 1915, 37, 2001; 1916, 38, 975).

EXPERIMENTAL.

Preparation of Calcium Carbonate Hexahydrate.—To a solution of 50 grams of sucrose in 500 c.c. of distilled and boiled-out water, at about 2° , was added finely powdered, freshly ignited calcium oxide. The addition of a little at a time and rapid stirring caused more to be dissolved than if the lime is added in quantity, and simply shaken up. In one experiment in which quicklime was added as above, the mixture rapidly stirred for three hours, then kept over-night, and the clear solution, after siphoning off from the undissolved sediment, again treated in the same way, it was found to be 0.166*N* with respect to calcium oxide after the second saturation, and 0.3*N* after the third. In another instance, a 0.59*N*-solution was obtained.

If large crystals were desired, a quantity of the sugar-lime solution was placed in a crystallising dish embedded in ice in a large pot in an ice-cupboard. Carbon dioxide, freed from dust by passage through a layer of cotton wool, was then allowed to displace the air in the pot. The surface of the solution soon became turbid and after an hour or two crystals began to grow downwards into the solution. At intervals of four or five hours, more carbon dioxide was introduced and as the crystals grew heavier, they fell to the bottom of the crystallising dish. Crystals more than 10 mm. in length were frequently formed in this manner.

To get some idea within what temperature limits the hexahydrate is formed, numerous experiments were performed in which carbon dioxide was injected through a capillary tube into the sugar-lime solution at temperatures ranging from 0° to 20° . The changes usually observed were that the solution, after remaining clear for a few seconds while the gas was being absorbed, became turbid owing to the formation of a jelly, like starch paste, then frothed for a minute or two, and finally the jelly disappeared and at the same

time a colourless, crystalline precipitate began to form. Table I summarises the results (a is the normality of the sugar-lime solution with respect to calcium oxide).

TABLE I.

a .	Temp.	Product.	a .	Temp.	Product.
0.59	5°	Hexahydrate	0.1	11°	Hexahydrate
0.3	6	"	0.09	15	"
0.1	8	"	0.09	17	Do. (traces)
0.1	10	"	0.09	20	No hexahydrate

The sugar-lime solution and other viscid solutions favour the formation of the hexahydrate and also lessen the rate of dehydration of the hexahydrate. In an experiment in which water was saturated with carbon dioxide at 14°, some milk of lime added, and more carbon dioxide passed into the liquid, a white precipitate was formed which displayed no crystals on microscopic examination even after standing for a day.

In another experiment, a 0.03*N*-sugar-lime solution was saturated with carbon dioxide at 9°, filtered in an atmosphere of carbon dioxide, and placed in an exsiccator filled with the gas and having sticks of potassium hydroxide to absorb the gas. A film grew on the surface and at the bottom of the solution which proved to be calcite. Under similar conditions, but at 2°, the hexahydrate crystals were formed.

A mixture of 10 c.c. each of a 10 per cent. solution of calcium chloride and an equivalent solution of sodium carbonate at +2° produced a white paste, which when examined under the microscope appeared to be gelatinous, but after three minutes small crystals appeared and these had the characteristic appearance of the hexahydrate. These small crystals became dehydrated rapidly in air or even under water.

Analysis of Calcium Carbonate Hexahydrate.—The difficulty of isolating hexahydrate crystals free from adherent moisture, but without loss of water of crystallisation, has been got over by Bütschli and by Vetter by rapidly washing the crystals with water and with absolute alcohol and blowing air over the residue. In this manner, Bütschli, using quantities of crystals weighing between 0.1375 and 0.2257 gram, found the water of crystallisation to be from 51.27 to 52.32 per cent. Similarly, Vetter, using 0.0858 to 0.1722 gram, found the percentage to vary between 51.1 and 51.97. After numerous trials in which percentages of water varying from 26 up to 56 were found, the following method was found to give good results. The crystals were examined under the microscope and, if found to have good faces free from etching, were washed six times with water at 2°. The crystals were broken up by kneading

them under water with a flexible spatula, the liquid swilled round and poured off from the large heavy fragments. In this way all the dehydrated and other small particles were decanted off, and only large fragments of crystals remained. These were then rapidly dried between filter-papers at $+2^{\circ}$ until no traces of moisture on the paper could be detected and the product resembled a colourless, crystalline, coarse sand. The drying should not occupy more than twenty minutes. The large fragments present a small surface and the escape of water of crystallisation is very slight compared with that observed in small crystals. The loss of weight at 180° was measured. The carbon dioxide was estimated either by the loss of weight on ignition or by liberating the gas by means of 0.503*N*-hydrochloric acid and absorbing it by potassium hydroxide solution in a Geissler potash bulb. The calcium oxide was determined by direct weighing and by titration with 0.508*N*-hydrochloric acid.

* Direct weighing.

† By titration.

By exposure to the air or immersion in water, the hexahydrate gradually becomes dehydrated and it is quite possible to obtain analytical figures corresponding to hydrates containing five, four, three, two, or one molecule of water of crystallisation. Microscopic examination invariably shows etched crystals present in preparations giving figures corresponding to these lower hydrates. As an example may be quoted the analysis (5) in Table II of a preparation in which the drying occupied two hours, and others from preparations more dehydrated could be adduced.

It was thought that the temperature at which the hexahydrate crystals remained in equilibrium with air saturated with water vapour might be measured and therewith the vapour pressure of the hydrate determined. Accordingly, 3.9446 grams of crystals (analysis No. 4 above) were exposed to moist air in a closed vessel containing water and a large expanse of wet filter paper at $4^{\circ} \pm 2^{\circ}$.

The shallow weighing-bottle, which held the crystals, after being wiped with a dry cloth and the lid replaced, was weighed at intervals and the weighings showed only a slight increase and indicated that equilibrium had been attained. The figures obtained were:

Time (days)	1	2	4	5	6	7	8	11	12
Increase (mg.)	16.6	25.6	48.6	30.6	37.6	44.6	32.6	69.2	63.6

These figures are, however, entirely fallacious. After removal of adherent moisture from the residual solid, 0.4058 gram was heated at 150° and lost 0.0008 gram, thus proving that the hydrated carbonate had entirely lost its water of crystallisation. Microscopic examination showed the residue to consist of calcite. The water separated from the crystals had adhered to them, being in equilibrium with the water (vapour and liquid) in the closed vessel; hence the practical constancy in weight.

Transition Temperature Experiments.—In a preliminary experiment the changes undergone by perfectly transparent crystals were followed under the microscope, the crystals being immersed in water in a flat-bottomed glass dish, resting on a copper plate, which was heated by a small flame. At this comparatively rapid rate of heating the crystals quickly became opaque at 19°.

The great difference between the density of the hexahydrate and that of calcite suggested the use of the dilatometer for measuring the transition temperature. The relative molecular volumes of calcium carbonate hexahydrate and of calcium carbonate (calcite) + $6\text{H}_2\text{O}$ should be $208/1.77 = 117.5$ and $100/2.72 + 108.1 = 144.7$, respectively.

This being so, the increase in volume due to the change of the hydrate crystals into calcite crystals and free water should be easily measurable.

FIG. 1.

In Table III are given the time, temperature, and scale readings, which are shown graphically in Fig. 1. The measurements in series No. 1 were made in a dilatometer with a bulb 125 mm. long and 14 mm. in bore. The bulb was filled with large, dried crystals treated as if for analysis. The apparatus had all been cooled in ice and the operations of filling and sealing the bulb tube were effected as quickly as possible. Cold wet paraffin oil was then introduced with the aid of an air-pump. The dilatometer with mm. scale attached to the capillary tube was inserted into a 6-gallon drum filled with ice water and provided with a mechanical stirrer. Readings, too numerous to be fully recorded here, were taken at

intervals of ten minutes, the temperature being raised from 6.6° to 15.1° in three hours. The temperature was then lowered and at night the thermostat was filled with ice. As will be obvious from the diagram, lowering of the temperature does not inhibit the change from hexahydrate to anhydrous calcium carbonate. It may also be noted that at the conclusion of each experiment the product showed the characteristic appearance of calcite on microscopic examination.

In series No. 2, the conditions of experiment were those in series No. 1, except that a thermos flask replaced the iron drum and thus the temperature could be kept constant for a lengthened period. From the curve in Fig. 1 it is obvious that until the temperature approached 5° the hydrate was fairly stable, but that once change had set in, the lowering of the temperature did not stop it.

In series Nos. 3 and 4, the dilatometer bulb was 95 mm. long and 10 mm. in internal diameter. The bulb was filled with crystals, which had been thoroughly washed with ice-cold water but not exposed to the air. The crystals, mixed with water, were sucked into the bulb, which had a small plug of cotton wool to prevent the crystals getting into the capillary, and in this way the bulb was filled with practically unetched crystals. After the bulb had been sealed, water was brought in to fill the space unoccupied by crystals. Readings were made at much longer intervals than in the first two series, and it will be observed that the curves follow each other closely. In No. 4, a long capillary tube allowed of the change of volume due to dehydration being followed to completion.

Solubility of Calcium Carbonate Hexahydrate.—The water used was boiled-out water and all the glass apparatus was washed with sodium hydroxide, with nitric acid, and repeatedly with water. The evaporation was carried out in a platinum basin on a steam-bath under a glass funnel. A glass bottle of 2,400 c.c. capacity was fitted with a rubber bung carrying a stirrer and a thermometer. This bottle, in a perforated zinc container, was immersed in ice and water, the temperature being near 2° . A blank experiment was made as follows: Water was boiled in distilling flasks holding 1.5 litres, then cooled to 2° , the neck and side tube being plugged with cotton wool, and transferred to the large bottle and stirred for twelve hours. It was then siphoned off through a tube with cotton-wool filter into a similar large bottle and evaporated in the platinum basin. The residue from 1,200 c.c. of water weighed 0.0077 gram. Presumably less than this quantity was present in the water used in the two following determinations, in the first of which well-washed crystals of the hydrate were brought into the large bottle and stirred for twelve hours at 2° and kept over-night before the solution was siphoned off. In the second determination, fresh

water was added to the undissolved hydrate residue of the first determination. The presence of a quantity of dehydrated crystals probably accounts for the smaller solubility in the second experiment. The volume of solution evaporated in the first determination was 1,970 c.c. and in the second 2,000 c.c. The solid residue per 1,000 c.c. after deducting 0.00641 gram as allowance for dissolved solid in the water, amounted to 0.0418 gram in the first and to 0.0303 gram in the second experiment. The total residue of the second experiment lost 45.09 per cent. of its weight on ignition, the percentage of carbon dioxide in calcium carbonate being 44.0 per cent., thus showing that this residue consisted of practically pure calcium carbonate.

CCLXXV.—*The Constitution of Soap Solutions: Migration Data for Potassium Oleate and Potassium Laurate.*

By JAMES WILLIAM MCBAIN and RICHARD CHARLES BOWDEN.*

THE theory of colloidal electrolytes was developed † in order to reconcile the data for conductivity, osmotic pressure, and viscosity of solutions of soap, proteins, dyes, and many other substances. The essential assumption was the conception of the ionic micelle, a colloidal particle exhibiting conductivity much greater than that of the sum total of all the single ions which had been aggregated to form it. Although a large amount of quantitative evidence of many kinds has been obtained in support of this assumption, it was essential to establish it by the direct experimental measurements described in the present paper. The results are in surprisingly good agreement with all the data obtained by other methods.

EXPERIMENTAL.

In doubtful or difficult cases the only trustworthy method of determining mobilities is the original analytical or Hittorf

method. This is particularly the case in view of the fact that movement of various particles in an electrical field is of the same order of magnitude as the movement of ions, in spite of the enormous difference in equivalent conductivity. In the present instance the equivalent conductivity of the ionic micelle is distinctly greater than that of any ordinary ion.

Elaborate care has been taken in the measurements here described in the hope of obtaining trustworthy and moderately accurate data. Unknown and uncontrollable reactions at the electrodes were eliminated through the interposition of guard solutions of potassium sulphate between the soap solution and each of the electrodes. In place of the three portions into which the solution is usually divided after electrolysis, use has been made of seven, in order to follow with more certainty the changes of concentration throughout the apparatus. Silver coulometers were used at both ends of the apparatus to detect any leakage of current. They were found to give identical results within 0.1 per cent. All determinations were made at 18.0°.

Analyses were made for both constituents of the soap solution both at the anode and the cathode, so that each experiment gave four more or less independent determinations of the migration number. In very few instances in the literature has a measurement been made of the movement of both anion and cation and in this case the fact that the two together are found exactly to account for the total current affords a useful check on the possible nature of the ions in solution; for instance, the effect of hydrolysis alkalinity is seen to be negligible in conformity with previous work.

The Apparatus Employed (Fig. 1).—The migration apparatus consisted of three U-tubes, A, B, and C, made from 1-cm. borosilicate tubing and united by ground joints at D and E. The total capacity was 130 c.c. The platinum electrodes were sealed in through the hollow ground stoppers, F and G, just below the stop-cocks. The tubes were cleaned before each experiment with dichromate mixture.

The apparatus has first to be set up with potassium sulphate solution without contaminating the rest of the apparatus. This is done by introducing the sulphate solution through the openings F and G, those at D and E (free from vaseline) being closed with rubber stoppers. By momentarily loosening the rubber stoppers, the solution is allowed to go round the bend to the required extent (which is further in the case of the anode). When the outside legs have been filled nearly to the top, the electrode stoppers are replaced, all vaseline is removed from H and K, and the tube is weighed. The three U-tubes are now put together and mounted

on a stand, joints D and E having been well vaselined and pressed together by stout, rubber bands.

Soap solution is now placed in the apparatus, but the first portions in A and C have to be introduced through a capillary pipette with upturned flaring tip (Fig. 1a), held just in the surface of the liquid so as to avoid any mixing of sulphate and soap solutions. The levels are equalised and stoppers H, I, J, and K well vaselined and closed. The apparatus is kept in the thermostat for twenty minutes before the current is turned on.

At the conclusion of the experiment, five consecutive middle portions are removed by means of pipettes through I and J, for

FIG. 1.

The migration apparatus.

FIG. 1a.

weighing and analysis, the boundaries of the portions being indicated by the dotted lines in the figure. Tubes A and C are then detached (H, K, D, and E being freed from vaseline) and weighed together with the rubber stoppers at D and E. This gives the weights of the anode and cathode solutions which have to be corrected for the weight of gas evolved during electrolysis as calculated from the coulometer readings.

All vessels, instruments, and solutions were carefully standardised before use.

Materials.—The authors' thanks are due to Mr. Elsdon of Salford for a supply of methyl laurate, from which some of the lauric acid used was isolated during the years after the war in which it could not be obtained commercially. This was used in experiments

5 to 11. In subsequent experiments lauric acid, and finally potassium laurate, supplied by Kahlbaum, were employed. The solutions of oleate were made up from oleic acid "Kahlbaum," potassium drippings, and conductivity water in the manner previously described (T., 1914, 105, 417). The purest potassium sulphate obtainable was twice recrystallised. Chesebrough vaseline was used for greasing joints in the apparatus after being boiled out with four changes of distilled water, filtered, and dried.

Method of Analysis of Soap Solution.—To a weighed quantity of solution, washed into a beaker, a measured excess of standard hydrochloric acid is added slowly from a pipette with vigorous stirring. The precipitated fatty acid is filtered off and washed free from hydrochloric acid with distilled water. The filtrate is titrated with standard alkali, phenolphthalein being used, for the determination of the total concentration of soap and hydroxide. The fatty acid is dissolved in boiled-out ether-alcohol and titrated with potassium hydroxide, the solvent at the end point being 70 to 80 per cent. boiled-out alcohol. All calculations are based upon weight of water as solvent, and concentrations are expressed in weight normality referred to 1000 grams of water.

In recording the migration results, for the sake of clearness of comparison, all the data are expressed in terms of gain or loss of fatty acid radicle. For instance, a gain in potassium at the cathode amounting to 15.8 per cent. of the total number of equivalents electrolysed, as measured by the coulometer readings, which would usually be expressed as a value for the transference number of the kation, K , $= 1 - n = 0.158$, is here expressed as $n = 0.842$ or 84.2 per cent.

Experimental Data.—Table I shows the results of three preliminary experiments with solutions of potassium oleate. These experiments were carried out in an apparatus made with soda-glass, and in experiments 1 and 2 the only available materials were solutions which had been kept for a long time in Jena bottles with well-vaselined stoppers. Further, in experiment 1 the analysis of the middle portion was used as the basis of the calculations for the end portions. Three middle portions were actually employed. Five per cent. potassium sulphate solutions were used at the electrodes. The current was 7 milliamps. for 120 minutes, in each case 80 volts being used. The coulometer reading was between 62 and 69 milligrams of silver.

Subsequent experiments were carried out in the borosilicate apparatus, seven portions being analysed in each case. The original solutions were analysed in quadruplicate both for potassium and oleate radicles. In experiment 24, 80 volts were used, and

Although the apparatus was not designed for use with dilute solutions, it was nevertheless of great interest to carry out an experiment at a dilution where the soap had been found by previous methods to be an ordinary crystalloidal electrolyte. The data for such a case are shown in Table V. The predicted value for a simple potassium salt of any acid of high molecular weight is 0.24.

Experiments 15 to 18 with 0.2*N*-potassium laurate, and 19 and 20 with 1.0*N*-potassium laurate, yield transference data in which the solvent is aqueous glycerol. Here the soap should be slightly less colloidal than in pure water; this is borne out by the data

correction for hydration of soap would greatly alter them or leave them substantially unaffected. This has a decisive bearing upon the question as to how much neutral soap is involved in the ionic micelle.

The method employed is that suggested by Nernst, in 1900, since used by Buchböck and by Washburn, etc. It depends on the use of a non-electrolyte as reference substance and the measurement of its apparent movement during electrolysis.

The selection of a suitable reference substance is attended with considerable difficulty in the case of soap solution, and in spite of prolonged search a completely satisfactory substance has yet to be found. It must be such that it will not migrate with the current, will not react with the electrodes, solvent, solute, or products of electrolysis, and finally must not be sorbed by soap. Miss Laing (T., 1921, 119, 1669) has shown that out of a large number of substances, glycerol was the only one not sorbed by soap fibres in the presence of saturated solution of sodium chloride.

The analysis of dilute solutions of glycerol in the presence of large amounts of soap is open to large sources of error, owing to the necessity for decomposing and removing the soap and to volatilisation of glycerol during evaporation of the milky aqueous residues. Further, a small error in the determination of the reference substance is highly magnified when expressed in terms of hydration.

In experiments 15 to 20, after removal of the soap and neutralisation, the filtrates were evaporated, the glycerol was extracted by ether-alcohol (1 to 3), and the extracts were evaporated; the glycerol, now in a small flask, was finally dried for forty-eight hours in a vacuum desiccator. A condenser with ground-in joint was then fitted and the acetin analysis carried out by the international method (*J. Ind. Eng. Chem.*, 1911, 3, 679). In experiments 21—24, a modification of the dichromate method was employed which was developed by Bennett and will be described in another communication. This permits of much greater accuracy in the analysis of dilute solutions of glycerol in presence of soap made from pure saturated fatty acids.

The amount of water moved relative to the glycerol per equivalent of current is obtainable directly from the complete analysis of the contents of either the anode or cathode compartment. In experiments 21—24, use was made of the value of the Hittorf number previously obtained, the results being calculated as follows:

The weight of water and soap is first corrected for the Hittorf movement of potassium and laurate relative to the water, which leaves the weight of soap and water in the same proportion as in the original solution and hence yields the weight of water present after electrolysis. This is compared with the amount of water which before electrolysis accompanied the amount of glycerol determined by analysis, the difference being the water transported. The results, given in Tables VIII, IX, and X, are expressed both in terms of water transported per equivalent of current and in terms of the correction to be added to the Hittorf number for the effect of hydration. It will be seen that the correction cannot exceed one unit in the first decimal place.

Discussion of Results.

Migration Data.—The final results of the foregoing tables are collected in Table XI. The transference number expected for an ordinary potassium salt of a heavy organic acid is 0·24. It is at once apparent that this value is approached only in the most dilute solution of the lower soap, where other methods have shown an almost complete breakdown into a simple crystalloidal electrolyte resembling the acetate.

TABLE XI.

Transference numbers of potassium soap solutions.

Soap.	N _w .	Solvent.	Transport number.	Ratio L/K.
K oleate	0·25	Water	0·75	3·00
"	0·5	"	0·70	2·33
K laurate	0·05	"	0·28	0·39
"	0·2	"	0·67	2·03
"	1·0	"	0·55	1·22
"	0·2	(4%) Glycerol	0·63	1·70
"	1·0	(4·5%) "	0·48	0·92
Predicted for crystalloidal soap			0·24	0·31

In all solutions containing colloidal soap the movement of fatty radicle is many times greater than 0·24. This is in accordance

with the high mobility of the ionic micelle, which has been shown to conduct as well as the potassium-ion. Further, it is proof of the movement of neutral colloidal soap, whether wholly or only partly carried in the ionic micelle.

McBain and Salmon recognised two alternative possibilities; namely, that the ionic micelle could consist almost entirely of aggregations of hydrated fatty ions, or that these colloidal particles could contain all the neutral colloid. They argued that some at

FIG. 2.

The relative proportions of the various constituents of solutions of pure potassium oleate at 18°. (The asterisk * marks the field showing the proportion of acid soap, 2KOl, HCl, present.)

least of the neutral colloid is contained in the ionic micelle on account of the distinct although slight differences between the solutions of potassium and sodium soaps. However, the differences between the various soaps must now be largely ascribed to primary differences in the neutral colloid.

The present results show decisively that the ionic micelle contains but little of the neutral colloid. The proportions of the constituents present in potassium laurate solutions are given in T., 922, 121, 2328, and those in the solutions of potassium oleate in Fig. 2, deduced by Miss M. H. Norris from conductivity and

freezing-point data.* There is in the laurate about one and a half times, and in the oleate about 2.3 times as much undissociated colloidal soap as there is of aggregated fatty ions (compare the diagrams, T., 1922, 121, 2328, 2330). Hence, if all this is contained in the ionic micelle, which conducts as well as the potassium-ion, each equivalent of laurate- or oleate-ion in the ionic micelle will have to carry with it 1.5 times and 2.3 times as much soap, respectively, which would bring the migration numbers up to 1.25 and 1.65, whereas the observed numbers are only 0.6 and 0.7. This shows that most of the neutral colloid must lead an independent existence as neutral micelle.

This conclusion cannot be shaken by assuming great hydration of the ionic micelle, for an impossible degree of hydration would be required. In a normal solution of soap each discrepancy of 0.1 in the migration number means that the difference in the amount of water carried in opposite directions by potassium-ions and ionic micelle is equal to the volume of water which dissolves 0.1 gram-equivalent of soap, that is, 100 grams of water or 5.5 mols. If the hydration of the potassium-ion is 6 mols., and it carries half the current, the movement of water due to it will be 3 mols. towards the cathode; hence to obtain a total movement of 5.5 mols. in the opposite direction the ionic micelle would have to be hydrated to the extent of 17 mols. of water per equivalent of fatty ion contained in it, which is probably fairly near the truth. There are only 55 mols. of water present altogether in a normal solution, and taking into account the degree of dissociation, which is 40 per cent. and 30 per cent., respectively, for the two soaps under discussion, 9.2 and 6.9 mols. of water would be required for the hydration of these ions; and it has been shown that the neutral soap is also heavily hydrated. It is evident that an attempt to correct the observed values on the basis of hydration so as to bring them up to 1.25 and 1.65, respectively, would involve most of the water that the solution contains, and further the hydration would have to increase nearly in proportion to the dilution.

Consideration of the apparent transference of glycerol shows that no correction for hydration could add more than 0.1 to the migration number. The almost negligible movement of the glycerol can be only partly due to slight sorption by the soap. Bennett has recently found that, although glycerol is taken up by soap fibres in the absence of salt, yet the amount is so small in comparison with the hydration that the apparent sorption is always negative.

* The following values were involved in Miss Norris's calculations:—mobilities of the simple fatty ions = 20.7; ionic micelle = $K' = 64.7$; $OH' = 174$; $K_{KOH} = 0.07$.

It will be shown in another, more comprehensive investigation of soap sols, gels, and curds by Miss Laing that all the data admit of only one explanation. The ionic micelle conducts like an ordinary ion of mobility comparable with that of the potassium-ion and consisting chiefly of aggregations of fatty ions with hydration of the magnitude of that here assumed.* The neutral colloid also moves with the electric current and although it possesses but few charges, so that its conductivity per chemical equivalent is almost negligible, nevertheless the conductivity per electrical charge is comparable with that of a slow ion. It is shown that all these movements in the electrical field, whether of ions, of colloidal particles, or of diaphragms, are but particular cases of ordinary electrolytic migration.

The last point remaining for discussion concerns the fact that the migration number distinctly falls off in the more concentrated solutions. This may be accounted for by the influence of hydration as already discussed, since the influence of a definite degree of hydration must be directly proportional to the concentration of the solution. Again, any electrophoresis of the neutral colloid may be noticeable only in more dilute solution.

However, something more may be involved here. Now that the ionic micelle is seen largely to consist of aggregated ions there is no sufficient explanation of the fact that the dissociation of the colloidal electrolyte is so little affected by change in concentration. Unless either the ionic micelle or the neutral micelle itself changes, increase in concentration should very rapidly drive back the dissociation, as in Pauli's experiments with acid albumin. The change cannot be due to increasing amounts of neutral colloid in the ionic micelle, for the migration numbers move in the opposite direction. Possibly it is due to diminishing hydration.

Summary.

1. Careful migration determinations have been made of solutions of potassium oleate and laurate in water and dilute aqueous glycerol.
2. Only in dilute solution, where all the soap is crystalloidal, is the ordinary migration number observed; in all other solutions, where the soap is a colloidal electrolyte, the migration of the fatty radicle is several times greater than this, corresponding to the high mobility of the ionic micelle.
3. The transference values are such as to show, in accordance

* The ultra-filtration data of Jenkins lead to a calculated mobility of ionic micelle in potassium oleate solutions equal to 77.6 mhos (not 77.9 as printed in T., 1922, 121, 2330) and a hydration of 15 mols. of water (not 16 as previously recorded, *ibid.*, p. 2330).

with the results of ultra-filtration, that most of the neutral colloidal soap is not contained in the ionic micelle, but exists independently as neutral micelle.

4. The apparent transference of glycerol as reference substance shows that the results are not much affected by taking into account hydration of the ions and ionic micelle.

5. Dilute aqueous glycerol distinctly lessens the amount of colloid present.

Our thanks are due to the Research Fund Committee of the Chemical Society and to the Colston Research Society of the University of Bristol for grants for the purchase of materials.

CCLXXVI.—*The Distribution of Normal Fatty Acids between Water and Benzene.*

By FREDERICK STANLEY BROWN and CHARLES R. BURY.

MEASUREMENTS of the distribution of the first six normal fatty acids between benzene and water at 25° have been undertaken with the object of determining how this varies from member to member of a homologous series.

The apparatus used for the purpose is shown in Fig. 1. The bulb was of about 250 c.c. capacity, and the capillary tube about 1 mm. in bore; it was nearly filled with approximately equal volumes of benzene and a concentrated aqueous solution of the acid under investigation. It was supported in a thermostat maintained at $25.00^\circ \pm 0.03^\circ$, and occasionally shaken vigorously: preliminary experiments showed that equilibrium was only attained after about an hour with concentrated solutions; with dilute solutions, it was attained more rapidly. Twenty c.c. of the benzene layer were then withdrawn directly in a pipette and analysed: by forcing air (through a soda-lime tower to absorb carbon dioxide) into the top of the vessel, a small quantity of the water layer was driven through the capillary tube; the first cubic centimetre or so of this was neglected, the remainder collected in a test-tube, from which 20 c.c. were pipetted off for analysis. After half an hour, two more samples were taken as before: when these duplicate determinations did not

agree with the first to 1 part in 500, the results were neglected. The vessel was then filled up with amounts of the pure solvents equal to those of the solutions withdrawn, and the distribution again determined at a lower concentration, and so on, until one layer became too dilute for analysis. Two entirely independent series of determinations were carried out with each acid, except hexoic.

The samples from both layers were titrated with baryta, phenolphthalein being used as indicator. The baryta was standardised with succinic acid, which had been recrystallised. Weights were calibrated by Richards's method (*J. Amer. Chem. Soc.*, 1900, **22**, 144) and all volumetric apparatus was standardised. Precautions were taken to prevent access of carbon dioxide during titration, and all water used was freed from this by boiling it in a flask of Jena glass, through which a current of carbon dioxide-free air was passed until it was cold. Benzene was freed from thiophen and distilled within 0.1°.

Formic Acid.—A sample of Kahlbaum's acid was fractionally distilled: the product had a constant boiling point of 100.5° (on an unstandardised thermometer). The results obtained for the distribution are shown below, C_w and C_b are, respectively, the concentrations in the water and the benzene layers, expressed as normalities. In order to save space, only about a third of our results are quoted for all the acids except hexoic.

Series.	C_w .	C_b .	C_b (calc.).	Diff.
A	6.806 N	0.0348 N	0.0315 N	— 0.0033
A	5.483	0.0233	(0.0233)	—
B	4.689	0.0188	0.0187	— 0.0001
A	3.933	0.0147	0.0146	— 0.0001
B	3.757	0.0138	(0.0138)	—
B	3.400	0.0117	0.0119	+ 0.0002

Owing to the low solubility of formic acid in benzene, determinations were difficult, and have only been made over a narrow range of concentrations. Previous determinations at 13–15° have been made by Georgevics (*Z. physikal. Chem.*, 1913, **84**, 353), who found the ratio of the concentrations in the two layers independent of the total concentration, within the limits of his experimental error. During the course of our work, measurements at 25° have been published by Gordon and Reid (*J. Physical Chem.*, 1922, **26**, 773), but their results are expressed as concentrations per weight of solution: so far as can be ascertained, they are substantially in agreement with our figures.

Acetic Acid.—A sample of glacial acetic acid was twice fractionated by freezing, the crystals being separated from the mother-liquor by centrifuging: it was then distilled.

Series.	C_w .	C_b .	C_s (calc.).	Diff.
A	11.137 <i>N</i>	3.111 <i>N</i>	2.047 <i>N</i>	— 1.064
B	10.812	2.692	1.946	— 0.746
A	8.710	1.463	1.356	— 0.107
A	7.546	1.089	1.062	— 0.027
B	6.101	0.739	0.743	+ 0.004
A	5.444	0.614	(0.614)	—

B	0.633	0.0165	(0.0165)	—
B	0.531	0.0125	0.0133	+ 0.0008

Previous determinations by Herz and Fischer (*Ber.*, 1905, 38, 1138) are in close agreement with our figures, although the temperature at which they worked is unknown; they did not carry their measurements to such high concentrations as we have done. A few rough experiments at 6° have also been made by Nernst (*Z. physikal. Chem.*, 1891, 8, 110).

Propionic Acid.—A sample of Kahlbaum's acid was fractionally distilled: practically all came over between 139.0° and 140.8°, water being the main impurity.

Hexoic Acid.—Owing to the smallness of the quantity of acid available, no attempt was made to purify it; it boiled at 210°.

FIG. 2.

Only one series of measurements was made, and experiments were carried out on a smaller scale than with the other acids.

C_w	C_b	C_b (calc.).	Diff.
0.0162 <i>N</i>	0.619 <i>N</i>	(0.619 <i>N</i>)	—
0.0131	0.413	0.414	+ 0.001
0.0114	0.328	0.321	— 0.007
0.0102	0.256	0.253	— 0.003
0.0091	0.210	(0.210)	—
0.0078	0.159	0.154	— 0.005

The results for all the acids are shown diagrammatically in Fig. 2, in which the logarithms of the concentrations in the water layer have been plotted against those in the benzene layer.

When the concentration of acid in the benzene layer is greater than about 0.75*N*, no formula can be found to represent the results even approximately. It is probable that at this concentration water becomes noticeably soluble in the benzene layer, so that the nature of the solvent is altered.

At lower concentrations, the results are best represented by a formula first suggested by Nernst (*loc. cit.*), $C_w^n/C_b = k$, where k and n are two constants: k is the reciprocal of the concentration in benzene when that in water is unity; n , according to Nernst, is the degree of association of the acid in the benzene layer. From the method by which this formula was deduced, it can only be expected to be an approximate relation, and n should be a whole number; actually, the formula represents the experimental results at low concentrations within the limits of experimental error, while n is not a whole number, but has values from 1.4 to 1.9. The formula assumes that the degree of association is a constant independent of concentration; determinations of the molecular weight of associated substances in benzene solution by many investigators show that this assumption is unjustifiable. The interpretation of the formula is discussed by Georgevics; in any case, it is improbable that n has the significance attached to it by Nernst.

The above equation has been used to calculate the values shown under the heading $C_b(\text{calc.})$ for each acid. The values of the constants used were as follows:

Acid.	n .	k .	Acid.	n .	k .
Formic	1.395	460.2	Butyric	1.700	0.1757
Acetic	1.681	28.10	Valeric	1.819	0.0138
Propionic	1.712	1.716	Hexoic	1.893	0.00066

The value of n increases irregularly as the number of carbon atoms in the molecule increases: k decreases rapidly, but rather more regularly, for if the logarithm of k is plotted against the number of carbon atoms, an approximately straight line is obtained.

CCLXXVII.—*The Isomerism of the Oximes. Part XIV.* *3-Nitro- and 3-Bromo-p-dimethylaminobenzaldoximes.*

By OSCAR LISLE BRADY and RICHARD TRUSZKOWSKI.

PREVIOUS work has shown that *p*-dimethylaminobenzaldoxime could not be converted into a *syn*-isomeric, although two isomeric carbanilino-derivatives could be obtained (Brady and Dunn, T., 1914, 105, 2872). The possible explanation which was suggested was that in the ordinary method of conversion the hydrogen chloride formed a salt with the dimethylamino-group and therefore was not attached to the oximino-group, a necessary condition

of inversion of the configuration. Derivatives of this compound have now been studied with the idea that the introduction of bromine or of the nitro-group into the nucleus would lower the basicity of the dimethylamino-group and perhaps favour the addition of hydrogen chloride to the oximino-complex.

Noelting and Demant (*Ber.*, 1904, **37**, 1028) have prepared 3-nitro-*p*-dimethylaminobenzaldoxime and claim to have obtained an isomeride melting 8° lower than the ordinary compound. The preparation of the oxime was, however, incidental to other work, and they did not study the compound in any detail; indeed they give no evidence of the individuality of the supposed isomeride, nor do they record any attempt to determine its configuration. The matter has been reinvestigated, but Noelting and Demant's claim of the isolation of an isomeride cannot be substantiated. The oxime, as usually prepared, has been proved to have the *anti*-configuration, but no evidence of the formation of a *syn*-isomeride by any of the usual methods could be obtained. It was found, on repeating Noelting and Demant's method for the preparation of the supposed isomeride, that when 3-nitro-*p*-dimethylaminobenzaldehyde was treated in alcoholic solution with hydroxylamine hydrochloride and a trace of hydrochloric acid, an impure oxime was obtained which melted some 8° lower than that prepared by the usual method. This drop in melting point, however, was found to be due to incomplete oximation and consequent contamination of the product with unchanged aldehyde which cannot be removed satisfactorily by crystallisation. In order to be quite sure on the point, the configuration of the impure oxime as prepared by Noelting and Demant's method was determined by treatment with acetic anhydride in the usual way, when an acetyl derivative was formed identical with that obtained from the *anti*-oxime.

3-Bromo-*p*-dimethylaminobenzaldoxime has been prepared and investigated; here again the oxime was found to have the *anti*-configuration, and no indication of the formation of a *syn*-isomeride was obtained.

In view of the fact that *p*-dimethylaminobenzaldoxime on treatment with phenylcarbimide gives a carbanilino-*syn*-derivative (Brady and Dunn, *loc. cit.*), the action of this reagent on the two substituted oximes has been investigated, but in both cases the carbanilino-compound obtained was found to have the *anti*-configuration.

EXPERIMENTAL.

3-Nitro-*p*-dimethylaminobenzaldoxime.—*p*-Dimethylaminobenzaldehyde was nitrated by the method of Sachs and Lewin (*Ber.*, 1902, **35**, 3576) and the 3-nitro-*p*-dimethylaminobenzaldehyde

converted into the oxime by boiling in alcoholic solution for thirty minutes with slightly more than the calculated quantity of hydroxylamine hydrochloride and sufficient solid potassium carbonate to neutralise the hydrogen chloride combined with the base. The product was poured into water and the precipitated oxime crystallised from alcohol, when it melted at 130°. The configuration was determined through the acetyl derivative, which was prepared by warming the oxime at 30° with excess of acetic anhydride until solution was complete, decomposing the excess of anhydride with sodium carbonate solution, and crystallising from alcohol the solid which separated. *Acetyl-3-nitro-p-dimethylaminobenzantialdoxime* was obtained in deep orange needles melting at 109°. It was hydrolysed by heating for half an hour on the water-bath with 2*N*-sodium hydroxide, when it dissolved completely, and carbon dioxide precipitated the original *anti*-oxime from the alkaline solution; the *anti*-configuration was thus established. The oxime obtained by hydrolysis is difficult to purify, and is apparently contaminated with a small quantity of 3-nitro-*p*-hydroxybenzantialdoxime formed by the hydrolysis of the dimethylamino-group; if the reaction is too prolonged, the latter compound is the sole product of the change.

Attempts to Prepare 3-Nitro-p-dimethylaminobenzsynaldoxime.—Noelting and Demant prepared their supposed isomeride by using Beckmann's method of preparation of the *syn*-oximes (*Annalen*, 1909, 365, 202), but after several attempts we have found that the above *anti*-compound is obtained by this method and not a *syn*-isomeride. Ten grams of 3-nitro-*p*-dimethylaminobenzaldehyde were dissolved in absolute alcohol, a concentrated aqueous solution of 3.5 grams of hydroxylamine hydrochloride was added, and the mixture kept in a thermostat for four hours at 50°. The precipitate obtained on pouring the solution into excess of aqueous sodium carbonate melted at 122° and, when mixed with the *anti*-oxime, at 124°. Crystallisation did not effect purification satisfactorily, but on treatment with dilute sodium hydroxide solution a considerable amount of material did not dissolve, and this was found to be unchanged aldehyde. The alkaline solution on treatment with a saturated solution of ammonium chloride gave a precipitate of the *anti*-oxime which, however, was difficult to obtain quite pure, melting some 2° lower than that obtained in the usual way, even after crystallisation. In another preparation, 5 grams of the aldehyde in absolute alcohol were warmed with 3 grams of hydroxylamine hydrochloride and one drop of concentrated hydrochloric acid for five hours at 50°. On cooling, some hydrochloride of the oxime separated out and on pouring the whole of

the mixture into sodium carbonate solution a crude oxime was obtained melting at 122° and, when mixed with the *anti*-oxime, at 124°. Crystallisation from acetone and water raised the melting point to 128°, but again it was found impossible to obtain the melting point as high as in the case of the oxime prepared by the usual method. In no case did admixture of the *anti*-oxime depress the melting point of the oxime prepared in this way, but lest in this case the form of the binary fusion curve should be such that no depression would occur, the identity of the compounds has been confirmed by acetylation. Three grams of the crude product prepared in acid solution and melting at 122° were treated with acetic anhydride at 30° and the solution was poured into excess of aqueous sodium carbonate. The product after crystallisation from acetone and water was found to be identical with the acetyl-3-nitro-*p*-dimethylaminobenzantialdoxime previously prepared. The *syn*-isomeride under these conditions would have given the nitrile, and there seems to be no doubt of the identity of the two compounds. It has not been possible to ascertain the nature of the impurity other than aldehyde in the oxime prepared by Beckmann's method, but it is possible that it is 3-nitro-*p*-hydroxybenzaldehyde.

Attempts have also been made to bring about the conversion into the *syn*-isomeride in the usual way through the hydrochloride. Five grams of the *anti*-oxime were dissolved in dry ether and the solution was saturated with dry hydrogen chloride, when a monohydrochloride was precipitated as a white, crystalline powder melting and decomposing at 170° (Found: Cl = 13.6. $C_9H_{12}O_3N_3Cl$ requires Cl = 14.4 per cent.). The substitution of chloroform for ether in the above method (compare Forster and Dunn, T., 1909, 95, 425), precipitating the hydrochloride from a solution of the *anti*-oxime in boiling benzene (compare Brady and Dunn, this vol., p. 1783), or decomposing the hydrochloride by solution in 2*N*-sodium hydroxide and precipitating the oxime with ammonium chloride solution failed to lead to the formation of a *syn*-oxime. The method of Dunstan and Thole (P., 1911, 27, 233), which consists in suspending the oxime in concentrated hydrochloric acid and saturating the liquid with hydrogen chloride, gave similar results, though in this case a certain amount of hydrolysis of the oxime occurred, as aldehyde was isolated from the product.

Carbanilino-3-nitro-*p*-dimethylaminobenzantialdoxime,

—To a solution of 2.1 grams of 3-nitro-*p*-dimethylaminobenzantialdoxime in dry ether an ethereal solution of 1.8 grams of phenylcarbimide was added. A red, crystalline precipitate of the carb-

anilino-derivative rapidly formed, which crystallised from benzene in red needles melting and decomposing at 138° (Found: N = 16.9. $C_{16}H_{16}O_4N_4$ requires N = 17.0 per cent.). The compound was hydrolysed by heating for an hour with 2*N*-sodium hydroxide on the water-bath, when it dissolved. On cooling and extracting with ether, aniline was obtained, and the alkaline liquor on the addition of a concentrated solution of ammonium chloride gave a precipitate of 3-nitro-*p*-dimethylaminobenzantialdoxime. The regeneration of the oxime establishes the *anti*-configuration of the carbanilino-derivative. The original precipitated compound was practically pure and no change in configuration occurred during crystallisation.

3-Bromo-*p*-dimethylaminobenzaldehyde.—Fourteen grams of *p*-dimethylaminobenzaldehyde were dissolved in 100 c.c. of glacial acetic acid, and 16 grams of bromine in 30 c.c. of glacial acetic acid added slowly. A red, crystalline precipitate, which appears to be a highly brominated product, separated and after its removal the clear solution was poured into water, when a heavy, faintly green oil was precipitated. This was extracted with ether, the solution dried and evaporated, and the residual uncrystallisable oil distilled under diminished pressure, when 3-bromo-*p*-dimethylaminobenzaldehyde was obtained as a pale yellow liquid boiling at $165^{\circ}/28$ mm. (Found: Br = 33.9. $C_9H_{10}ONBr$ requires Br = 35.1 per cent.).

3-Bromo-*p*-dimethylaminobenzantialdoxime.—Ten grams of the above aldehyde, 3.5 grams of hydroxylamine hydrochloride, and 3.5 grams of potassium carbonate were boiled under reflux with alcohol for an hour. On pouring into water, the oxime separated as a white solid which after crystallisation from benzene and light petroleum melted at $97-98^{\circ}$ (Found: N = 11.4. $C_9H_{11}ON_2Br$ requires N = 11.5 per cent.). The oxime was orientated by dissolving 5 grams in excess of acetic anhydride at 30° and pouring the solution into a large excess of aqueous sodium carbonate. When all the anhydride had been decomposed, the solid which separated was crystallised from alcohol, when *acetyl*-3-bromo-*p*-dimethylaminobenzantialdoxime was obtained in white, glistening plates melting at 71° (Found: N = 10.0. $C_{11}H_{13}O_2N_2Br$ requires N = 9.8 per cent.). On hydrolysis with 2*N*-sodium hydroxide, the compound regenerates the original oxime, the *anti*-configuration of which is thus established.

Attempts to Prepare 3-Bromo-*p*-dimethylaminobenzsynaldoxime.—Five grams of 3-bromo-*p*-dimethylaminobenzaldehyde were dissolved in alcohol, 5 grams of hydroxylamine hydrochloride added, followed by one drop of concentrated hydrochloric acid, and the mixture was heated at 50° for five hours. On cooling, a copious

precipitate of the hydrochloride of the oxime was obtained; this was collected, dissolved in 2*N*-sodium hydroxide, and the oxime precipitated with a saturated solution of ammonium chloride; the *anti*-oxime, however, was obtained. When a solution of the *anti*-oxime in dry ether or in boiling benzene was saturated with dry hydrogen chloride, a crystalline mono-hydrochloride was obtained melting and decomposing at 140—141° (Found: Cl = 12.6. $C_9H_{15}ON_2ClBr$ requires Cl = 12.7 per cent.). This hydrochloride, however, on decomposition by any of the usual methods, regenerated the *anti*-oxime, no evidence of conversion into a *syn*-isomeride being obtained.

Carbanilino-3-bromo-p-dimethylaminobenzantialdoxime,

—This compound was precipitated on mixing dry ethereal solutions of 2.4 grams of 3-bromo-*p*-dimethylaminobenzantialdoxime and 2.1 grams of phenylcarbimide. It crystallises from benzene in pale yellow needles melting and decomposing at 127° (Found: N = 11.6. $C_{16}H_{16}O_2N_3Br$ requires N = 11.6 per cent.). Hydrolysis, as in the case of the nitro-compound above, indicates that it has the *anti*-configuration.

3-Bromo-p-dimethylaminobenzonitrile and 3-Bromo-p-dimethylaminobenzoic Acid.—Three grams of acetyl-3-bromo-*p*-dimethylaminobenzantialdoxime were boiled under reflux with 30 c.c. of acetic anhydride for an hour. On decomposing the excess of anhydride with sodium carbonate solution, an oil was obtained which was extracted with ether, the solution dried, and the solvent evaporated. The residual oil, when dissolved in light petroleum and left, deposited white crystals of the nitrile melting at 39—40° (Found: N = 12.4. $C_9H_9N_2Br$ requires N = 12.4 per cent.). One gram of the nitrile was boiled for an hour with 2*N*-sodium hydroxide. On cooling and acidifying with dilute hydrochloric acid, a precipitate formed which redissolved in excess of the acid; sodium carbonate solution was then cautiously added until a maximum amount of precipitate was formed. The acid so precipitated was crystallised from benzene, when it was obtained in white, glistening plates melting at 170° (Found: N = 5.7. $H_{10}O_2NBr$ requires N = 5.7 per cent.).

We wish to express our thanks to the Department of Scientific and Industrial Research for a grant which has enabled one of us (L. T.) to take part in this work.

UNIVERSITY COLLEGE, LONDON. [Received, August 3rd, 1923.]

CCLXXVIII.—*The Chemistry of the Three-carbon System. Part II. Tautomeric Nitriles and Cyano-esters.*

By STANLEY FRANCIS BIRCH and GEORGE ARMAND ROBERT KON.

IN Part I of this series (this vol., p. 1361), it has been shown that cyclohexenylacetone exhibits three-carbon tautomerism, reacting in the two forms

and it was suggested that the cause of the phenomenon was to be sought in the competition between the influence of the negative carbonyl group and that of the cyclohexane ring, the one favouring the $\alpha\beta$ -, the other the $\beta\gamma$ -position of the double linking. It was also suggested that a similar condition of tautomerism accounted for the reactions of ethyl α -cyanocyclohexylideneacetate,

It might reasonably be expected that a number of substances fulfilling the required conditions, that is, possessing a potentially tautomeric three-carbon system terminated by a suitable negative "activating group" at one end and forming part of a cyclohexane or other ring at the other extremity, would exhibit tautomerism of this nature. We have therefore studied the behaviour of certain nitriles and cyano-esters and the results obtained fully justify such a prediction. It can be concluded that the cyano-group, although not as strong an activating group alone as when it is reinforced by a carboxyl group, is sufficient to produce tautomerism in a potentially tautomeric system; whilst the cyclopentane ring has, as might be expected, an influence similar to that of the cyclohexane ring in determining the position of the double linking. An attempt was made to ascertain whether a *gem*-dialkyl group could function in a manner analogous to that of the 5- or 6-membered ring in this respect.

The reason for a possible movement of the double bond in this case would be the tendency often displayed by a double bond to move towards an alkyl group. This is particularly noticeable in such cases as the well-known conversion of methylitaconic acid into ethylidenesuccinic acid, ethylcitraconic acid behaving in a similar manner:

it is worthy of note that the double bond moves away from the doubly conjugated position. The behaviour of Fichter, Kiefer, and Bernoulli's unsaturated acids (*Ber.*, 1909, **42**, 4710) is, apparently, a phenomenon of a similar nature. The evidence we have accumulated on this point up to the present, whilst pointing to the probability of our assumption, cannot be taken as conclusive and requires further experimental confirmation.

The nitriles examined were Δ^1 -cyclopentenyl- and Δ^1 -cyclohexenyl-acetonitriles (I and II) and some of their alkyl derivatives.

An examination of their physical properties and the fact that no trace of cyclohexanone or cyclopentanone, respectively, could be obtained on oxidation with ozone, suggested the above formulæ as expressing their constitution in ordinary circumstances; in addition to this, they were found to condense with piperonal, giving good yields of the compounds (III) and (IV).

They can, however, react in an $\alpha\beta$ -form, because they condense with cyanoacetamide in the presence of sodium ethoxide, thus:

an analogous compound (VI) is obtained from Δ^1 -cyclopentenyl-acetonitrile. The structure of the compound (V) is apparent from the fact that on hydrolysis with dilute hydrochloric acid it passes into the imide (VII), whilst sulphuric acid leads to a quantitative yield of cyclohexane-1:1-diacetic acid (VIII).

The yields of the compounds (V) and (VI) are poor, never exceeding 30 per cent.; this is doubtless due to the well-known inhibiting action of ammonia, which begins to be evolved at an early stage of the reaction. The nitrile which fails to react can, however, be recovered and used again, thus proving that the poor yield is

not due to a limited content of $\alpha\beta$ -modification present in the original nitrile; and this fact, coupled with the ready formation of the piperonylidene compounds derived from the $\beta\gamma$ -form, definitely proves the tautomeric nature of the nitriles.

Moreover, it has been found that these compounds possess a mobile hydrogen atom replaceable by an alkyl group; thus two successive methylations of the cyclohexane compound lead to a product containing about 80 per cent. of the methyl derivative as shown by analysis and by the physical properties of the mixture; a complete separation, which was easy in the case of ketones (compare Part I, *loc. cit.*), could not be effected.

The methyl and other alkyl derivatives can, however, be very readily obtained in good yield by the elimination of the carbethoxyl group from the corresponding cyano-esters (see Part I); this applies also to the corresponding cyclopentane compound (X) which we prepared from the ester (IX) (Harding and Haworth, T., 1910, 97, 486) by the action of sodium ethoxide at 35°:

This process yields the alkylated nitriles in a high state of purity and therefore it was of great interest to compare their physical properties with those of the unsubstituted nitriles. In the above reaction, the alkyl compounds must of necessity be produced in their $\beta\gamma$ -form, the parent ester having that constitution. We were, therefore, not a little surprised to find that the molecular refractivities showed an appreciable exaltation, apparently due to the presence of conjugated unsaturated linkings. The phenyl compound (XI) (Harding and Haworth, *loc. cit.*) and the isoamyl compound (XII) were then prepared and were found to behave in the same manner, and it may be mentioned that as the comparisons were made between the actual experimental values for $[R_L]_D$, the effect of possible deviations from the calculated constants is completely eliminated.

It would therefore appear that the alkylated nitriles are best represented by the $\alpha\beta$ -formulae such as (XI) and (XII), although they are doubtless first produced in their $\beta\gamma$ -form. In accordance with this formulation, the oxidation of these compounds with ozone leads to the production of the corresponding ketones, although we have not yet succeeded in inducing these nitriles to undergo the condensation reactions characteristic of $\alpha\beta$ -unsaturated

substances; this failure is doubtless to be attributed to steric factors.

The comparative stability of the $\alpha\beta$ -phase of these compounds must be attributed to the attraction exercised by the alkyl group in the α -position, a factor already discussed on p. 2440.

With regard to the cyano-esters studied, it was found that ethyl α -cyanocyclopentylideneacetate (XIII) (Harding and Haworth, *loc. cit.*) behaves in every way like the analogous cyclohexane compound. The ordinary reactions of the substance are best represented by the $\alpha\beta$ -formula, in accordance with which it readily combines with ethyl cyanoacetate and ammonia to give a good yield of the imide (XIV) previously prepared by Kon and Thorpe (T., 1919, 115, 686).

On the other hand, it behaves like a typical mono-substituted cyanoacetic ester and readily undergoes methylation, passing into the compound (IX) (p. 2442) which, as already mentioned, can only possess the $\beta\gamma$ -structure, so that the tautomeric nature of the ester (XIII) is, we think, beyond question.

We have prepared the dimethyl- and diethyl-analogues of ethyl α -cyanocyclopentylideneacetate and have examined some of their properties. The first of these compounds, ethyl α -cyano- $\beta\beta$ -dimethylacrylate, has already been prepared by Komppa (*Ber.*, 1900, 33, 3530) and also by Scheiber and Meisel (*Ber.*, 1915, 48, 238), who showed that on oxidation with ozone the compound yields acetone, in accordance with the formula $\text{CMe}_2\cdot\text{C}(\text{CN})\cdot\text{CO}_2\text{Et}$; they were, however, unable to condense the substance with ethyl cyanoacetate or ethyl acetoacetate. We now find that the substance reacts readily with ethyl cyanoacetate in the presence of alcoholic ammonia, yielding the well-known ω -imide of $\alpha\alpha'$ -dicyano- $\beta\beta$ -dimethylglutaric acid (Guareschi and Grande, *Atti R. Accad. Sci. Torino*, 1899, 34, 924), so that the $\alpha\beta$ -structure of the compound is beyond dispute. On the other hand, we were unable to effect the methylation of the substance and thus demonstrate the existence of a $\beta\gamma$ -phase of the ester, because the action of either sodium or sodium ethoxide converts it with the greatest ease into ethyl 2:6-dicyano-1:1:5-trimethyl- $\Delta^{2:4}$ -cyclohexadien-3-ol-6-carboxylate (XV), a solid melting at 135°, identical with the product of the direct condensation of ethyl sodiocyanoacetate and acetone obtained by Gardner and Haworth (T., 1909, 95, 1955). The same substance appears to have been obtained by Scheiber and Meisel, although

these authors assigned to it a different empirical formula and were, apparently, unaware of the previous investigation.

Now the formation of this substance is very simply explained by the condensation of the cyano-ester with its own sodio-derivative, the latter being derived from the $\beta\gamma$ -form of the ester, thus:

a molecule of alcohol being eliminated in the process.

It would appear very likely that the compound m. p. 135° was produced by a similar reaction in the direct condensation of acetone and ethyl sodiocyanoacetate.

Ethyl α -cyano- $\beta\beta$ -diethylacrylate, $\text{CEt}_2\text{C}(\text{CN})\cdot\text{CO}_2\text{Et}$, was then prepared, but we have not yet succeeded in obtaining it in sufficiently pure condition. The specimen prepared condensed very readily with ethyl cyanoacetate and ammonia, giving an almost quantitative yield of the imide $\text{CEt}_2\text{C} \begin{smallmatrix} \text{CH}(\text{CN})\cdot\text{CO} \\ \text{CH}(\text{CN})\cdot\text{CO} \end{smallmatrix} \text{NH}$ (Guareschi, *Mem.*

R. Accad. Sci. Torino, 1901, 50, 235); the attempts made to methylate the ester have not yet given a definite result, and therefore the existence of the $\beta\gamma$ -form of the substance is not definitely proved. It is interesting to note that a compound analogous to the ester melting at 135° does not appear to be formed by the action of sodium ethoxide on the unsaturated ester.

EXPERIMENTAL.

Δ^1 -cyclohexenylacetonitrile.

This substance was prepared by Harding, Haworth, and Perkin's method (T., 1908, 93, 1949) by the condensation of ethyl sodiocyanoacetate with cyclohexanone; the alternative method is not to be recommended, as the cyano-ester is very difficult to hydrolyse. The nitrile in ethereal solution should be well washed with alkali, then with water; the pure substance boils at $112^\circ/27$ mm., and has d_4^{25} 0.94727, n_D^{25} 1.47869, $[R_L]_D$ 36.20 (calc. 36.30); another specimen showed d_4^{25} 0.94897, n_D^{25} 1.47897, $[R_L]_D$ 36.18.

Condensation with Sodiocyanoacetamide.—To a suspension prepared by adding cyanoacetamide (8.4 grams) to sodium (2.3 grams) dissolved in absolute alcohol (60 c.c.) were added 10 c.c. of the nitrile and the mixture was heated on the steam-bath for about

an hour. A yellow colour gradually developed, the solid became more gelatinous, and ammonia began to be evolved after a few minutes. After dilution with water, a white precipitate of imino-compound was formed; on acidifying the mother-liquors with acetic acid, a further precipitate was obtained, containing a good deal of a second substance (see below).

The imino-compound (V) readily dissolves in dilute mineral acids and is reprecipitated by the addition of sodium acetate, the crystalline powder obtained decomposing somewhat indefinitely at about 276° .

The compound, which was not analysed, was converted into the imide of α -cyano-cyclohexane-1:1-diacetic acid (VII) by boiling for a short time with dilute hydrochloric acid. The imide crystallised on cooling the solution and was recrystallised from dilute alcohol; it formed lustrous plates, m. p. $213-215^{\circ}$ (Found: N = 13.84. $C_{11}H_{14}O_2N_2$ requires N = 13.58 per cent.). When hydrolysed with 60 per cent. sulphuric acid, it gave a quantitative yield of cyclohexane-1:1-diacetic acid, melting at 181° .

The second compound produced in the condensation of the nitrile with sodiocyanoacetamide melts at 207° after crystallisation from alcohol and forms colourless prisms soluble in alkalis with a bright yellow colour. It appears to be formed by the condensation of the nitrile with two molecules of cyanoacetamide (Found: C = 61.76; H = 6.01; N = 20.63. $C_{14}H_{16}O_2N_4$ requires C = 61.73; H = 5.92; N = 20.59 per cent.). It gives cyclohexane-1:1-diacetic acid on hydrolysis, but its constitution has not been ascertained.

Condensation with Piperonal.—A mixture of equimolecular proportions of the components was mixed with a little alcoholic sodium ethoxide. After twenty-four hours, the crystalline precipitate of the piperonylidene compound (III) was filtered off and the mother-liquor diluted with a little water, a second crop of crystals being ultimately obtained. These, after crystallisation from alcohol, formed clusters of yellow needles melting at 127° ; the yield was 70 per cent. of the theoretical (Found: N = 5.33. $C_{18}H_{15}O_2N$ requires N = 5.28 per cent.). The compound dissolves with a fine purple colour in concentrated sulphuric acid.

Methylation.—The nitrile (1 mol.) was added to sodium methoxide (1 mol.) in methyl alcohol, an excess of methyl iodide being gradually added to the orange solution. The mixture was warmed for about two hours, the nitrile then isolated in the usual manner and again subjected to methylation. On isolation, it formed a colourless liquid boiling at $118^{\circ}/36$ mm., and having d_4^{25} 0.94535, n_D^{25} 1.49032, $[R_L]_D$ 41.34 (calc. for methylated substance) (Found:

N = 10.92. Calc., N = 10.38 per cent.); the analytical result thus shows an approximate content of 80 per cent. of the methylated substance, a conclusion supported by the physical properties.

α -cycloHexylidenepropionitrile.

This substance was prepared by the method described in our previous communication (*loc. cit.*, p. 1374). The substance had d_4^{20} 0.94210, n_D^{20} 1.49032, $[R_L]_D$ 41.49 (calc. 40.91), thus showing an exaltation of about 0.6 unit.

Oxidation.—Ozone was passed through a moist chloroform solution of the nitrile for several days and after the solvent had been removed the mixture was warmed with water and finally distilled in steam. The distillate, which contained a good deal of unchanged nitrile, gave on treatment with semicarbazide acetate prisms melting at 165–166° and consisting of cyclohexanonesemicarbazone; this was confirmed by comparison with a genuine specimen.

Attempts to alkylate the nitrile or to condense it with sodio-cyanoacetamide were unsuccessful.

α -cycloHexylidenisoeptonitrile.

This nitrile was prepared for comparison, ethyl α -cyanocyclohexylideneacetate being converted, by means of sodium ethoxide and isoamyl iodide, into the isoamyl compound, which was treated with sodium ethoxide, when it passed quantitatively into ethyl carbonate and the new nitrile, boiling at 157°/23 mm. The nitrile had d_4^{20} 0.90369, n_D^{20} 1.48181, $[R_L]_D$ 60.29 (calc. 59.39) (Found: N = 7.44. $C_{13}H_{21}N$ requires N = 7.32 per cent.).

α -cycloHexylidenephnylacetoneitrile.

This substance, prepared by the method of Harding and Haworth (*loc. cit.*), boiled at 192–193°/25 mm.; it had d_4^{20} 1.02981, n_D^{20} 1.56343, $[R_L]_D$ 62.21 (calc. 61.50). It appears to be difficult to obtain this substance in a pure condition.

α -cycloPenteneacetoneitrile.

This substance was prepared in the same way as the cyclohexene analogue and was carefully purified. It boiled at 99°/33 mm., and had d_4^{20} 0.93940, n_D^{20} 1.46808, $[R_L]_D$ 31.69 (calc. 31.68).

Condensation with Sodicyanoacetamide.—The condensation with sodicyanoacetamide was carried out as described on p. 2444. The iminoimide (VI) was obtained as a sandy powder, blackening and decomposing at about 290°; when boiled with hydrochloric acid, it gave the imide, which formed stout prisms melting at

200—202° and on hydrolysis with sulphuric acid gave a quantitative yield of cyclopentane-1 : 1-diacetic acid, m. p. 177°, identified by comparison with a genuine specimen (Kon and Thorpe, *loc. cit.*).

Condensation with Piperonal.—The condensation with piperonal was carried out as described on p. 2445 and an equally good yield of the piperonylidene compound (IV) was obtained; this forms slender, yellow needles melting at 120° and dissolving in concentrated sulphuric acid with a fine red colour (Found: N = 6.03. $C_{15}H_{13}O_2N$ requires N = 5.85 per cent.).

α -cyclopentylidenepropionitrile.

The compound was prepared in the same way as the higher homologue and boiled at 131°/63 mm.; it had d_4^{20} 0.924661, n_D^{20} 1.47623, and $[R_L]_D$ 36.92 (calc. 36.30).

Oxidation with ozone under the conditions described on p. 2446 led to the formation of cyclopentanone, which was isolated as its semicarbazone and identified by direct comparison with a genuine specimen.

Ethyl α -Cyano- β -dimethylacrylate.

This substance was prepared as follows: a mixture of acetone (58 grams), ethyl cyanoacetate (113 grams), and piperidine (1 c.c.) was warmed on the steam-bath for an hour and kept for two days, when a considerable amount of water had separated. Ether was then added, the solution washed with dilute hydrochloric acid and with water, carefully dried with sodium sulphate, and distilled. The fraction 117—127°/20 mm. represents the practically pure ester, which readily solidifies when cooled in ice (Komppa, *loc. cit.*). The yield is about 60 per cent.

Condensation with Ethyl Cyanoacetate.—Equimolecular quantities of the two esters were mixed with saturated alcoholic ammonia (3 mols.) and kept for twenty-four hours. On working up the product in the usual way (Kon and Thorpe, *loc. cit.*), an almost quantitative yield of the ω -imide of $\alpha\alpha'$ -dicyano- β -dimethylglutaric acid, melting at 216—217°, was obtained.
